The "Hello, World" program starts with a `using` directive that references the `System` namespace. Namespaces provide a hierarchical means of organizing C# programs and libraries. Namespaces contain types and other namespaces—for example, the `System` namespace contains a number of types, such as the `Console` class referenced in the program, and a number of other namespaces, such as `IO` and `Collections`. A `using` directive that references a given namespace enables unqualified use of the types that are members of that namespace. Because of the `using` directive, the program can use `Console.WriteLine` as shorthand for `System.Console.WriteLine`.

The `Hello` class declared by the "Hello, World" program has a single member, the method named `Main`. The `Main` method is declared with the static modifier. While instance methods can reference a particular enclosing object instance using the keyword `this`, static methods operate without reference to a particular object. By convention, a static method named `Main` serves as the entry point of a program.

The output of the program is produced by the `WriteLine` method of the `Console` class in the `System` namespace. This class is provided by the standard class libraries, which, by default, are automatically referenced by the compiler.

There's a lot more to learn about C#. The following topics provide an overview of the elements of the C# language. These overviews will provide basic information about all elements of the language and give you the information necessary to dive deeper into elements of the C# language:

- [Program Structure](#)
 - Learn the key organizational concepts in the C# language: **programs, namespaces, types, members, and assemblies**.
- [Types and Variables](#)
 - Learn about **value types, reference types**, and **variables** in the C# language.
- [Expressions](#)
 - **Expressions** are constructed from **operands** and **operators**. Expressions produce a value.
- [Statements](#)
 - You use **statements** to express the actions of a program.
- [Classes and objects](#)
 - **Classes** are the most fundamental of C#'s types. **Objects** are instances of a class. Classes are built using **members**, which are also covered in this topic.
- [Structs](#)
 - **Structs** are data structures that, unlike classes, are value types.
- [Arrays](#)
 - An **array** is a data structure that contains a number of variables that are accessed through computed indices.
- [Interfaces](#)
 - An **interface** defines a contract that can be implemented by classes and structs. An interface can contain methods, properties, events, and indexers. An interface does not provide implementations of the members it defines—it merely specifies the members that must be supplied by classes or structs that implement the interface.

- [Enums](#)
 - An **enum type** is a distinct value type with a set of named constants.
- [Delegates](#)
 - A **delegate type** represents references to methods with a particular parameter list and return type. Delegates make it possible to treat methods as entities that can be assigned to variables and passed as parameters. Delegates are similar to the concept of function pointers found in some other languages, but unlike function pointers, delegates are object-oriented and type-safe.
- [Attributes](#)
 - **Attributes** enable programs to specify additional declarative information about types, members, and other entities.

What's new in C# 8.0

3/28/2019 • 11 minutes to read • [Edit Online](#)

There are many enhancements to the C# language that you can try out already with preview 2. The new features added in preview 2 are:

- [Pattern matching enhancements:](#)
 - [Switch expressions](#)
 - [Property patterns](#)
 - [Tuple patterns](#)
 - [Positional patterns](#)
- [Using declarations](#)
- [Static local functions](#)
- [Disposable ref structs](#)

The following language features first appeared in C# 8.0 preview 1:

- [Nullable reference types](#)
- [Asynchronous streams](#)
- [Indices and ranges](#)

NOTE

This article was last updated for C# 8.0 preview 2.

The remainder of this article briefly describes these features. Where in-depth articles are available, links to those tutorials and overviews are provided.

More patterns in more places

Pattern matching gives tools to provide shape-dependent functionality across related but different kinds of data. C# 7.0 introduced syntax for type patterns and constant patterns by using the `is` expression and the `switch` statement. These features represented the first tentative steps toward supporting programming paradigms where data and functionality live apart. As the industry moves toward more microservices and other cloud-based architectures, other language tools are needed.

C# 8.0 expands this vocabulary so you can use more pattern expressions in more places in your code. Consider these features when your data and functionality are separate. Consider pattern matching when your algorithms depend on a fact other than the runtime type of an object. These techniques provide another way to express designs.

In addition to new patterns in new places, C# 8.0 adds **recursive patterns**. The result of any pattern expression is an expression. A recursive pattern is simply a pattern expression applied to the output of another pattern expression.

switch expressions

Often, a `switch` statement produces a value in each of its `case` blocks. **Switch expressions** enable you to use more concise expression syntax. There are fewer repetitive `case` and `break` keywords, and fewer curly braces. As an example, consider the following enum that lists the colors of the rainbow:

```

public enum Rainbow
{
    Red,
    Orange,
    Yellow,
    Green,
    Blue,
    Indigo,
    Violet
}

```

You could convert a `Rainbow` value to its RGB values using the following method containing a switch expression:

```

public static RGBColor FromRainbow(Rainbow colorBand) =>
    colorBand switch
    {
        Rainbow.Red      => new RGBColor(0xFF, 0x00, 0x00),
        Rainbow.Orange   => new RGBColor(0xFF, 0x7F, 0x00),
        Rainbow.Yellow   => new RGBColor(0xFF, 0xFF, 0x00),
        Rainbow.Green    => new RGBColor(0x00, 0xFF, 0x00),
        Rainbow.Blue     => new RGBColor(0x00, 0x00, 0xFF),
        Rainbow.Indigo   => new RGBColor(0x4B, 0x00, 0x82),
        Rainbow.Violet   => new RGBColor(0x94, 0x00, 0xD3),
        _                  => throw new ArgumentException(message: "invalid enum value", paramName:
nameof(colorBand)),
    };

```

There are several syntax improvements here:

- The variable comes before the `switch` keyword. The different order makes it visually easy to distinguish the switch expression from the switch statement.
- The `case` and `:` elements are replaced with `=>`. It's more concise and intuitive.
- The `default` case is replaced with a `_` discard.
- The bodies are expressions, not statements.

Contrast that with the equivalent code using the classic `switch` statement:

```

public static RGBColor FromRainbowClassic(Rainbow colorBand)
{
    switch (colorBand)
    {
        case Rainbow.Red:
            return new RGBColor(0xFF, 0x00, 0x00);
        case Rainbow.Orange:
            return new RGBColor(0xFF, 0x7F, 0x00);
        case Rainbow.Yellow:
            return new RGBColor(0xFF, 0xFF, 0x00);
        case Rainbow.Green:
            return new RGBColor(0x00, 0xFF, 0x00);
        case Rainbow.Blue:
            return new RGBColor(0x00, 0x00, 0xFF);
        case Rainbow.Indigo:
            return new RGBColor(0x4B, 0x00, 0x82);
        case Rainbow.Violet:
            return new RGBColor(0x94, 0x00, 0xD3);
        default:
            throw new ArgumentException(message: "invalid enum value", paramName: nameof(colorBand));
    };
}

```

The **property pattern** enables you to match on properties of the object examined. Consider an eCommerce site that must compute sales tax based on the buyer's address. That computation is not a core responsibility of an `Address` class. It will change over time, likely more often than address format changes. The amount of sales tax depends on the `state` property of the address. The following method uses the property pattern to compute the sales tax from the address and the price:

```
public static decimal ComputeSalesTax(Address location, decimal salePrice) =>
    location switch
    {
        { State: "WA" } => salePrice * 0.06M,
        { State: "MN" } => salePrice * 0.75M,
        { State: "MI" } => salePrice * 0.05M,
        // other cases removed for brevity...
        _ => 0M
    };
}
```

Pattern matching creates a concise syntax for expressing this algorithm.

Tuple patterns

Some algorithms depend on multiple inputs. **Tuple patterns** allow you to switch based on multiple values expressed as a `tuple`. The following code shows a switch expression for the game *rock, paper, scissors*:

```
public static string RockPaperScissors(string first, string second)
    => (first, second) switch
    {
        ("rock", "paper") => "rock is covered by paper. Paper wins.",
        ("rock", "scissors") => "rock breaks scissors. Rock wins.",
        ("paper", "rock") => "paper covers rock. Paper wins.",
        ("paper", "scissors") => "paper is cut by scissors. Scissors wins.",
        ("scissors", "rock") => "scissors is broken by rock. Rock wins.",
        ("scissors", "paper") => "scissors cuts paper. Scissors wins.",
        (_, _) => "tie"
    };
}
```

The messages indicate the winner. The discard case represents the three combinations for ties, or other text inputs.

Positional patterns

Some types include a `Deconstruct` method that deconstructs its properties into discrete variables. When a `Deconstruct` method is accessible, you can use **positional patterns** to inspect properties of the object and use those properties for a pattern. Consider the following `Point` class that includes a `Deconstruct` method to create discrete variables for `x` and `y`:

```
public class Point
{
    public int X { get; }
    public int Y { get; }

    public Point(int x, int y) => (X, Y) = (x, y);

    public void Deconstruct(out int x, out int y) =>
        (x, y) = (X, Y);
}
```

Additionally, consider the following enum that represents various positions of a quadrant:

```
public enum Quadrant
{
    Unknown,
    Origin,
    One,
    Two,
    Three,
    Four,
    OnBorder
}
```

The following method uses the **positional pattern** to extract the values of `x` and `y`. Then, it uses a `when` clause to determine the `Quadrant` of the point:

```
static Quadrant GetQuadrant(Point point) => point switch
{
    (0, 0) => Quadrant.Origin,
    var (x, y) when x > 0 && y > 0 => Quadrant.One,
    var (x, y) when x < 0 && y > 0 => Quadrant.Two,
    var (x, y) when x < 0 && y < 0 => Quadrant.Three,
    var (x, y) when x > 0 && y < 0 => Quadrant.Four,
    var (_, _) => Quadrant.OnBorder,
    _ => Quadrant.Unknown
};
```

The discard pattern in the preceding switch matches when either `x` or `y` is 0, but not both. A switch expression must either produce a value or throw an exception. If none of the cases match, the switch expression throws an exception. The compiler generates a warning for you if you do not cover all possible cases in your switch expression.

You can explore pattern matching techniques in this [advanced tutorial on pattern matching](#).

using declarations

A **using declaration** is a variable declaration preceded by the `using` keyword. It tells the compiler that the variable being declared should be disposed at the end of the enclosing scope. For example, consider the following code that writes a text file:

```
static void WriteLinesToFile(IEnumerable<string> lines)
{
    using var file = new System.IO.StreamWriter("WriteLines2.txt");
    foreach (string line in lines)
    {
        // If the line doesn't contain the word 'Second', write the line to the file.
        if (!line.Contains("Second"))
        {
            file.WriteLine(line);
        }
    }
    // file is disposed here
}
```

In the preceding example, the file is disposed when the closing brace for the method is reached. That's the end of the scope in which `file` is declared. The preceding code is equivalent to the following code using the classic [using statements](#) statement:

```

static void WriteLinesToFile(IEnumerable<string> lines)
{
    using (var file = new System.IO.StreamWriter("WriteLines2.txt"))
    {
        foreach (string line in lines)
        {
            // If the line doesn't contain the word 'Second', write the line to the file.
            if (!line.Contains("Second"))
            {
                file.WriteLine(line);
            }
        }
    } // file is disposed here
}

```

In the preceding example, the file is disposed when the closing brace associated with the `using` statement is reached.

In both cases, the compiler generates the call to `Dispose()`. The compiler generates an error if the expression in the `using` statement is not disposable.

Static local functions

You can now add the `static` modifier to local functions to ensure that local function doesn't capture (reference) any variables from the enclosing scope. Doing so generates `CS8421`, "A static local function can't contain a reference to <variable>."

Consider the following code. The local function `LocalFunction` accesses the variable `y`, declared in the enclosing scope (the method `M`). Therefore, `LocalFunction` can't be declared with the `static` modifier:

```

int M()
{
    int y;
    LocalFunction();
    return y;

    void LocalFunction() => y = 0;
}

```

The following code contains a static local function. It can be static because it doesn't access any variables in the enclosing scope:

```

int M()
{
    int y = 5;
    int x = 7;
    return Add(x, y);

    static int Add(int left, int right) => left + right;
}

```

Disposable ref structs

A `struct` declared with the `ref` modifier may not implement any interfaces and so cannot implement `IDisposable`. Therefore, to enable a `ref struct` to be disposed, it must have an accessible `void Dispose()` method. This also applies to `readonly ref struct` declarations.

Nullable reference types

Inside a nullable annotation context, any variable of a reference type is considered to be a **nonnullable reference type**. If you want to indicate that a variable may be null, you must append the type name with the `?` to declare the variable as a **nullable reference type**.

For nonnullable reference types, the compiler uses flow analysis to ensure that local variables are initialized to a non-null value when declared. Fields must be initialized during construction. The compiler generates a warning if the variable is not set by a call to any of the available constructors or by an initializer. Furthermore, nonnullable reference types can't be assigned a value that could be null.

Nullable reference types aren't checked to ensure they aren't assigned or initialized to null. However, the compiler uses flow analysis to ensure that any variable of a nullable reference type is checked against null before it's accessed or assigned to a nonnullable reference type.

You can learn more about the feature in the overview of [nullable reference types](#). Try it yourself in a new application in this [nullable reference types tutorial](#). Learn about the steps to migrate an existing codebase to make use of nullable reference types in the [migrating an application to use nullable reference types tutorial](#).

Asynchronous streams

Starting with C# 8.0, you can create and consume streams asynchronously. A method that returns an asynchronous stream has three properties:

1. It's declared with the `async` modifier.
2. It returns an `IAsyncEnumerable<T>`.
3. The method contains `yield return` statements to return successive elements in the asynchronous stream.

Consuming an asynchronous stream requires you to add the `await` keyword before the `foreach` keyword when you enumerate the elements of the stream. Adding the `await` keyword requires the method that enumerates the asynchronous stream to be declared with the `async` modifier and to return a type allowed for an `async` method. Typically that means returning a `Task` or `Task<TResult>`. It can also be a `ValueTask` or `ValueTask<TResult>`. A method can both consume and produce an asynchronous stream, which means it would return an `IAsyncEnumerable<T>`. The following code generates a sequence from 0 to 19, waiting 100 ms between generating each number:

```
public static async System.Collections.Generic.IAsyncEnumerable<int> GenerateSequence()
{
    for (int i = 0; i < 20; i++)
    {
        await Task.Delay(100);
        yield return i;
    }
}
```

You would enumerate the sequence using the `await foreach` statement:

```
await foreach (var number in GenerateSequence())
{
    Console.WriteLine(number);
}
```

You can try asynchronous streams yourself in our tutorial on [creating and consuming async streams](#).

Indices and ranges

Ranges and indices provide a succinct syntax for specifying subranges in an array, `Span<T>`, or `ReadOnlySpan<T>`.

You can specify an index **from the end**. You specify **from the end** using the `^` operator. You are familiar with `array[2]` meaning the element "2 from the start". Now, `array[^2]` means the element "2 from the end". The index `^0` means "the end", or the index that follows the last element.

You can specify a **range** with the **range operator**: `...`. For example, `0..^0` specifies the entire range of the array: 0 from the start up to, but not including 0 from the end. Either operand may use "from the start" or "from the end". Furthermore, either operand may be omitted. The defaults are `0` for the start index, and `^0` for the end index.

Let's look at a few examples. Consider the following array, annotated with its index from the start and from the end:

```
var words = new string[]
{
    // index from start      index from end
    "The",        // 0          ^9
    "quick",      // 1          ^8
    "brown",      // 2          ^7
    "fox",        // 3          ^6
    "jumped",     // 4          ^5
    "over",       // 5          ^4
    "the",        // 6          ^3
    "lazy",       // 7          ^2
    "dog"         // 8          ^1
};
```

The index of each element reinforces the concept of "from the start", and "from the end", and that ranges are exclusive of the end of the range. The "start" of the entire array is the first element. The "end" of the entire array is *past* the last element.

You can retrieve the last word with the `^1` index:

```
Console.WriteLine($"The last word is {words[^1]}");
// writes "dog"
```

The following code creates a subrange with the words "quick", "brown", and "fox". It includes `words[1]` through `words[3]`. The element `words[4]` is not in the range.

```
var quickBrownFox = words[1..4];
```

The following code creates a subrange with "lazy" and "dog". It includes `words[^2]` and `words[^1]`. The end index `words[^0]` is not included:

```
var lazyDog = words[^2..^0];
```

The following examples create ranges that are open ended for the start, end, or both:

```
var allWords = words[..]; // contains "The" through "dog".
var firstPhrase = words[..4]; // contains "The" through "fox"
var lastPhrase = words[6..]; // contains "the", "lazy" and "dog"
```

You can also declare ranges as variables:

```
Range phrase = 1..4;
```

The range can then be used inside the [] and [] characters:

```
var text = words[phrase];
```

What's new in C# 7.3

3/15/2019 • 6 minutes to read • [Edit Online](#)

There are two main themes to the C# 7.3 release. One theme provides features that enable safe code to be as performant as unsafe code. The second theme provides incremental improvements to existing features. In addition, new compiler options were added in this release.

The following new features support the theme of better performance for safe code:

- You can access fixed fields without pinning.
- You can reassign `ref` local variables.
- You can use initializers on `stackalloc` arrays.
- You can use `fixed` statements with any type that supports a pattern.
- You can use additional generic constraints.

The following enhancements were made to existing features:

- You can test `==` and `!=` with tuple types.
- You can use expression variables in more locations.
- You may attach attributes to the backing field of auto-implemented properties.
- Method resolution when arguments differ by `in` has been improved.
- Overload resolution now has fewer ambiguous cases.

The new compiler options are:

- `-publicsign` to enable Open Source Software (OSS) signing of assemblies.
- `-pathmap` to provide a mapping for source directories.

The remainder of this article provides details and links to learn more about each of the improvements.

Enabling more efficient safe code

You should be able to write C# code safely that performs as well as unsafe code. Safe code avoids classes of errors, such as buffer overruns, stray pointers, and other memory access errors. These new features expand the capabilities of verifiable safe code. Strive to write more of your code using safe constructs. These features make that easier.

Indexing `fixed` fields does not require pinning

Consider this struct:

```
unsafe struct S
{
    public fixed int myFixedField[10];
}
```

In earlier versions of C#, you needed to pin a variable to access one of the integers that are part of `myFixedField`. Now, the following code compiles without pinning the variable `p` inside a separate `fixed` statement:

```
class C
{
    static S s = new S();

    unsafe public void M()
    {
        int p = s.myFixedField[5];
    }
}
```

The variable `p` accesses one element in `myFixedField`. You don't need to declare a separate `int*` variable. Note that you still need an `unsafe` context. In earlier versions of C#, you need to declare a second fixed pointer:

```
class C
{
    static S s = new S();

    unsafe public void M()
    {
        fixed (int* ptr = s.myFixedField)
        {
            int p = ptr[5];
        }
    }
}
```

For more information, see the article on [fixed statement](#).

`ref` local variables may be reassigned

Now, `ref` locals may be reassigned to refer to different instances after being initialized. The following code now compiles:

```
ref VeryLargeStruct refLocal = ref veryLargeStruct; // initialization
refLocal = ref anotherVeryLargeStruct; // reassigned, refLocal refers to different storage.
```

For more information, see the article on [ref returns and ref locals](#), and the article on [foreach](#).

`stackalloc` arrays support initializers

You've been able to specify the values for elements in an array when you initialize it:

```
var arr = new int[3] {1, 2, 3};
var arr2 = new int[] {1, 2, 3};
```

Now, that same syntax can be applied to arrays that are declared with `stackalloc`:

```
int* pArr = stackalloc int[3] {1, 2, 3};
int* pArr2 = stackalloc int[] {1, 2, 3};
Span<int> arr = stackalloc [] {1, 2, 3};
```

For more information, see the [stackalloc statement](#) article in the language reference.

More types support the `fixed` statement

The `fixed` statement supported a limited set of types. Starting with C# 7.3, any type that contains a `GetPinnableReference()` method that returns a `ref T` or `ref readonly T` may be `fixed`. Adding this feature means that `fixed` can be used with `System.Span<T>` and related types.

For more information, see the [fixed statement](#) article in the language reference.

Enhanced generic constraints

You can now specify the type [System.Enum](#) or [System.Delegate](#) as base class constraints for a type parameter.

You can also use the new `unmanaged` constraint, to specify that a type parameter must be an **unmanaged type**. An **unmanaged type** is a type that isn't a reference type and doesn't contain any reference type at any level of nesting.

For more information, see the articles on [where generic constraints](#) and [constraints on type parameters](#).

Adding these constraints to existing types is an [incompatible change](#). Closed generic types may no longer meet these new constraints.

Make existing features better

The second theme provides improvements to features in the language. These features improve productivity when writing C#.

Tuples support `==` and `!=`

The C# tuple types now support `==` and `!=`. For more information, see the section covering [equality](#) in the article on [tuples](#).

Attach attributes to the backing fields for auto-implemented properties

This syntax is now supported:

```
[field: SomeThingAboutFieldAttribute]
public int SomeProperty { get; set; }
```

The attribute `SomeThingAboutFieldAttribute` is applied to the compiler generated backing field for `SomeProperty`. For more information, see [attributes](#) in the C# programming guide.

`in` method overload resolution tiebreaker

When the `in` argument modifier was added, these two methods would cause an ambiguity:

```
static void M(S arg);
static void M(in S arg);
```

Now, the by value (first in the preceding example) overload is better than the by readonly reference version. To call the version with the readonly reference argument, you must include the `in` modifier when calling the method.

NOTE

This was implemented as a bug fix. This no longer is ambiguous even with the language version set to "7.2".

For more information, see the article on the [in parameter modifier](#).

Extend expression variables in initializers

The syntax added in C# 7.0 to allow `out` variable declarations has been extended to include field initializers, property initializers, constructor initializers, and query clauses. It enables code such as the following example:

```

public class B
{
    public B(int i, out int j)
    {
        j = i;
    }
}

public class D : B
{
    public D(int i) : base(i, out var j)
    {
        Console.WriteLine($"The value of 'j' is {j}");
    }
}

```

Improved overload candidates

In every release, the overload resolution rules get updated to address situations where ambiguous method invocations have an "obvious" choice. This release adds three new rules to help the compiler pick the obvious choice:

1. When a method group contains both instance and static members, the compiler discards the instance members if the method was invoked without an instance receiver or context. The compiler discards the static members if the method was invoked with an instance receiver. When there is no receiver, the compiler includes only static members in a static context, otherwise both static and instance members. When the receiver is ambiguously an instance or type, the compiler includes both. A static context, where an implicit `this` instance receiver cannot be used, includes the body of members where no `this` is defined, such as static members, as well as places where `this` cannot be used, such as field initializers and constructor-initializers.
2. When a method group contains some generic methods whose type arguments do not satisfy their constraints, these members are removed from the candidate set.
3. For a method group conversion, candidate methods whose return type doesn't match up with the delegate's return type are removed from the set.

You'll only notice this change because you'll find fewer compiler errors for ambiguous method overloads when you are sure which method is better.

New compiler options

New compiler options support new build and DevOps scenarios for C# programs.

Public or Open Source signing

The `-publicsign` compiler option instructs the compiler to sign the assembly using a public key. The assembly is marked as signed, but the signature is taken from the public key. This option enables you to build signed assemblies from open-source projects using a public key.

For more information, see the [-publicsign compiler option](#) article.

pathmap

The `-pathmap` compiler option instructs the compiler to replace source paths from the build environment with mapped source paths. The `-pathmap` option controls the source path written by the compiler to PDB files or for the [CallerFilePathAttribute](#).

For more information, see the [-pathmap compiler option](#) article.

What's new in C# 7.2

3/19/2019 • 3 minutes to read • [Edit Online](#)

C# 7.2 is another point release that adds a number of useful features. One theme for this release is working more efficiently with value types by avoiding unnecessary copies or allocations.

The remaining features are small, nice-to-have features.

C# 7.2 uses the [language version selection](#) configuration element to select the compiler language version.

The new language features in this release are:

- [Techniques for writing safe efficient code](#)
 - A combination of syntax improvements that enable working with value types using reference semantics.
- [Non-trailing named arguments](#)
 - Named arguments can be followed by positional arguments.
- [Leading underscores in numeric literals](#)
 - Numeric literals can now have leading underscores before any printed digits.
- [private protected access modifier](#)
 - The `private protected` access modifier enables access for derived classes in the same assembly.
- [Conditional ref expressions](#)
 - The result of a conditional expression (`? :`) can now be a reference.

Safe efficient code enhancements

Language features introduced in 7.2 let you work with value types while using reference semantics. They are designed to increase performance by minimizing copying value types without incurring the memory allocations associated with using reference types. The features include:

- The `in` modifier on parameters, to specify that an argument is passed by reference but not modified by the called method. Adding the `in` modifier to an argument is a [source compatible change](#).
- The `ref readonly` modifier on method returns, to indicate that a method returns its value by reference but doesn't allow writes to that object. Adding the `ref readonly` modifier is a [source compatible change](#), if the return is assigned to a value. Adding the `readonly` modifier to an existing `ref` return statement is an [incompatible change](#). It requires callers to update the declaration of `ref` local variables to include the `readonly` modifier.
- The `readonly struct` declaration, to indicate that a struct is immutable and should be passed as an `in` parameter to its member methods. Adding the `readonly` modifier to an existing struct declaration is a [binary compatible change](#).
- The `ref struct` declaration, to indicate that a struct type accesses managed memory directly and must always be stack allocated. Adding the `ref` modifier to an existing `struct` declaration is an [incompatible change](#). A `ref struct` cannot be a member of a class or used in other locations where it may be allocated on the heap.

You can read more about all these changes in [Write safe efficient code](#).

Non-trailing named arguments

Method calls may now use named arguments that precede positional arguments when those named arguments are in the correct positions. For more information see [Named and optional arguments](#).

Leading underscores in numeric literals

The implementation of support for digit separators in C# 7.0 didn't allow the `_` to be the first character of the literal value. Hex and binary numeric literals may now begin with an `_`.

For example:

```
int binaryValue = 0b_0101_0101;
```

private protected access modifier

A new compound access modifier: `private protected` indicates that a member may be accessed by containing class or derived classes that are declared in the same assembly. While `protected internal` allows access by derived classes or classes that are in the same assembly, `private protected` limits access to derived types declared in the same assembly.

For more information see [access modifiers](#) in the language reference.

Conditional `ref` expressions

Finally, the conditional expression may produce a `ref` result instead of a value result. For example, you would write the following to retrieve a reference to the first element in one of two arrays:

```
ref var r = ref (arr != null ? ref arr[0] : ref otherArr[0]);
```

The variable `r` is a reference to the first value in either `arr` or `otherArr`.

For more information, see [conditional operator \(?:\)](#) in the language reference.

What's new in C# 7.1

6/2/2018 • 2 minutes to read • [Edit Online](#)

C# 7.1 is the first point release to the C# language. It marks an increased release cadence for the language. You can use the new features sooner, ideally when each new feature is ready. C# 7.1 adds the ability to configure the compiler to match a specified version of the language. That enables you to separate the decision to upgrade tools from the decision to upgrade language versions.

C# 7.1 adds the [language version selection](#) configuration element, three new language features and new compiler behavior.

The new language features in this release are:

- [async Main method](#)
 - The entry point for an application can have the `async` modifier.
- [default literal expressions](#)
 - You can use default literal expressions in default value expressions when the target type can be inferred.
- [Inferred tuple element names](#)
 - The names of tuple elements can be inferred from tuple initialization in many cases.

Finally, the compiler has two options `/refout` and `/refonly` that control [reference assembly generation](#).

To use the latest features in a point release, you need to [configure the compiler language version](#) and select the version.

Async main

An *async main* method enables you to use `await` in your `Main` method. Previously you would need to write:

```
static int Main()
{
    return DoAsyncWork().GetAwaiter().GetResult();
}
```

You can now write:

```
static async Task<int> Main()
{
    // This could also be replaced with the body
    // DoAsyncWork, including its await expressions:
    return await DoAsyncWork();
}
```

If your program doesn't return an exit code, you can declare a `Main` method that returns a [Task](#):

```
static async Task Main()
{
    await SomeAsyncMethod();
}
```

You can read more about the details in the [async main](#) topic in the programming guide.

Default literal expressions

Default literal expressions are an enhancement to default value expressions. These expressions initialize a variable to the default value. Where you previously would write:

```
Func<string, bool> whereClause = default(Func<string, bool>);
```

You can now omit the type on the right-hand side of the initialization:

```
Func<string, bool> whereClause = default;
```

You can learn more about this enhancement in the C# Programming Guide topic on [default value expressions](#).

This enhancement also changes some of the parsing rules for the [default keyword](#).

Inferred tuple element names

This feature is a small enhancement to the tuples feature introduced in C# 7.0. Many times when you initialize a tuple, the variables used for the right side of the assignment are the same as the names you'd like for the tuple elements:

```
int count = 5;
string label = "Colors used in the map";
var pair = (count: count, label: label);
```

The names of tuple elements can be inferred from the variables used to initialize the tuple in C# 7.1:

```
int count = 5;
string label = "Colors used in the map";
var pair = (count, label); // element names are "count" and "label"
```

You can learn more about this feature in the [Tuples](#) topic.

Reference assembly generation

There are two new compiler options that generate *reference-only assemblies*: [/refout](#) and [/refonly](#). The linked topics explain these options and reference assemblies in more detail.

What's new in C# 7.0

2/22/2019 • 25 minutes to read • [Edit Online](#)

C# 7.0 adds a number of new features to the C# language:

- [out variables](#)
 - You can declare `out` values inline as arguments to the method where they are used.
- [Tuples](#)
 - You can create lightweight, unnamed types that contain multiple public fields. Compilers and IDE tools understand the semantics of these types.
- [Discards](#)
 - Discards are temporary, write-only variables used in assignments when you don't care about the value assigned. They are particularly useful when deconstructing tuples and user-defined types, as well as when calling methods with `out` parameters.
- [Pattern Matching](#)
 - You can create branching logic based on arbitrary types and values of the members of those types.
- [ref locals and returns](#)
 - Method local variables and return values can be references to other storage.
- [Local Functions](#)
 - You can nest functions inside other functions to limit their scope and visibility.
- [More expression-bodied members](#)
 - The list of members that can be authored using expressions has grown.
- [throw Expressions](#)
 - You can throw exceptions in code constructs that previously were not allowed because `throw` was a statement.
- [Generalized async return types](#)
 - Methods declared with the `async` modifier can return other types in addition to `Task` and `Task<T>`.
- [Numeric literal syntax improvements](#)
 - New tokens improve readability for numeric constants.

The remainder of this topic discusses each of the features. For each feature, you'll learn the reasoning behind it. You'll learn the syntax. You'll see some sample scenarios where using the new feature will make you more productive as a developer.

`out` variables

The existing syntax that supports `out` parameters has been improved in this version.

Previously, you would need to separate the declaration of the `out` variable and its initialization into two different statements:

```
int numericResult;
if (int.TryParse(input, out numericResult))
    Console.WriteLine(numericResult);
else
    Console.WriteLine("Could not parse input");
```

You can now declare `out` variables in the argument list of a method call, rather than writing a separate declaration statement:

```
if (int.TryParse(input, out int result))
    Console.WriteLine(result);
else
    Console.WriteLine("Could not parse input");
```

You may want to specify the type of the `out` variable for clarity, as shown above. However, the language does support using an implicitly typed local variable:

```
if (int.TryParse(input, out var answer))
    Console.WriteLine(answer);
else
    Console.WriteLine("Could not parse input");
```

- The code is easier to read.
 - You declare the `out` variable where you use it, not on another line above.
- No need to assign an initial value.
 - By declaring the `out` variable where it is used in a method call, you can't accidentally use it before it is assigned.

The most common use for this feature will be the `Try` pattern. In this pattern, a method returns a `bool` indicating success or failure and an `out` variable that provides the result if the method succeeds.

When using the `out` variable declaration, the declared variable "leaks" into the outer scope of the if statement. This allows you to use the variable afterwards:

```
if (!int.TryParse(input, out int result))
{
    return null;
}

return result;
```

Tuples

NOTE

The new tuples features require the `ValueTuple` types. You must add the NuGet package `System.ValueTuple` in order to use it on platforms that do not include the types.

This is similar to other language features that rely on types delivered in the framework. Example include `async` and `await` relying on the `INotifyCompletion` interface, and LINQ relying on `IEnumerable<T>`. However, the delivery mechanism is changing as .NET is becoming more platform independent. The .NET Framework may not always ship on the same cadence as the language compiler. When new language features rely on new types, those types will be available as NuGet packages when the language features ship. As these new types get added to the .NET Standard API and delivered as part of the framework, the NuGet package requirement will be removed.

C# provides a rich syntax for classes and structs that is used to explain your design intent. But sometimes that rich syntax requires extra work with minimal benefit. You may often write methods that need a simple structure containing more than one data element. To support these scenarios *tuples* were added to C#. Tuples are lightweight data structures that contain multiple fields to represent the data members. The fields are not validated, and you cannot define your own methods

NOTE

Tuples were available before C# 7.0, but they were inefficient and had no language support. This meant that tuple elements could only be referenced as `Item1`, `Item2` and so on. C# 7.0 introduces language support for tuples, which enables semantic names for the fields of a tuple using new, more efficient tuple types.

You can create a tuple by assigning a value to each member:

```
var letters = ("a", "b");
```

That assignment creates a tuple whose members are `Item1` and `Item2`, which you can use in the same way as [Tuple](#). You can change the syntax to create a tuple that provides semantic names to each of the members of the tuple:

```
(string Alpha, string Beta) namedLetters = ("a", "b");
```

The `namedLetters` tuple contains fields referred to as `Alpha` and `Beta`. Those names exist only at compile time and are not preserved for example when inspecting the tuple using reflection at runtime.

In a tuple assignment, you can also specify the names of the fields on the right-hand side of the assignment:

```
var alphabetStart = (Alpha: "a", Beta: "b");
```

You can specify names for the fields on both the left and right-hand side of the assignment:

```
(string First, string Second) firstLetters = (Alpha: "a", Beta: "b");
```

The line above generates a warning, `CS8123`, telling you that the names on the right side of the assignment, `Alpha` and `Beta` are ignored because they conflict with the names on the left side, `First` and `Second`.

The examples above show the basic syntax to declare tuples. Tuples are most useful as return types for `private` and `internal` methods. Tuples provide a simple syntax for those methods to return multiple discrete values: You save the work of authoring a `class` or a `struct` that defines the type returned. There is no need for creating a new type.

Creating a tuple is more efficient and more productive. It is a simpler, lightweight syntax to define a data structure that carries more than one value. The example method below returns the minimum and maximum values found in a sequence of integers:

```
private static (int Max, int Min) Range(IEnumerable<int> numbers)
{
    int min = int.MaxValue;
    int max = int.MinValue;
    foreach(var n in numbers)
    {
        min = (n < min) ? n : min;
        max = (n > max) ? n : max;
    }
    return (max, min);
}
```

Using tuples in this way offers several advantages:

- You save the work of authoring a `class` or a `struct` that defines the type returned.
- You do not need to create new type.
- The language enhancements removes the need to call the `Create<T1>(T1)` methods.

The declaration for the method provides the names for the fields of the tuple that is returned. When you call the method, the return value is a tuple whose fields are `Max` and `Min`:

```
var range = Range(numbers);
```

There may be times when you want to unpack the members of a tuple that were returned from a method. You can do that by declaring separate variables for each of the values in the tuple. This is called *deconstructing* the tuple:

```
(int max, int min) = Range(numbers);
```

You can also provide a similar deconstruction for any type in .NET. This is done by writing a `Deconstruct` method as a member of the class. That `Deconstruct` method provides a set of `out` arguments for each of the properties you want to extract. Consider this `Point` class that provides a deconstructor method that extracts the `X` and `Y` coordinates:

```
public class Point
{
    public Point(double x, double y)
    {
        this.X = x;
        this.Y = y;
    }

    public double X { get; }
    public double Y { get; }

    public void Deconstruct(out double x, out double y)
    {
        x = this.X;
        y = this.Y;
    }
}
```

You can extract the individual fields by assigning a `Point` to a tuple:

```
var p = new Point(3.14, 2.71);
(double X, double Y) = p;
```

You are not bound by the names defined in the `Deconstruct` method. You can rename the extract variables as part of the assignment:

```
(double horizontalDistance, double verticalDistance) = p;
```

You can learn more in depth about tuples in the [tuples topic](#).

Discards

Often when deconstructing a tuple or calling a method with `out` parameters, you're forced to define a variable whose value you don't care about and don't intend to use. C# adds support for *discards* to handle this scenario. A

discard is a write-only variable whose name is `_` (the underscore character); you can assign all of the values that you intend to discard to the single variable. A discard is like an unassigned variable; apart from the assignment statement, the discard can't be used in code.

Discards are supported in the following scenarios:

- When deconstructing tuples or user-defined types.
- When calling methods with `out` parameters.
- In a pattern matching operation with the `is` and `switch` statements.
- As a standalone identifier when you want to explicitly identify the value of an assignment as a discard.

The following example defines a `QueryCityDataForYears` method that returns a 6-tuple that contains a data for a city for two different years. The method call in the example is concerned only with the two population values returned by the method and so treats the remaining values in the tuple as discards when it deconstructs the tuple.

```
using System;
using System.Collections.Generic;

public class Example
{
    public static void Main()
    {
        var (_, _, _, pop1, _, pop2) = QueryCityDataForYears("New York City", 1960, 2010);

        Console.WriteLine($"Population change, 1960 to 2010: {pop2 - pop1:N0}");
    }

    private static (string, double, int, int, int, int) QueryCityDataForYears(string name, int year1, int year2)
    {
        int population1 = 0, population2 = 0;
        double area = 0;

        if (name == "New York City") {
            area = 468.48;
            if (year1 == 1960) {
                population1 = 7781984;
            }
            if (year2 == 2010) {
                population2 = 8175133;
            }
            return (name, area, year1, population1, year2, population2);
        }

        return ("", 0, 0, 0, 0, 0);
    }
}

// The example displays the following output:
//      Population change, 1960 to 2010: 393,149
```

For more information, see [Discards](#).

Pattern matching

Pattern matching is a feature that allows you to implement method dispatch on properties other than the type of an object. You're probably already familiar with method dispatch based on the type of an object. In Object Oriented programming, virtual and override methods provide language syntax to implement method dispatching based on an object's type. Base and Derived classes provide different implementations. Pattern matching expressions extend this concept so that you can easily implement similar dispatch patterns for types and data elements that are not related through an inheritance hierarchy.

Pattern matching supports `is` expressions and `switch` expressions. Each enables inspecting an object and its properties to determine if that object satisfies the sought pattern. You use the `when` keyword to specify additional rules to the pattern.

`is expression`

The `is` pattern expression extends the familiar `is` operator to query an object beyond its type.

Let's start with a simple scenario. We'll add capabilities to this scenario that demonstrate how pattern matching expressions make algorithms that work with unrelated types easy. We'll start with a method that computes the sum of a number of die rolls:

```
public static int DiceSum(IEnumerable<int> values)
{
    return values.Sum();
}
```

You might quickly find that you need to find the sum of die rolls where some of the rolls are made with multiple dice (dice is the plural of die). Part of the input sequence may be multiple results instead of a single number:

```
public static int DiceSum2(IEnumerable<object> values)
{
    var sum = 0;
    foreach(var item in values)
    {
        if (item is int val)
            sum += val;
        else if (item is IEnumerable<object> subList)
            sum += DiceSum2(subList);
    }
    return sum;
}
```

The `is` pattern expression works quite well in this scenario. As part of checking the type, you write a variable initialization. This creates a new variable of the validated runtime type.

As you keep extending these scenarios, you may find that you build more `if` and `else if` statements. Once that becomes unwieldy, you'll likely want to switch to `switch` pattern expressions.

`switch statement updates`

The *match expression* has a familiar syntax, based on the `switch` statement already part of the C# language. Let's translate the existing code to use a match expression before adding new cases:

```

public static int DiceSum3(IEnumerable<object> values)
{
    var sum = 0;
    foreach (var item in values)
    {
        switch (item)
        {
            case int val:
                sum += val;
                break;
            case IEnumerable<object> subList:
                sum += DiceSum3(subList);
                break;
        }
    }
    return sum;
}

```

The match expressions have a slightly different syntax than the `is` expressions, where you declare the type and variable at the beginning of the `case` expression.

The match expressions also support constants. This can save time by factoring out simple cases:

```

public static int DiceSum4(IEnumerable<object> values)
{
    var sum = 0;
    foreach (var item in values)
    {
        switch (item)
        {
            case 0:
                break;
            case int val:
                sum += val;
                break;
            case IEnumerable<object> subList when subList.Any():
                sum += DiceSum4(subList);
                break;
            case IEnumerable<object> subList:
                break;
            case null:
                break;
            default:
                throw new InvalidOperationException("unknown item type");
        }
    }
    return sum;
}

```

The code above adds cases for `0` as a special case of `int`, and `null` as a special case when there is no input. This demonstrates one important new feature in switch pattern expressions: the order of the `case` expressions now matters. The `0` case must appear before the general `int` case. Otherwise, the first pattern to match would be the `int` case, even when the value is `0`. If you accidentally order match expressions such that a later case has already been handled, the compiler will flag that and generate an error.

This same behavior enables the special case for an empty input sequence. You can see that the case for an `IEnumerable` item that has elements must appear before the general `IEnumerable` case.

This version has also added a `default` case. The `default` case is always evaluated last, regardless of the order it appears in the source. For that reason, convention is to put the `default` case last.

Finally, let's add one last `case` for a new style of die. Some games use percentile dice to represent larger ranges of

numbers.

NOTE

Two 10-sided percentile dice can represent every number from 0 through 99. One die has sides labelled `00`, `10`, `20`, ..., `90`. The other die has sides labeled `0`, `1`, `2`, ..., `9`. Add the two die values together and you can get every number from 0 through 99.

To add this kind of die to your collection, first define a type to represent the percentile dice. The `TensDigit` property stores values `0`, `10`, `20`, up to `90`:

```
public struct PercentileDice
{
    public int OnesDigit { get; }
    public int TensDigit { get; }

    public PercentileDice(int tensDigit, int onesDigit)
    {
        this.OnesDigit = onesDigit;
        this.TensDigit = tensDigit;
    }
}
```

Then, add a `case` match expression for the new type:

```
public static int DiceSum5(IEnumerable<object> values)
{
    var sum = 0;
    foreach (var item in values)
    {
        switch (item)
        {
            case 0:
                break;
            case int val:
                sum += val;
                break;
            case PercentileDice dice:
                sum += dice.TensDigit + dice.OnesDigit;
                break;
            case IEnumerable<object> subList when subList.Any():
                sum += DiceSum5(subList);
                break;
            case IEnumerable<object> subList:
                break;
            case null:
                break;
            default:
                throw new InvalidOperationException("unknown item type");
        }
    }
    return sum;
}
```

The new syntax for pattern matching expressions makes it easier to create dispatch algorithms based on an object's type, or other properties, using a clear and concise syntax. Pattern matching expressions enable these constructs on data types that are unrelated by inheritance.

You can learn more about pattern matching in the topic dedicated to [pattern matching in C#](#).

Ref locals and returns

This feature enables algorithms that use and return references to variables defined elsewhere. One example is working with large matrices, and finding a single location with certain characteristics. One method would return the two indices for a single location in the matrix:

```
public static (int i, int j) Find(int[,] matrix, Func<int, bool> predicate)
{
    for (int i = 0; i < matrix.GetLength(0); i++)
        for (int j = 0; j < matrix.GetLength(1); j++)
            if (predicate(matrix[i, j]))
                return (i, j);
    return (-1, -1); // Not found
}
```

There are many issues with this code. First of all, it's a public method that's returning a tuple. The language supports this, but user defined types (either classes or structs) are preferred for public APIs.

Second, this method is returning the indices to the item in the matrix. That leads callers to write code that uses those indices to dereference the matrix and modify a single element:

```
var indices = MatrixSearch.Find(matrix, (val) => val == 42);
Console.WriteLine(indices);
matrix[indices.i, indices.j] = 24;
```

You'd rather write a method that returns a *reference* to the element of the matrix that you want to change. You could only accomplish this by using unsafe code and returning a pointer to an `int` in previous versions.

Let's walk through a series of changes to demonstrate the ref local feature and show how to create a method that returns a reference to internal storage. Along the way, you'll learn the rules of the ref return and ref local feature that protects you from accidentally misusing it.

Start by modifying the `Find` method declaration so that it returns a `ref int` instead of a tuple. Then, modify the return statement so it returns the value stored in the matrix instead of the two indices:

```
// Note that this won't compile.
// Method declaration indicates ref return,
// but return statement specifies a value return.
public static ref int Find2(int[,] matrix, Func<int, bool> predicate)
{
    for (int i = 0; i < matrix.GetLength(0); i++)
        for (int j = 0; j < matrix.GetLength(1); j++)
            if (predicate(matrix[i, j]))
                return matrix[i, j];
    throw new InvalidOperationException("Not found");
}
```

When you declare that a method returns a `ref` variable, you must also add the `ref` keyword to each return statement. That indicates return by reference, and helps developers reading the code later remember that the method returns by reference:

```

public static ref int Find3(int[,] matrix, Func<int, bool> predicate)
{
    for (int i = 0; i < matrix.GetLength(0); i++)
        for (int j = 0; j < matrix.GetLength(1); j++)
            if (predicate(matrix[i, j]))
                return ref matrix[i, j];
    throw new InvalidOperationException("Not found");
}

```

Now that the method returns a reference to the integer value in the matrix, you need to modify where it's called.

The `var` declaration means that `valItem` is now an `int` rather than a tuple:

```

var valItem = MatrixSearch.Find3(matrix, (val) => val == 42);
Console.WriteLine(valItem);
valItem = 24;
Console.WriteLine(matrix[4, 2]);

```

The second `WriteLine` statement in the example above prints out the value `42`, not `24`. The variable `valItem` is an `int`, not a `ref int`. The `var` keyword enables the compiler to specify the type, but will not implicitly add the `ref` modifier. Instead, the value referred to by the `ref return` is *copied* to the variable on the left-hand side of the assignment. The variable is not a `ref` local.

In order to get the result you want, you need to add the `ref` modifier to the local variable declaration to make the variable a reference when the return value is a reference:

```

ref var item = ref MatrixSearch.Find3(matrix, (val) => val == 42);
Console.WriteLine(item);
item = 24;
Console.WriteLine(matrix[4, 2]);

```

Now, the second `WriteLine` statement in the example above will print out the value `24`, indicating that the storage in the matrix has been modified. The local variable has been declared with the `ref` modifier, and it will take a `ref` return. You must initialize a `ref` variable when it is declared, you cannot split the declaration and the initialization.

The C# language has three other rules that protect you from misusing the `ref` locals and returns:

- You cannot assign a standard method return value to a `ref` local variable.
 - That disallows statements like `ref int i = sequence.Count();`
- You cannot return a `ref` to a variable whose lifetime does not extend beyond the execution of the method.
 - That means you cannot return a reference to a local variable or a variable with a similar scope.
- `ref` locals and returns can't be used with `async` methods.
 - The compiler can't know if the referenced variable has been set to its final value when the `async` method returns.

The addition of `ref` locals and `ref` returns enable algorithms that are more efficient by avoiding copying values, or performing dereferencing operations multiple times.

Adding `ref` to the return value is a [source compatible change](#). Existing code compiles, but the `ref` return value is copied when assigned. Callers must update the storage for the return value to a `ref` local variable to store the return as a reference.

For more information, see the [ref keyword](#) article.

Local functions

Many designs for classes include methods that are called from only one location. These additional private methods keep each method small and focused. However, they can make it harder to understand a class when reading it the first time. These methods must be understood outside of the context of the single calling location.

For those designs, *local functions* enable you to declare methods inside the context of another method. This makes it easier for readers of the class to see that the local method is only called from the context in which it is declared.

There are two very common use cases for local functions: public iterator methods and public async methods. Both types of methods generate code that reports errors later than programmers might expect. In the case of iterator methods, any exceptions are observed only when calling code that enumerates the returned sequence. In the case of async methods, any exceptions are only observed when the returned `Task` is awaited.

Let's start with an iterator method:

```
public static IEnumerable<char> AlphabetSubset(char start, char end)
{
    if (start < 'a' || start > 'z')
        throw new ArgumentOutOfRangeException(paramName: nameof(start), message: "start must be a letter");
    if (end < 'a' || end > 'z')
        throw new ArgumentOutOfRangeException(paramName: nameof(end), message: "end must be a letter");

    if (end <= start)
        throw new ArgumentException($"{nameof(end)} must be greater than {nameof(start)}");
    for (var c = start; c < end; c++)
        yield return c;
}
```

Examine the code below that calls the iterator method incorrectly:

```
var resultSet = Iterator.AlphabetSubset('f', 'a');
Console.WriteLine("iterator created");
foreach (var thing in resultSet)
    Console.Write($"{thing}, ");
```

The exception is thrown when `resultSet` is iterated, not when `resultSet` is created. In this contained example, most developers could quickly diagnose the problem. However, in larger codebases, the code that creates an iterator often isn't as close to the code that enumerates the result. You can refactor the code so that the public method validates all arguments, and a private method generates the enumeration:

```
public static IEnumerable<char> AlphabetSubset2(char start, char end)
{
    if (start < 'a' || start > 'z')
        throw new ArgumentOutOfRangeException(paramName: nameof(start), message: "start must be a letter");
    if (end < 'a' || end > 'z')
        throw new ArgumentOutOfRangeException(paramName: nameof(end), message: "end must be a letter");

    if (end <= start)
        throw new ArgumentException($"{nameof(end)} must be greater than {nameof(start)}");
    return alphabetSubsetImplementation(start, end);
}

private static IEnumerable<char> alphabetSubsetImplementation(char start, char end)
{
    for (var c = start; c < end; c++)
        yield return c;
}
```

This refactored version will throw exceptions immediately because the public method is not an iterator method; only the private method uses the `yield return` syntax. However, there are potential problems with this refactoring.

The private method should only be called from the public interface method, because otherwise all argument validation is skipped. Readers of the class must discover this fact by reading the entire class and searching for any other references to the `alphabetSubsetImplementation` method.

You can make that design intent more clear by declaring the `alphabetSubsetImplementation` as a local function inside the public API method:

```
public static IEnumerable<char> AlphabetSubset3(char start, char end)
{
    if (start < 'a' || start > 'z')
        throw new ArgumentOutOfRangeException(paramName: nameof(start), message: "start must be a letter");
    if (end < 'a' || end > 'z')
        throw new ArgumentOutOfRangeException(paramName: nameof(end), message: "end must be a letter");

    if (end <= start)
        throw new ArgumentException($"{nameof(end)} must be greater than {nameof(start)}");

    return alphabetSubsetImplementation();

    I Enumerable<char> alphabetSubsetImplementation()
    {
        for (var c = start; c < end; c++)
            yield return c;
    }
}
```

The version above makes it clear that the local method is referenced only in the context of the outer method. The rules for local functions also ensure that a developer can't accidentally call the local function from another location in the class and bypass the argument validation.

The same technique can be employed with `async` methods to ensure that exceptions arising from argument validation are thrown before the asynchronous work begins:

```
public Task<string> PerformLongRunningWork(string address, int index, string name)
{
    if (string.IsNullOrWhiteSpace(address))
        throw new ArgumentException(message: "An address is required", paramName: nameof(address));
    if (index < 0)
        throw new ArgumentOutOfRangeException(paramName: nameof(index), message: "The index must be non-negative");
    if (string.IsNullOrWhiteSpace(name))
        throw new ArgumentException(message: "You must supply a name", paramName: nameof(name));

    return longRunningWorkImplementation();

    async Task<string> longRunningWorkImplementation()
    {
        var interimResult = await FirstWork(address);
        var secondResult = await SecondStep(index, name);
        return $"The results are {interimResult} and {secondResult}. Enjoy.";
    }
}
```

NOTE

Some of the designs that are supported by local functions could also be accomplished using *lambda expressions*. Those interested can [read more about the differences](#)

More expression-bodied members

C# 6 introduced [expression-bodied members](#) for member functions, and read-only properties. C# 7.0 expands the allowed members that can be implemented as expressions. In C# 7.0, you can implement *constructors*, *finalizers*, and `get` and `set` accessors on *properties* and *indexers*. The following code shows examples of each:

```
// Expression-bodied constructor
public ExpressionMembersExample(string label) => this.Label = label;

// Expression-bodied finalizer
~ExpressionMembersExample() => Console.Error.WriteLine("Finalized!");

private string label;

// Expression-bodied get / set accessors.
public string Label
{
    get => label;
    set => this.label = value ?? "Default label";
}
```

NOTE

This example does not need a finalizer, but it is shown to demonstrate the syntax. You should not implement a finalizer in your class unless it is necessary to release unmanaged resources. You should also consider using the [SafeHandle](#) class instead of managing unmanaged resources directly.

These new locations for expression-bodied members represent an important milestone for the C# language: These features were implemented by community members working on the open-source [Roslyn](#) project.

Changing a method to an expression bodied member is a [binary compatible change](#).

Throw expressions

In C#, `throw` has always been a statement. Because `throw` is a statement, not an expression, there were C# constructs where you could not use it. These included conditional expressions, null coalescing expressions, and some lambda expressions. The addition of expression-bodied members adds more locations where `throw` expressions would be useful. So that you can write any of these constructs, C# 7.0 introduces *throw expressions*.

The syntax is the same as you've always used for `throw` statements. The only difference is that now you can place them in new locations, such as in a conditional expression:

```
public string Name
{
    get => name;
    set => name = value ??
        throw new ArgumentNullException(paramName: nameof(value), message: "New name must not be null");
}
```

This features enables using throw expressions in initialization expressions:

```
private ConfigResource loadedConfig = LoadConfigResourceOrDefault() ??
    throw new InvalidOperationException("Could not load config");
```

Previously, those initializations would need to be in a constructor, with the throw statements in the body of the constructor:

```
public ApplicationOptions()
{
    loadedConfig = LoadConfigResourceOrDefault();
    if (loadedConfig == null)
        throw new InvalidOperationException("Could not load config");

}
```

NOTE

Both of the preceding constructs will cause exceptions to be thrown during the construction of an object. Those are often difficult to recover from. For that reason, designs that throw exceptions during construction are discouraged.

Generalized async return types

Returning a `Task` object from `async` methods can introduce performance bottlenecks in certain paths. `Task` is a reference type, so using it means allocating an object. In cases where a method declared with the `async` modifier returns a cached result, or completes synchronously, the extra allocations can become a significant time cost in performance critical sections of code. It can become very costly if those allocations occur in tight loops.

The new language feature means that `async` methods may return other types in addition to `Task`, `Task<T>` and `void`. The returned type must still satisfy the `async` pattern, meaning a `GetAwaiter` method must be accessible. As one concrete example, the `ValueTask` type has been added to the .NET framework to make use of this new language feature:

```
public async ValueTask<int> Func()
{
    await Task.Delay(100);
    return 5;
}
```

NOTE

You need to add the NuGet package `System.Threading.Tasks.Extensions` in order to use the `ValueTask<TResult>` type.

A simple optimization would be to use `ValueTask` in places where `Task` would be used before. However, if you want to perform extra optimizations by hand, you can cache results from `async` work and reuse the result in subsequent calls. The `ValueTask` struct has a constructor with a `Task` parameter so that you can construct a `ValueTask` from the return value of any existing `async` method:

```
public ValueTask<int> CachedFunc()
{
    return (cache) ? new ValueTask<int>(cacheResult) : new ValueTask<int>(LoadCache());
}

private bool cache = false;
private int cacheResult;
private async Task<int> LoadCache()
{
    // simulate async work:
    await Task.Delay(100);
    cacheResult = 100;
    cache = true;
    return cacheResult;
}
```

As with all performance recommendations, you should benchmark both versions before making large scale changes to your code.

When the return value is the target of an `await` statement, changing an API from a `Task<TResult>` to a `ValueTask<TResult>` is a [source compatible change](#). In general, changing to `ValueTask` is not.

Numeric literal syntax improvements

Misreading numeric constants can make it harder to understand code when reading it for the first time. This often occurs when those numbers are used as bit masks or other symbolic rather than numeric values. C# 7.0 includes two new features to make it easier to write numbers in the most readable fashion for the intended use: *binary literals*, and *digit separators*.

For those times when you are creating bit masks, or whenever a binary representation of a number makes the most readable code, write that number in binary:

```
public const int One = 0b0001;
public const int Two = 0b0010;
public const int Four = 0b0100;
public const int Eight = 0b1000;
```

The `0b` at the beginning of the constant indicates that the number is written as a binary number.

Binary numbers can get very long, so it's often easier to see the bit patterns by introducing the `_` as a digit separator:

```
public const int Sixteen = 0b0001_0000;
public const int ThirtyTwo = 0b0010_0000;
public const int SixtyFour = 0b0100_0000;
public const int OneHundredTwentyEight = 0b1000_0000;
```

The digit separator can appear anywhere in the constant. For base 10 numbers, it would be common to use it as a thousands separator:

```
public const long BillionsAndBillions = 100_000_000_000;
```

The digit separator can be used with `decimal`, `float` and `double` types as well:

```
public const double AvogadroConstant = 6.022_140_857_747_474e23;
public const decimal GoldenRatio = 1.618_033_988_749_894_848_204_586_834_365_638_117_720_309_179M;
```

Taken together, you can declare numeric constants with much more readability.

What's New in C# 6

1/8/2019 • 9 minutes to read • [Edit Online](#)

The 6.0 release of C# contained many features that improve productivity for developers. The overall effect of these features is that you write more concise code that is also more readable. The syntax contains less ceremony for many common practices. It's easier to see the design intent with less ceremony. Learn these features well, and you'll be more productive and write more readable code. You can concentrate more on your features than on the constructs of the language.

The rest of this article provides an overview of each of these features, with a link to explore each feature. You can also explore the features in an [interactive tutorial on C# 6](#) in the tutorials section.

Read-only auto-properties

Read-only auto-properties provide a more concise syntax to create immutable types. You declare the auto-property with only a get accessor:

```
public string FirstName { get; }  
public string LastName { get; }
```

The `FirstName` and `LastName` properties can be set only in the body of a constructor:

```
public Student(string firstName, string lastName)  
{  
    if (IsNullOrEmptyWhiteSpace(lastName))  
        throw new ArgumentException(message: "Cannot be blank", paramName: nameof(lastName));  
    FirstName = firstName;  
    LastName = lastName;  
}
```

Trying to set `LastName` in another method generates a `CS0200` compilation error:

```
public class Student  
{  
    public string LastName { get; }  
  
    public void ChangeName(string newLastName)  
    {  
        // Generates CS0200: Property or indexer cannot be assigned to -- it is read only  
        LastName = newLastName;  
    }  
}
```

This feature enables true language support for creating immutable types and uses the more concise and convenient auto-property syntax.

If adding this syntax doesn't remove an accessible method, it's a [binary compatible change](#).

Auto-property initializers

Auto-property initializers let you declare the initial value for an auto-property as part of the property declaration.

```
public ICollection<double> Grades { get; } = new List<double>();
```

The `Grades` member is initialized where it's declared. That makes it easier to perform the initialization exactly once. The initialization is part of the property declaration, making it easier to equate the storage allocation with the public interface for `Student` objects.

Expression-bodied function members

Many members that you write are single statements that could be single expressions. Write an expression-bodied member instead. It works for methods and read-only properties. For example, an override of `ToString()` is often a great candidate:

```
public override string ToString() => $"{LastName}, {FirstName}";
```

You can also use this syntax for read-only properties:

```
public string FullName => $"{FirstName} {LastName}";
```

Changing an existing member to an expression bodied member is a [binary compatible change](#).

using static

The *using static* enhancement enables you to import the static methods of a single class. You specify the class you're using:

```
using static System.Math;
```

The `Math` does not contain any instance methods. You can also use `using static` to import a class' static methods for a class that has both static and instance methods. One of the most useful examples is `String`:

```
using static System.String;
```

NOTE

You must use the fully qualified class name, `System.String` in a static using statement. You cannot use the `string` keyword instead.

When imported from a `static using` statement, extension methods are only in scope when called using the extension method invocation syntax. They aren't in scope when called as a static method. You'll often see this in LINQ queries. You can import the LINQ pattern by importing `Enumerable`, or `Queryable`.

```
using static System.Linq.Enumerable;
```

You typically call extension methods using extension method invocation expressions. Adding the class name in the rare case where you call them using static method call syntax resolves ambiguity.

The `static using` directive also imports any nested types. You can reference any nested types without qualification.

Null-conditional operators

The *null conditional operator* makes null checks much easier and fluid. Replace the member access `. . .` with `? . .`:

```
var first = person?.FirstName;
```

In the preceding example, the variable `first` is assigned `null` if the `person` object is `null`. Otherwise, it is assigned the value of the `FirstName` property. Most importantly, the `? . .` means that this line of code doesn't generate a `NullReferenceException` if the `person` variable is `null`. Instead, it short-circuits and returns `null`. You can also use a null conditional operator for array or indexer access. Replace `[]` with `?[]` in the index expression.

The following expression returns a `string`, regardless of the value of `person`. You often use this construct with the *null coalescing operator* to assign default values when one of the properties is `null`. When the expression short-circuits, the `null` value returned is typed to match the full expression.

```
first = person?.FirstName ?? "Unspecified";
```

You can also use `? . .` to conditionally invoke methods. The most common use of member functions with the null conditional operator is to safely invoke delegates (or event handlers) that may be `null`. You'll call the delegate's `Invoke` method using the `? . .` operator to access the member. You can see an example in the [delegate patterns](#) article.

The rules of the `? . .` operator ensure that the left-hand side of the operator is evaluated only once. It enables many idioms, including the following example using event handlers:

```
// preferred in C# 6:  
this.SomethingHappened?.Invoke(this, eventArgs);
```

Ensuring that the left side is evaluated only once also enables you to use any expression, including method calls, on the left side of the `? . .`.

String interpolation

With C# 6, the new [string interpolation](#) feature enables you to embed expressions in a string. Simply preface the string with `$` and use expressions between `{}` and `}` instead of ordinals:

```
public string FullName => $"{FirstName} {LastName}";
```

This example uses properties for the substituted expressions. You can use any expression. For example, you could compute a student's grade point average as part of the interpolation:

```
public string GetGradePointPercentage() =>  
    $"Name: {LastName}, {FirstName}. G.P.A: {Grades.Average():F2}";
```

The preceding line of code formats the value for `Grades.Average()` as a floating-point number with two decimal places.

Often, you may need to format the string produced using a specific culture. You use the fact that the object produced by a string interpolation can be implicitly converted to [System.FormattableString](#). The [FormattableString](#) instance contains the composite format string and the results of evaluating the expressions before converting them to strings. Use the `FormattableString.ToString(IFormatProvider)` method to specify the culture when formatting a

string. The following example produces a string using the German (de-DE) culture. (By default, the German culture uses the ',' character for the decimal separator, and the '.' character as the thousands separator.)

```
FormattableString str = $"Average grade is {s.Grades.Average()}";
var gradeStr = str.ToString(new System.Globalization.CultureInfo("de-DE"));
```

To get started with string interpolation, see the [String interpolation in C# interactive tutorial](#), the [String interpolation article](#), and the [String interpolation in C# tutorial](#).

Exception filters

Exception Filters are clauses that determine when a given catch clause should be applied. If the expression used for an exception filter evaluates to `true`, the catch clause performs its normal processing on an exception. If the expression evaluates to `false`, then the `catch` clause is skipped. One use is to examine information about an exception to determine if a `catch` clause can process the exception:

```
public static async Task<string> MakeRequest()
{
    WebRequestHandler webRequestHandler = new WebRequestHandler();
    webRequestHandler.AllowAutoRedirect = false;
    using (HttpClient client = new HttpClient(webRequestHandler))
    {
        var stringTask = client.GetStringAsync("https://docs.microsoft.com/en-us/dotnet/about/");
        try
        {
            var responseText = await stringTask;
            return responseText;
        }
        catch (System.Net.Http.HttpRequestException e) when (e.Message.Contains("301"))
        {
            return "Site Moved";
        }
    }
}
```

The `nameof` expression

The `nameof` expression evaluates to the name of a symbol. It's a great way to get tools working whenever you need the name of a variable, a property, or a member field. One of the most common uses for `nameof` is to provide the name of a symbol that caused an exception:

```
if (IsNullOrEmpty(lastName))
    throw new ArgumentException(message: "Cannot be blank", paramName: nameof(lastName));
```

Another use is with XAML-based applications that implement the `INotifyPropertyChanged` interface:

```

public string LastName
{
    get { return lastName; }
    set
    {
        if (value != lastName)
        {
            lastName = value;
            PropertyChanged?.Invoke(this,
                new PropertyChangedEventArgs(nameof(LastName)));
        }
    }
}
private string lastName;

```

Await in Catch and Finally blocks

C# 5 had several limitations around where you could place `await` expressions. With C# 6, you can now use `await` in `catch` or `finally` expressions. This is most often used with logging scenarios:

```

public static async Task<string> MakeRequestAndLogFailures()
{
    await logMethodEntrance();
    var client = new System.Net.Http.HttpClient();
    var streamTask = client.GetStringAsync("https://localhost:10000");
    try {
        var responseText = await streamTask;
        return responseText;
    } catch (System.Net.Http.HttpRequestException e) when (e.Message.Contains("301"))
    {
        await logError("Recovered from redirect", e);
        return "Site Moved";
    }
    finally
    {
        await logMethodExit();
        client.Dispose();
    }
}

```

The implementation details for adding `await` support inside `catch` and `finally` clauses ensure that the behavior is consistent with the behavior for synchronous code. When code executed in a `catch` or `finally` clause throws, execution looks for a suitable `catch` clause in the next surrounding block. If there was a current exception, that exception is lost. The same happens with awaited expressions in `catch` and `finally` clauses: a suitable `catch` is searched for, and the current exception, if any, is lost.

NOTE

This behavior is the reason it's recommended to write `catch` and `finally` clauses carefully, to avoid introducing new exceptions.

Initialize associative collections using indexers

Index Initializers is one of two features that make collection initializers more consistent with index usage. In earlier releases of C#, you could use *collection initializers* with sequence style collections, including [Dictionary< TKey, TValue >](#), by adding braces around key and value pairs:

```
private Dictionary<int, string> messages = new Dictionary<int, string>
{
    { 404, "Page not Found"},
    { 302, "Page moved, but left a forwarding address."},
    { 500, "The web server can't come out to play today."}
};
```

You can use them with `Dictionary<TKey,TValue>` collections and other types where the accessible `Add` method accepts more than one argument. The new syntax supports assignment using an index into the collection:

```
private Dictionary<int, string> webErrors = new Dictionary<int, string>
{
    [404] = "Page not Found",
    [302] = "Page moved, but left a forwarding address.",
    [500] = "The web server can't come out to play today."
};
```

This feature means that associative containers can be initialized using syntax similar to what's been in place for sequence containers for several versions.

Extension `Add` methods in collection initializers

Another feature that makes collection initialization easier is the ability to use an *extension method* for the `Add` method. This feature was added for parity with Visual Basic. The feature is most useful when you have a custom collection class that has a method with a different name to semantically add new items.

Improved overload resolution

This last feature is one you probably won't notice. There were constructs where the previous version of the C# compiler may have found some method calls involving lambda expressions ambiguous. Consider this method:

```
static Task DoThings()
{
    return Task.FromResult(0);
}
```

In earlier versions of C#, calling that method using the method group syntax would fail:

```
Task.Run(DoThings);
```

The earlier compiler couldn't distinguish correctly between `Task.Run(Action)` and `Task.Run(Func<Task>())`. In previous versions, you'd need to use a lambda expression as an argument:

```
Task.Run(() => DoThings());
```

The C# 6 compiler correctly determines that `Task.Run(Func<Task>())` is a better choice.

Deterministic compiler output

The `-deterministic` option instructs the compiler to produce a byte-for-byte identical output assembly for successive compilations of the same source files.

By default, every compilation produces unique output on each compilation. The compiler adds a timestamp, and a GUID generated from random numbers. You use this option if you want to compare the byte-for-byte output to

ensure consistency across builds.

For more information, see the [-deterministic compiler option](#) article.

The history of C#

3/16/2019 • 8 minutes to read • [Edit Online](#)

This article provides a history of each major release of the C# language. The C# team is continuing to innovate and add new features. Detailed language feature status, including features considered for upcoming releases can be found [on the dotnet/roslyn repository](#) on GitHub.

IMPORTANT

The C# language relies on types and methods in what the C# specification defines as a *standard library* for some of the features. The .NET platform delivers those types and methods in a number of packages. One example is exception processing. Every `throw` statement or expression is checked to ensure the object being thrown is derived from `Exception`. Similarly, every `catch` is checked to ensure that the type being caught is derived from `Exception`. Each version may add new requirements. To use the latest language features in older environments, you may need to install specific libraries. These dependencies are documented in the page for each specific version. You can learn more about the [relationships between language and library](#) for background on this dependency.

The C# build tools consider the latest major language release the default language version. There may be point releases between major releases, detailed in other articles in this section. To use the latest features in a point release, you need to [configure the compiler language version](#) and select the version. There have been three point releases since C# 7.0:

- [C# 7.3](#):
 - C# 7.3 is currently available in [Visual Studio 2017 version 15.7](#), and in the [.NET Core 2.1 SDK 2.1.300 RC1](#).
- [C# 7.2](#):
 - C# 7.2 is currently available in [Visual Studio 2017 version 15.5](#), and in the [.NET Core 2.0 SDK](#).
- [C# 7.1](#):
 - These features were added in [Visual Studio 2017 version 15.3](#), and in the [.NET Core 2.0 SDK](#).

C# version 1.0

When you go back and look, C# version 1.0 looked a lot like Java. As [part of its stated design goals for ECMA](#), it sought to be a "simple, modern, general-purpose object-oriented language." At the time, looking like Java meant it achieved those early design goals.

But if you look back on C# 1.0 now, you'd find yourself a little dizzy. It lacked the built-in async capabilities and some of the slick functionality around generics you take for granted. As a matter of fact, it lacked generics altogether. And [LINQ](#)? Not available yet. Those additions would take some years to come out.

C# version 1.0 looked stripped of features, compared to today. You'd find yourself writing some verbose code. But yet, you have to start somewhere. C# version 1.0 was a viable alternative to Java on the Windows platform.

The major features of C# 1.0 included:

- [Classes](#)
- [Structs](#)
- [Interfaces](#)
- [Events](#)
- [Properties](#)

- [Delegates](#)
- [Expressions](#)
- [Statements](#)
- [Attributes](#)
- [Literals](#)

C# version 1.2

C# version 1.2 shipped with Visual Studio 2003. It contained a few small enhancements to the language. Most notable is that starting with this version, the code generated in a `foreach` loop called `Dispose` on an `IEnumerator` when that `IEnumerator` implemented `IDisposable`.

C# version 2.0

Now things start to get interesting. Let's take a look at some major features of C# 2.0, released in 2005, along with Visual Studio 2005:

- [Generics](#)
- [Partial types](#)
- [Anonymous methods](#)
- [Nullable types](#)
- [Iterators](#)
- [Covariance and contravariance](#)

Other C# 2.0 features added capabilities to existing features:

- Getter/setter separate accessibility
- Method group conversions (delegates)
- Static classes
- Delegate inference

While C# may have started as a generic Object-Oriented (OO) language, C# version 2.0 changed that in a hurry. Once they had their feet under them, they went after some serious developer pain points. And they went after them in a significant way.

With generics, types and methods can operate on an arbitrary type while still retaining type safety. For instance, having a `List<T>` lets you have `List<string>` or `List<int>` and perform type-safe operations on those strings or integers while you iterate through them. Using generics is better than creating `ListInt` that derives from `ArrayList` or casting from `object` for every operation.

C# version 2.0 brought iterators. To put it succinctly, iterators let you examine all the items in a `List` (or other Enumerable types) with a `foreach` loop. Having iterators as a first-class part of the language dramatically enhanced readability of the language and people's ability to reason about the code.

And yet, C# continued to play a bit of catch-up with Java. Java had already released versions that included generics and iterators. But that would soon change as the languages continued to evolve apart.

C# version 3.0

C# version 3.0 came in late 2007, along with Visual Studio 2008, though the full boat of language features would actually come with .NET Framework version 3.5. This version marked a major change in the growth of C#. It established C# as a truly formidable programming language. Let's take a look at some major features in this version:

- [Auto-implemented properties](#)
- [Anonymous types](#)
- [Query expressions](#)
- [Lambda expressions](#)
- [Expression trees](#)
- [Extension methods](#)
- [Implicitly typed local variables](#)
- [Partial methods](#)
- [Object and collection initializers](#)

In retrospect, many of these features seem both inevitable and inseparable. They all fit together strategically. It's generally thought that C# version's killer feature was the query expression, also known as Language-Integrated Query (LINQ).

A more nuanced view examines expression trees, lambda expressions, and anonymous types as the foundation upon which LINQ is constructed. But, in either case, C# 3.0 presented a revolutionary concept. C# 3.0 had begun to lay the groundwork for turning C# into a hybrid Object-Oriented / Functional language.

Specifically, you could now write SQL-style, declarative queries to perform operations on collections, among other things. Instead of writing a `for` loop to compute the average of a list of integers, you could now do that as simply as `list.Average()`. The combination of query expressions and extension methods made it look as though that list of integers had gotten a whole lot smarter.

It took time for people to really grasp and integrate the concept, but they gradually did. And now, years later, code is much more concise, simple, and functional.

C# version 4.0

C# version 4.0 would have had a difficult time living up to the groundbreaking status of version 3.0. With version 3.0, C# had moved the language firmly out from the shadow of Java and into prominence. The language was quickly becoming elegant.

The next version did introduce some interesting new features:

- [Dynamic binding](#)
- [Named/optional arguments](#)
- [Generic covariant and contravariant](#)
- [Embedded interop types](#)

Embedded interop types alleviated a deployment pain. Generic covariance and contravariance give you more power to use generics, but they're a bit academic and probably most appreciated by framework and library authors. Named and optional parameters let you eliminate many method overloads and provide convenience. But none of those features are exactly paradigm altering.

The major feature was the introduction of the `dynamic` keyword. The `dynamic` keyword introduced into C# version 4.0 the ability to override the compiler on compile-time typing. By using the `dynamic` keyword, you can create constructs similar to dynamically typed languages like JavaScript. You can create a `dynamic x = "a string"` and then add six to it, leaving it up to the runtime to sort out what should happen next.

Dynamic binding gives you the potential for errors but also great power within the language.

C# version 5.0

C# version 5.0 was a focused version of the language. Nearly all of the effort for that version went into another groundbreaking language concept: the `async` and `await` model for asynchronous programming. Here is the

major features list:

- [Asynchronous members](#)
- [Caller info attributes](#)

See Also

- [Code Project: Caller Info Attributes in C# 5.0](#)

The caller info attribute lets you easily retrieve information about the context in which you're running without resorting to a ton of boilerplate reflection code. It has many uses in diagnostics and logging tasks.

But `async` and `await` are the real stars of this release. When these features came out in 2012, C# changed the game again by baking asynchrony into the language as a first-class participant. If you've ever dealt with long running operations and the implementation of webs of callbacks, you probably loved this language feature.

C# version 6.0

With versions 3.0 and 5.0, C# had added major new features in an object-oriented language. With version 6.0, it would go away from doing a dominant killer feature and instead release many smaller features that made C# programming more productive. Here are some of them:

- [Static imports](#)
- [Exception filters](#)
- [Auto-property initializers](#)
- [Expression bodied members](#)
- [Null propagator](#)
- [String interpolation](#)
- [nameof operator](#)
- [Index initializers](#)

Other new features include:

- [Await in catch/finally blocks](#)
- [Default values for getter-only properties](#)

Each of these features is interesting in its own right. But if you look at them altogether, you see an interesting pattern. In this version, C# eliminated language boilerplate to make code more terse and readable. So for fans of clean, simple code, this language version was a huge win.

They did one other thing along with this version, though it's not a traditional language feature in itself. They released [Roslyn the compiler as a service](#). The C# compiler is now written in C#, and you can use the compiler as part of your programming efforts.

C# version 7.0

The most recent major version is C# version 7.0. This version has some evolutionary and cool stuff in the vein of C# 6.0, but without the compiler as a service. Here are some of the new features:

- [Out variables](#)
- [Tuples and deconstruction](#)
- [Pattern matching](#)
- [Local functions](#)
- [Expanded expression bodied members](#)
- [Ref locals and returns](#)

Other features included:

- [Discards](#)
- [Binary Literals and Digit Separators](#)
- [Throw expressions](#)

All of these features offer cool new capabilities for developers and the opportunity to write even cleaner code than ever. A highlight is condensing the declaration of variables to use with the `out` keyword and by allowing multiple return values via tuple.

But C# is being put to ever broader use. .NET Core now targets any operating system and has its eyes firmly on the cloud and on portability. These new capabilities certainly occupy the language designers' thoughts and time, in addition to coming up with new features.

Article originally published on the [NDepend blog](#), courtesy of Erik Dietrich and Patrick Smacchia.

Relationships between language features and library types

5/4/2018 • 2 minutes to read • [Edit Online](#)

The C# language definition requires a standard library to have certain types and certain accessible members on those types. The compiler generates code that uses these required types and members for many different language features. When necessary, there are NuGet packages that contain types needed for newer versions of the language when writing code for environments where those types or members have not been deployed yet.

This dependency on standard library functionality has been part of the C# language since its first version. In that version, examples included:

- [Exception](#) - used for all compiler generated exceptions.
- [String](#) - the C# `string` type is a synonym for [String](#).
- [Int32](#) - synonym of `int`.

That first version was simple: the compiler and the standard library shipped together, and there was only one version of each.

Subsequent versions of C# have occasionally added new types or members to the dependencies. Examples include: [INotifyCompletion](#), [CallerFilePathAttribute](#) and [CallerMemberNameAttribute](#). C# 7.0 continues this by adding a dependency on [ValueTuple](#) to implement the [tuples](#) language feature.

The language design team works to minimize the surface area of the types and members required in a compliant standard library. That goal is balanced against a clean design where new library features are incorporated seamlessly into the language. There will be new features in future versions of C# that require new types and members in a standard library. It's important to understand how to manage those dependencies in your work.

Managing your dependencies

C# compiler tools are now decoupled from the release cycle of the .NET libraries on supported platforms. In fact, different .NET libraries have different release cycles: the .NET Framework on Windows is released as a Windows Update, .NET Core ships on a separate schedule, and the Xamarin versions of library updates ship with the Xamarin tools for each target platform.

The majority of time, you won't notice these changes. However, when you are working with a newer version of the language that requires features not yet in the .NET libraries on that platform, you'll reference the NuGet packages to provide those new types. As the platforms your app supports are updated with new framework installations, you can remove the extra reference.

This separation means you can use new language features even when you are targeting machines that may not have the corresponding framework.

Version and update considerations for C# developers

9/25/2018 • 2 minutes to read • [Edit Online](#)

Compatibility is a very important goal as new features are added to the C# language. In almost all cases, existing code can be recompiled with a new compiler version without any issue.

More care may be required when you adopt new language features in a library. You may be creating a new library with features found in the latest version and need to ensure apps built using previous versions of the compiler can use it. Or you may be upgrading an existing library and many of your users may not have upgraded versions yet. As you make decisions on adopting new features, you'll need to consider two variations of compatibility: source compatible and binary compatible.

Binary compatible changes

Changes to your library are **binary compatible** when your updated library can be used without rebuilding applications and libraries that use it. Dependent assemblies are not required to be rebuilt, nor are any source code changes required. Binary compatible changes are also source compatible changes.

Source compatible changes

Changes to your library are **source compatible** when applications and libraries that use your library do not require source code changes, but the source must be recompiled against the new version to work correctly.

Incompatible changes

If a change is neither **source compatible** nor **binary compatible**, source code changes along with recompilation are required in dependent libraries and applications.

Evaluate your library

These compatibility concepts affect the public and protected declarations for your library, not its internal implementation. Adopting any new features internally are always **binary compatible**.

Binary compatible changes provide new syntax that generates the same compiled code for public declarations as the older syntax. For example, changing a method to an expression-bodied member is a **binary compatible** change:

Original code:

```
public double CalculateSquare(double value)
{
    return value * value;
}
```

New code:

```
public double CalculateSquare(double value) => value * value;
```

Source compatible changes introduce syntax that changes the compiled code for a public member, but in a way that is compatible with existing call sites. For example, changing a method signature from a by value parameter to

an `in` by reference parameter is source compatible, but not binary compatible:

Original code:

```
public double CalculateSquare(double value) => value * value;
```

New code:

```
public double CalculateSquare(in double value) => value * value;
```

The [What's new](#) articles note if introducing a feature that affects public declarations is source compatible or binary compatible.

Types (C# Programming Guide)

3/26/2019 • 11 minutes to read • [Edit Online](#)

Types, Variables, and Values

C# is a strongly-typed language. Every variable and constant has a type, as does every expression that evaluates to a value. Every method signature specifies a type for each input parameter and for the return value. The .NET class library defines a set of built-in numeric types as well as more complex types that represent a wide variety of logical constructs, such as the file system, network connections, collections and arrays of objects, and dates. A typical C# program uses types from the class library as well as user-defined types that model the concepts that are specific to the program's problem domain.

The information stored in a type can include the following:

- The storage space that a variable of the type requires.
- The maximum and minimum values that it can represent.
- The members (methods, fields, events, and so on) that it contains.
- The base type it inherits from.
- The location where the memory for variables will be allocated at run time.
- The kinds of operations that are permitted.

The compiler uses type information to make sure that all operations that are performed in your code are *type safe*. For example, if you declare a variable of type `int`, the compiler allows you to use the variable in addition and subtraction operations. If you try to perform those same operations on a variable of type `bool`, the compiler generates an error, as shown in the following example:

```
int a = 5;
int b = a + 2; //OK

bool test = true;

// Error. Operator '+' cannot be applied to operands of type 'int' and 'bool'.
int c = a + test;
```

NOTE

C and C++ developers, notice that in C#, `bool` is not convertible to `int`.

The compiler embeds the type information into the executable file as metadata. The common language runtime (CLR) uses that metadata at run time to further guarantee type safety when it allocates and reclaims memory.

Specifying Types in Variable Declarations

When you declare a variable or constant in a program, you must either specify its type or use the `var` keyword to let the compiler infer the type. The following example shows some variable declarations that use both built-in numeric types and complex user-defined types:

```

// Declaration only:
float temperature;
string name;
MyClass myClass;

// Declaration with initializers (four examples):
char firstLetter = 'C';
var limit = 3;
int[] source = { 0, 1, 2, 3, 4, 5 };
var query = from item in source
            where item <= limit
            select item;

```

The types of method parameters and return values are specified in the method signature. The following signature shows a method that requires an [int](#) as an input argument and returns a string:

```

public string GetName(int ID)
{
    if (ID < names.Length)
        return names[ID];
    else
        return String.Empty;
}
private string[] names = { "Spencer", "Sally", "Doug" };

```

After a variable is declared, it cannot be re-declared with a new type, and it cannot be assigned a value that is not compatible with its declared type. For example, you cannot declare an [int](#) and then assign it a Boolean value of [true](#). However, values can be converted to other types, for example when they are assigned to new variables or passed as method arguments. A *type conversion* that does not cause data loss is performed automatically by the compiler. A conversion that might cause data loss requires a *cast* in the source code.

For more information, see [Casting and Type Conversions](#).

Built-in Types

C# provides a standard set of built-in numeric types to represent integers, floating point values, Boolean expressions, text characters, decimal values, and other types of data. There are also built-in `string` and `object` types. These are available for you to use in any C# program. For more information about the built-in types, see [Reference Tables for Types](#).

Custom Types

You use the `struct`, `class`, `interface`, and `enum` constructs to create your own custom types. The .NET class library itself is a collection of custom types provided by Microsoft that you can use in your own applications. By default, the most frequently used types in the class library are available in any C# program. Others become available only when you explicitly add a project reference to the assembly in which they are defined. After the compiler has a reference to the assembly, you can declare variables (and constants) of the types declared in that assembly in source code. For more information, see [.NET Class Library](#).

The Common Type System

It is important to understand two fundamental points about the type system in .NET:

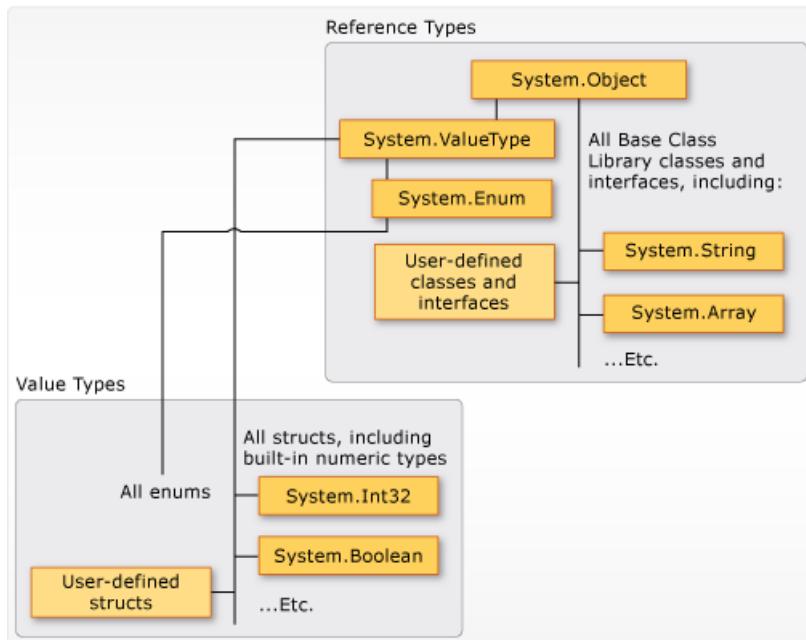

- It supports the principle of inheritance. Types can derive from other types, called *base types*. The derived type inherits (with some restrictions) the methods, properties, and other members of the base type. The base type can in turn derive from some other type, in which case the derived type inherits the members of

both base types in its inheritance hierarchy. All types, including built-in numeric types such as `System.Int32` (C# keyword: `int`), derive ultimately from a single base type, which is `System.Object` (C# keyword: `object`). This unified type hierarchy is called the [Common Type System](#) (CTS). For more information about inheritance in C#, see [Inheritance](#).

- Each type in the CTS is defined as either a *value type* or a *reference type*. This includes all custom types in the .NET class library and also your own user-defined types. Types that you define by using the `struct` keyword are value types; all the built-in numeric types are `structs`. Types that you define by using the `class` keyword are reference types. Reference types and value types have different compile-time rules, and different run-time behavior.

The following illustration shows the relationship between value types and reference types in the CTS.

The following image shows value types and reference types in the CTS:

NOTE

You can see that the most commonly used types are all organized in the `System` namespace. However, the namespace in which a type is contained has no relation to whether it is a value type or reference type.

Value Types

Value types derive from `System.ValueType`, which derives from `System.Object`. Types that derive from `System.ValueType` have special behavior in the CLR. Value type variables directly contain their values, which means that the memory is allocated inline in whatever context the variable is declared. There is no separate heap allocation or garbage collection overhead for value-type variables.

There are two categories of value types: `struct` and `enum`.

The built-in numeric types are `structs`, and they have properties and methods that you can access:

```
// Static method on type byte.  
byte b = byte.MaxValue;
```

But you declare and assign values to them as if they were simple non-aggregate types:

```
byte num = 0xA;
int i = 5;
char c = 'Z';
```

Value types are *sealed*, which means, for example, that you cannot derive a type from [System.Int32](#), and you cannot define a struct to inherit from any user-defined class or struct because a struct can only inherit from [System.ValueType](#). However, a struct can implement one or more interfaces. You can cast a struct type to any interface type that it implements; this causes a *boxing* operation to wrap the struct inside a reference type object on the managed heap. Boxing operations occur when you pass a value type to a method that takes a [System.Object](#) or any interface type as an input parameter. For more information, see [Boxing and Unboxing](#).

You use the [struct](#) keyword to create your own custom value types. Typically, a struct is used as a container for a small set of related variables, as shown in the following example:

```
public struct Coords
{
    public int x, y;

    public Coords(int p1, int p2)
    {
        x = p1;
        y = p2;
    }
}
```

For more information about structs, see [Structs](#). For more information about value types in .NET, see [Value Types](#).

The other category of value types is [enum](#). An enum defines a set of named integral constants. For example, the [System.IO.FileMode](#) enumeration in the .NET class library contains a set of named constant integers that specify how a file should be opened. It is defined as shown in the following example:

```
public enum FileMode
{
    CreateNew = 1,
    Create = 2,
    Open = 3,
    OpenOrCreate = 4,
    Truncate = 5,
    Append = 6,
}
```

The [System.IO.FileMode.Create](#) constant has a value of 2. However, the name is much more meaningful for humans reading the source code, and for that reason it is better to use enumerations instead of constant literal numbers. For more information, see [System.IO.FileMode](#).

All enums inherit from [System.Enum](#), which inherits from [System.ValueType](#). All the rules that apply to structs also apply to enums. For more information about enums, see [Enumeration Types](#).

Reference Types

A type that is defined as a [class](#), [delegate](#), array, or [interface](#) is a *reference type*. At run time, when you declare a variable of a reference type, the variable contains the value [null](#) until you explicitly create an object by using the [new](#) operator, or assign it an object that has been created elsewhere by using [new](#), as shown in the following example:

```
MyClass mc = new MyClass();
MyClass mc2 = mc;
```

An interface must be initialized together with a class object that implements it. If `MyClass` implements `IMyInterface`, you create an instance of `IMyInterface` as shown in the following example:

```
IMyInterface iface = new MyClass();
```

When the object is created, the memory is allocated on the managed heap, and the variable holds only a reference to the location of the object. Types on the managed heap require overhead both when they are allocated and when they are reclaimed by the automatic memory management functionality of the CLR, which is known as *garbage collection*. However, garbage collection is also highly optimized, and in most scenarios it does not create a performance issue. For more information about garbage collection, see [Automatic Memory Management](#).

All arrays are reference types, even if their elements are value types. Arrays implicitly derive from the `System.Array` class, but you declare and use them with the simplified syntax that is provided by C#, as shown in the following example:

```
// Declare and initialize an array of integers.  
int[] nums = { 1, 2, 3, 4, 5 };  
  
// Access an instance property of System.Array.  
int len = nums.Length;
```

Reference types fully support inheritance. When you create a class, you can inherit from any other interface or class that is not defined as `sealed`, and other classes can inherit from your class and override your virtual methods. For more information about how to create your own classes, see [Classes and Structs](#). For more information about inheritance and virtual methods, see [Inheritance](#).

Types of Literal Values

In C#, literal values receive a type from the compiler. You can specify how a numeric literal should be typed by appending a letter to the end of the number. For example, to specify that the value 4.56 should be treated as a float, append an "f" or "F" after the number: `4.56f`. If no letter is appended, the compiler will infer a type for the literal. For more information about which types can be specified with letter suffixes, see the reference pages for individual types in [Value Types](#).

Because literals are typed, and all types derive ultimately from `System.Object`, you can write and compile code such as the following:

```
string s = "The answer is " + 5.ToString();  
// Outputs: "The answer is 5"  
Console.WriteLine(s);  
  
Type type = 12345.GetType();  
// Outputs: "System.Int32"  
Console.WriteLine(type);
```

Generic Types

A type can be declared with one or more *type parameters* that serve as a placeholder for the actual type (the *concrete type*) that client code will provide when it creates an instance of the type. Such types are called *generic types*. For example, the .NET type `System.Collections.Generic.List<T>` has one type parameter that by convention is given the name *T*. When you create an instance of the type, you specify the type of the objects that the list will contain, for example, string:

```
List<string> stringList = new List<string>();
stringList.Add("String example");
// compile time error adding a type other than a string:
stringList.Add(4);
```

The use of the type parameter makes it possible to reuse the same class to hold any type of element, without having to convert each element to [object](#). Generic collection classes are called *strongly-typed collections* because the compiler knows the specific type of the collection's elements and can raise an error at compile-time if, for example, you try to add an integer to the `stringList` object in the previous example. For more information, see [Generics](#).

Implicit Types, Anonymous Types, and Nullable Types

As stated previously, you can implicitly type a local variable (but not class members) by using the [var](#) keyword. The variable still receives a type at compile time, but the type is provided by the compiler. For more information, see [Implicitly Typed Local Variables](#).

In some cases, it is inconvenient to create a named type for simple sets of related values that you do not intend to store or pass outside method boundaries. You can create *anonymous types* for this purpose. For more information, see [Anonymous Types](#).

Ordinary value types cannot have a value of [null](#). However, you can create nullable value types by affixing a `?` after the type. For example, `int?` is an `int` type that can also have the value [null](#). In the CTS, nullable types are instances of the generic struct type `System.Nullable<T>`. Nullable types are especially useful when you are passing data to and from databases in which numeric values might be null. For more information, see [Nullable Types](#).

Namespaces (C# Programming Guide)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Namespaces are heavily used in C# programming in two ways. First, the .NET Framework uses namespaces to organize its many classes, as follows:

```
System.Console.WriteLine("Hello World!");
```

`System` is a namespace and `Console` is a class in that namespace. The `using` keyword can be used so that the complete name is not required, as in the following example:

```
using System;
```

```
Console.WriteLine("Hello");
Console.WriteLine("World!");
```

For more information, see the [using Directive](#).

Second, declaring your own namespaces can help you control the scope of class and method names in larger programming projects. Use the `namespace` keyword to declare a namespace, as in the following example:

```
namespace SampleNamespace
{
    class SampleClass
    {
        public void SampleMethod()
        {
            System.Console.WriteLine(
                "SampleMethod inside SampleNamespace");
        }
    }
}
```

The name of the namespace must be a valid C# [identifier name](#).

Namespaces Overview

Namespaces have the following properties:

- They organize large code projects.
- They are delimited by using the `.` operator.
- The `using` directive obviates the requirement to specify the name of the namespace for every class.
- The `global` namespace is the "root" namespace: `global::System` will always refer to the .NET `System` namespace.

C# Language Specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

Types, variables, and values

8/29/2018 • 6 minutes to read • [Edit Online](#)

C# is a strongly-typed language. Every variable and constant has a type, as does every expression that evaluates to a value. Every method signature specifies a type for each input parameter and for the return value. The .NET Framework class library defines a set of built-in numeric types as well as more complex types that represent a wide variety of logical constructs, such as the file system, network connections, collections and arrays of objects, and dates. A typical C# program uses types from the class library as well as user-defined types that model the concepts that are specific to the program's problem domain.

The information stored in a type can include the following:

- The storage space that a variable of the type requires.
- The maximum and minimum values that it can represent.
- The members (methods, fields, events, and so on) that it contains.
- The base type it inherits from.
- The location where the memory for variables will be allocated at run time.
- The kinds of operations that are permitted.

The compiler uses type information to make sure that all operations that are performed in your code are *type safe*.

For example, if you declare a variable of type `int`, the compiler allows you to use the variable in addition and subtraction operations. If you try to perform those same operations on a variable of type `bool`, the compiler generates an error, as shown in the following example:

```
int a = 5;
int b = a + 2; //OK

bool test = true;

// Error. Operator '+' cannot be applied to operands of type 'int' and 'bool'.
int c = a + test;
```

NOTE

C and C++ developers, notice that in C#, `bool` is not convertible to `int`.

The compiler embeds the type information into the executable file as metadata. The common language runtime (CLR) uses that metadata at run time to further guarantee type safety when it allocates and reclaims memory.

Specifying types in variable declarations

When you declare a variable or constant in a program, you must either specify its type or use the `var` keyword to let the compiler infer the type. The following example shows some variable declarations that use both built-in numeric types and complex user-defined types:

```
// Declaration only:  
float temperature;  
string name;  
MyClass myClass;  
  
// Declaration with initializers (four examples):  
char firstLetter = 'C';  
var limit = 3;  
int[] source = { 0, 1, 2, 3, 4, 5 };  
var query = from item in source  
            where item <= limit  
            select item;
```

The types of method parameters and return values are specified in the method signature. The following signature shows a method that requires an [int](#) as an input argument and returns a string:

```
public string GetName(int ID)  
{  
    if (ID < names.Length)  
        return names[ID];  
    else  
        return String.Empty;  
}  
private string[] names = { "Spencer", "Sally", "Doug" };
```

After a variable is declared, it cannot be re-declared with a new type, and it cannot be assigned a value that is not compatible with its declared type. For example, you cannot declare an [int](#) and then assign it a Boolean value of [true](#). However, values can be converted to other types, for example when they are assigned to new variables or passed as method arguments. A *type conversion* that does not cause data loss is performed automatically by the compiler. A conversion that might cause data loss requires a *cast* in the source code.

For more information, see [Casting and type conversions](#).

Built-in types

C# provides a standard set of built-in numeric types to represent integers, floating point values, Boolean expressions, text characters, decimal values, and other types of data. There are also built-in [string](#) and [object](#) types. These are available for you to use in any C# program. For a more information about the built-in types, see [Reference table for types](#).

Custom types

You use the [struct](#), [class](#), [interface](#), and [enum](#) constructs to create your own custom types. The .NET Framework class library itself is a collection of custom types provided by Microsoft that you can use in your own applications. By default, the most frequently used types in the class library are available in any C# program. Others become available only when you explicitly add a project reference to the assembly in which they are defined. After the compiler has a reference to the assembly, you can declare variables (and constants) of the types declared in that assembly in source code.

Generic types

A type can be declared with one or more *type parameters* that serve as a placeholder for the actual type (the *concrete type*) that client code will provide when it creates an instance of the type. Such types are called *generic types*. For example, the .NET Framework type [List<T>](#) has one type parameter that by convention is given the name *T*. When you create an instance of the type, you specify the type of the objects that the list will contain, for example, [string](#):

```
List<string> strings = new List<string>();
```

The use of the type parameter makes it possible to reuse the same class to hold any type of element, without having to convert each element to `object`. Generic collection classes are called *strongly-typed collections* because the compiler knows the specific type of the collection's elements and can raise an error at compile-time if, for example, you try to add an integer to the `strings` object in the previous example. For more information, see [Generics](#).

Implicit types, anonymous types, and tuple types

As stated previously, you can implicitly type a local variable (but not class members) by using the `var` keyword. The variable still receives a type at compile time, but the type is provided by the compiler. For more information, see [Implicitly typed local variables](#).

In some cases, it is inconvenient to create a named type for simple sets of related values that you do not intend to store or pass outside method boundaries. You can create *anonymous types* for this purpose. For more information, see [Anonymous types](#).

It's common to want to return more than one value from a method. You can create *tuple types* that return multiple values in a single method call. For more information, see [Tuples](#)

The Common type system

It is important to understand two fundamental points about the type system in the .NET Framework:

- It supports the principle of inheritance. Types can derive from other types, called *base types*. The derived type inherits (with some restrictions) the methods, properties, and other members of the base type. The base type can in turn derive from some other type, in which case the derived type inherits the members of both base types in its inheritance hierarchy. All types, including built-in numeric types such as `Int32` (C# keyword: `int`), derive ultimately from a single base type, which is `Object` (C# keyword: `object`). This unified type hierarchy is called the [Common type system](#) (CTS). For more information about inheritance in C#, see [Inheritance](#).
- Each type in the CTS is defined as either a *value type* or a *reference type*. This includes all custom types in the .NET Framework class library and also your own user-defined types. Types that you define by using the `struct` keyword are value types; all the built-in numeric types are **structs**. For more information about value types, see [Structs](#). Types that you define by using the `class` keyword are reference types. For more information about reference types, see [Classes](#). Reference types and value types have different compile-time rules, and different run-time behavior.

Classes (C# Programming Guide)

1/23/2019 • 5 minutes to read • [Edit Online](#)

Reference types

A type that is defined as a [class](#) is a *reference type*. At run time, when you declare a variable of a reference type, the variable contains the value [null](#) until you explicitly create an instance of the class by using the [new](#) operator, or assign it an object of a compatible type that may have been created elsewhere, as shown in the following example:

```
//Declaring an object of type MyClass.  
MyClass mc = new MyClass();  
  
//Declaring another object of the same type, assigning it the value of the first object.  
MyClass mc2 = mc;
```

When the object is created, enough memory is allocated on the managed heap for that specific object, and the variable holds only a reference to the location of said object. Types on the managed heap require overhead both when they are allocated and when they are reclaimed by the automatic memory management functionality of the CLR, which is known as *garbage collection*. However, garbage collection is also highly optimized and in most scenarios, it does not create a performance issue. For more information about garbage collection, see [Automatic memory management and garbage collection](#).

Declaring Classes

Classes are declared by using the [class](#) keyword followed by a unique identifier, as shown in the following example:

```
//[access modifier] - [class] - [identifier]  
public class Customer  
{  
    // Fields, properties, methods and events go here...  
}
```

The `class` keyword is preceded by the access level. Because [public](#) is used in this case, anyone can create instances of this class. The name of the class follows the `class` keyword. The name of the class must be a valid C# [identifier name](#). The remainder of the definition is the class body, where the behavior and data are defined. Fields, properties, methods, and events on a class are collectively referred to as *class members*.

Creating objects

Although they are sometimes used interchangeably, a class and an object are different things. A class defines a type of object, but it is not an object itself. An object is a concrete entity based on a class, and is sometimes referred to as an instance of a class.

Objects can be created by using the [new](#) keyword followed by the name of the class that the object will be based on, like this:

```
Customer object1 = new Customer();
```

When an instance of a class is created, a reference to the object is passed back to the programmer. In the previous example, `object1` is a reference to an object that is based on `Customer`. This reference refers to the new object but

does not contain the object data itself. In fact, you can create an object reference without creating an object at all:

```
Customer object2;
```

We don't recommend creating object references such as this one that don't refer to an object because trying to access an object through such a reference will fail at run time. However, such a reference can be made to refer to an object, either by creating a new object, or by assigning it to an existing object, such as this:

```
Customer object3 = new Customer();
Customer object4 = object3;
```

This code creates two object references that both refer to the same object. Therefore, any changes to the object made through `object3` are reflected in subsequent uses of `object4`. Because objects that are based on classes are referred to by reference, classes are known as reference types.

Class inheritance

Classes fully support *inheritance*, a fundamental characteristic of object-oriented programming. When you create a class, you can inherit from any other interface or class that is not defined as [sealed](#), and other classes can inherit from your class and override class virtual methods.

Inheritance is accomplished by using a *derivation*, which means a class is declared by using a *base class* from which it inherits data and behavior. A base class is specified by appending a colon and the name of the base class following the derived class name, like this:

```
public class Manager : Employee
{
    // Employee fields, properties, methods and events are inherited
    // New Manager fields, properties, methods and events go here...
}
```

When a class declares a base class, it inherits all the members of the base class except the constructors. For more information, see [Inheritance](#).

Unlike C++, a class in C# can only directly inherit from one base class. However, because a base class may itself inherit from another class, a class may indirectly inherit multiple base classes. Furthermore, a class can directly implement more than one interface. For more information, see [Interfaces](#).

A class can be declared [abstract](#). An abstract class contains abstract methods that have a signature definition but no implementation. Abstract classes cannot be instantiated. They can only be used through derived classes that implement the abstract methods. By contrast, a [sealed](#) class does not allow other classes to derive from it. For more information, see [Abstract and Sealed Classes and Class Members](#).

Class definitions can be split between different source files. For more information, see [Partial Classes and Methods](#).

Example

The following example defines a public class that contains an [auto-implemented property](#), a method, and a special method called a constructor. For more information, see [Properties, Methods](#), and [Constructors](#) topics. The instances of the class are then instantiated with the `new` keyword.

```

using System;

public class Person
{
    // Constructor that takes no arguments:
    public Person()
    {
        Name = "unknown";
    }

    // Constructor that takes one argument:
    public Person(string name)
    {
        Name = name;
    }

    // Auto-implemented readonly property:
    public string Name { get; }

    // Method that overrides the base class (System.Object) implementation.
    public override string ToString()
    {
        return Name;
    }
}
class TestPerson
{
    static void Main()
    {
        // Call the constructor that has no parameters.
        var person1 = new Person();
        Console.WriteLine(person1.Name);

        // Call the constructor that has one parameter.
        var person2 = new Person("Sarah Jones");
        Console.WriteLine(person2.Name);
        // Get the string representation of the person2 instance.
        Console.WriteLine(person2);

        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
// Output:
// unknown
// Sarah Jones
// Sarah Jones

```

Nullable reference types

3/9/2019 • 7 minutes to read • [Edit Online](#)

C# 8.0 introduces **nullable reference types** and **non-nullable reference types** that enable you to make important statements about the properties for reference type variables:

- **A reference is not supposed to be null.** When variables aren't supposed to be null, the compiler enforces rules that ensure it is safe to dereference these variables without first checking that it isn't null:
 - The variable must be initialized to a non-null value.
 - The variable can never be assigned the value `null`.
- **A reference may be null.** When variables may be null, the compiler enforces different rules to ensure that you've correctly checked for a null reference:
 - The variable may only be dereferenced when the compiler can guarantee that the value isn't null.
 - These variables may be initialized with the default `null` value and may be assigned the value `null` in other code.

This new feature provides significant benefits over the handling of reference variables in earlier versions of C# where the design intent couldn't be determined from the variable declaration. The compiler didn't provide safety against null reference exceptions for reference types:

- **A reference can be null.** No warnings are issued when a reference type is initialized to null, or later assigned to null.
- **A reference is assumed to be not null.** The compiler doesn't issue any warnings when reference types are dereferenced. (With nullable references, the compiler issues warnings whenever you dereference a variable that may be null).

With the addition of nullable reference types, you can declare your intent more clearly. The `null` value is the correct way to represent that a variable doesn't refer to a value. Don't use this feature to remove all `null` values from your code. Rather, you should declare your intent to the compiler and other developers that read your code. By declaring your intent, the compiler informs you when you write code that is inconsistent with that intent.

A **nullable reference type** is noted using the same syntax as **nullable value types**: a `?` is appended to the type of the variable. For example, the following variable declaration represents a nullable string variable, `name`:

```
string? name;
```

Any variable where the `?` is not appended to the type name is a **non-nullable reference type**. That includes all reference type variables in existing code when you have enabled this feature.

The compiler uses static analysis to determine if a nullable reference is known to be non-null. The compiler warns you if you dereference a nullable reference when it may be null. You can override this behavior by using the **null-forgiving operator** (`!`) following a variable name. For example, if you know the `name` variable isn't null but the compiler issues a warning, you can write the following code to override the compiler's analysis:

```
name!.Length;
```

You can read details about this operator in the [draft nullable reference types](#) specification proposal on GitHub.

Nullability of types

Any reference type can have one of four *nullabilities*, which describes when warnings are generated:

- **Nonnullable**: Null can't be assigned to variables of this type. Variables of this type don't need to be null-checked before dereferencing.
- **Nullable**: Null can be assigned to variables of this type. Dereferencing variables of this type without first checking for `null` causes a warning.
- **Oblivious**: This is the pre-C# 8 state. Variables of this type can be dereferenced or assigned without warnings.
- **Unknown**: This is generally for type parameters where constraints don't tell the compiler that the type must be *nullable* or *nonnullable*.

The nullability of a type in a variable declaration is controlled by the *nullable context* in which the variable is declared.

Nullable contexts

Nullable contexts enable fine-grained control for how the compiler interprets reference type variables. The **nullable annotation context** of any given source line is `enabled` or `disabled`. You can think of the pre-C# 8 compiler as compiling all your code in a `disabled` nullable context: Any reference type may be null. The **nullable warnings context** may be set to `enabled`, `disabled`, or `safeonly`. The nullable warnings context specifies the warnings generated by the compiler using its flow analysis.

The nullable annotation context and nullable warning context can be set for a project using the `NullableContextOptions` element in your `csproj` file. This element configures how the compiler interprets the nullability of types and what warnings are generated. Valid settings are:

- `enable` : The nullable annotation context is **enabled**. The nullable warning context is **enabled**.
 - Variables of a reference type, `string` for example, are non-nullable. All nullability warnings are enabled.
- `disable` : The nullable annotation context is **disabled**. The nullable warning context is **disabled**.
 - Variables of a reference type are oblivious, just like earlier versions of C#. All nullability warnings are disabled.
- `safeonly` : The nullable annotation context is **enabled**. The nullable warning context is **safeonly**.
 - Variables of a reference type are nonnullable. All safety nullability warnings are enabled.
- `warnings` : The nullable annotation context is **disabled**. The nullable warning context is **enabled**.
 - Variables of a reference type are oblivious. All nullability warnings are enabled.
- `safeonlywarnings` : The nullable annotation context is **disabled**. The nullable warning context is **safeonly**.
 - Variables of a reference type are oblivious. All safety nullability warnings are enabled.

You can also use directives to set these same contexts anywhere in your project:

- `#nullable enable` : Sets the nullable annotation context and nullable warning context to **enabled**.
- `#nullable disable` : Sets the nullable annotation context and nullable warning context to **disabled**.
- `#nullable safeonly` : Set the nullable annotation context to **enabled**, and the warning context to **safeonly**.
- `#nullable restore` : Restores the nullable annotation context and nullable warning context to the project settings.
- `#pragma warning disable nullable` : Set the nullable warning context to **disabled**.
- `#pragma warning enable nullable` : Set the nullable warning context to **enabled**.
- `#pragma warning restore nullable` : Restores the nullable warning context to the project settings.
- `#pragma warning safeonly nullable` : Sets the nullable warning context to **safeonly**.

The default nullable annotation and warning contexts are `disabled`. That decision means that your existing code compiles without changes and without generating any new warnings.

The differences between the `enabled` and `safeonly` nullable warning contexts are warnings for assigning a nullable reference to a non-nullable reference. The following assignment generates a warning in an `enabled` warning context, but not a `safeonly` warning context. However, the second line, where `s` is dereferenced, generates a warning in a `safeonly` context:

```
string s = null; // warning when nullable warning context is enabled.  
var txt = s.ToString(); // warning when nullable warnings context is safeonly, or enabled.
```

Nullable annotation context

The compiler uses the following rules in a disabled nullable annotation context:

- You can't declare nullable references in a disabled context.
- All reference variables may be assigned to null.
- No warnings are generated when a variable of a reference type is dereferenced.
- The null-forgiving operator may not be used in a disabled context.

The behavior is the same as previous versions of C#.

The compiler uses the following rules in an enabled nullable annotation context:

- Any variable of a reference type is a **non-nullable reference**.
- Any non-nullable reference may be dereferenced safely.
- Any nullable reference type (noted by `?` after the type in the variable declaration) may be null. Static analysis determines if the value is known to be non-null when it is dereferenced. If not, the compiler warns you.
- You can use the null-forgiving operator to declare that a nullable reference isn't null.

In an enabled nullable annotation context, the `?` character appended to a reference type declares a **nullable reference type**. The **null forgiveness operator** (`!`) may be appended to an expression to declare that the expression isn't null.

Nullable warning context

The nullable warning context is distinct from the nullable annotation context. Warnings can be enabled even when the new annotations are disabled. The compiler uses static flow analysis to determine the **null state** of any reference. The null state is either **not null** or **maybe null** when the *nullable warning context* isn't **disabled**. If you dereference a reference when the compiler has determined it's **maybe null**, the compiler warns you. The state of a reference is **maybe null** unless the compiler can determine one of two conditions:

1. The variable has been definitely assigned to a non-null value.
2. The variable or expression has been checked against null before de-referencing it.

The compiler generates warnings whenever you dereference a variable or expression in a **maybe null** state when the nullable warning context is `enabled` or `safeonly`. Furthermore, warnings are generated when a **maybe null** variable or expression is assigned to a nonnullable reference type when the nullable annotation context is `enabled`.

Structs

1/23/2019 • 4 minutes to read • [Edit Online](#)

A *struct* is a value type. When a struct is created, the variable to which the struct is assigned holds the struct's actual data. When the struct is assigned to a new variable, it is copied. The new variable and the original variable therefore contain two separate copies of the same data. Changes made to one copy do not affect the other copy.

Value type variables directly contain their values, which means that the memory is allocated inline in whatever context the variable is declared. There is no separate heap allocation or garbage collection overhead for value-type variables.

There are two categories of value types: [struct](#) and [enum](#).

The built-in numeric types are structs, and they have properties and methods that you can access:

```
// Static method on type Byte.  
byte b = Byte.MaxValue;
```

But you declare and assign values to them as if they were simple non-aggregate types:

```
byte num = 0xA;  
int i = 5;  
char c = 'Z';
```

Value types are *sealed*, which means, for example, that you cannot derive a type from [Int32](#), and you cannot define a struct to inherit from any user-defined class or struct because a struct can only inherit from [ValueType](#). However, a struct can implement one or more interfaces. You can cast a struct type to an interface type; this causes a *boxing* operation to wrap the struct inside a reference type object on the managed heap. Boxing operations occur when you pass a value type to a method that takes an [Object](#) as an input parameter. For more information, see [Boxing and Unboxing](#).

You use the [struct](#) keyword to create your own custom value types. Typically, a struct is used as a container for a small set of related variables, as shown in the following example:

```
public struct Coords  
{  
    public int x, y;  
  
    public Coords(int p1, int p2)  
    {  
        x = p1;  
        y = p2;  
    }  
}
```

For more information about value types in the .NET Framework, see [Common Type System](#).

Structs share most of the same syntax as classes, although structs are more limited than classes:

- Within a struct declaration, fields cannot be initialized unless they are declared as `const` or `static`.
- A struct cannot declare a default constructor (a constructor without parameters) or a finalizer.
- Structs are copied on assignment. When a struct is assigned to a new variable, all the data is copied, and any

modification to the new copy does not change the data for the original copy. This is important to remember when working with collections of value types such as `Dictionary<string, myStruct>`.

- Structs are value types and classes are reference types.
- Unlike classes, structs can be instantiated without using a `new` operator.
- Structs can declare constructors that have parameters.
- A struct cannot inherit from another struct or class, and it cannot be the base of a class. All structs inherit directly from [ValueType](#), which inherits from [Object](#).
- A struct can implement interfaces.

Literal values

In C#, literal values receive a type from the compiler. You can specify how a numeric literal should be typed by appending a letter to the end of the number. For example, to specify that the value 4.56 should be treated as a float, append an "f" or "F" after the number: `4.56f`. If no letter is appended, the compiler will infer the `double` type for the literal. For more information about which types can be specified with letter suffixes, see the reference pages for individual types in [Value Types](#).

Because literals are typed, and all types derive ultimately from [Object](#), you can write and compile code such as the following:

```
string s = "The answer is " + 5.ToString();
// Outputs: "The answer is 5"
Console.WriteLine(s);

Type type = 12345.GetType();
// Outputs: "System.Int32"
Console.WriteLine(type);

var x = 123_456;
string s2 = "I can use an underscore as a digit separator: " + x;
// Outputs: "I can use an underscore as a digit separator: 123456"
Console.WriteLine(s2);

var b = 0b1010_1011_1100_1110_1111;
string s3 = "I can specify bit patterns: " + b.ToString();
// Outputs: "I can specify bit patterns: 703727"
Console.WriteLine(s3);
```

The last two examples demonstrate language features introduced in C# 7.0. The first allows you to use an underscore character as a *digit separator* inside numeric literals. You can put them wherever you want between digits to improve readability. They have no effect on the value.

The second demonstrates *binary literals*, which allow you to specify bit patterns directly instead of using hexadecimal notation.

Nullable types

Ordinary value types cannot have a value of `null`. However, you can create nullable value types by affixing a `?` after the type. For example, `int?` is an `int` type that can also have the value `null`. In the CTS, nullable types are instances of the generic struct type `Nullable<T>`. Nullable types are especially useful when you are passing data to and from databases in which numeric values might be null. For more information, see [Nullable Types \(C# Programming Guide\)](#).

C# tuple types

2/28/2019 • 20 minutes to read • [Edit Online](#)

C# tuples are types that you define using a lightweight syntax. The advantages include a simpler syntax, rules for conversions based on number (referred to as cardinality) and types of elements, and consistent rules for copies, equality tests, and assignments. As a tradeoff, tuples do not support some of the object-oriented idioms associated with inheritance. You can get an overview in the section on [tuples in the What's new in C# 7.0 article](#).

In this article, you'll learn the language rules governing tuples in C# 7.0 and later versions, different ways to use them, and initial guidance on working with tuples.

NOTE

The new tuples features require the `ValueTuple` types. You must add the NuGet package `System.ValueTuple` in order to use it on platforms that do not include the types.

This is similar to other language features that rely on types delivered in the framework. Examples include `async` and `await` relying on the `INotifyCompletion` interface, and LINQ relying on `IEnumerable<T>`. However, the delivery mechanism is changing as .NET is becoming more platform independent. The .NET Framework may not always ship on the same cadence as the language compiler. When new language features rely on new types, those types will be available as NuGet packages when the language features ship. As these new types get added to the .NET Standard API and delivered as part of the framework, the NuGet package requirement will be removed.

Let's start with the reasons for adding new tuple support. Methods return a single object. Tuples enable you to package multiple values in that single object more easily.

The .NET Framework already has generic `Tuple` classes. These classes, however, had two major limitations. For one, the `Tuple` classes named their properties `Item1`, `Item2`, and so on. Those names carry no semantic information. Using these `Tuple` types does not enable communicating the meaning of each of the properties. The new language features enable you to declare and use semantically meaningful names for the elements in a tuple.

The `Tuple` classes cause more performance concerns because they are reference types. Using one of the `Tuple` types means allocating objects. On hot paths, allocating many small objects can have a measurable impact on your application's performance. Therefore, the language support for tuples leverages the new `valueTuple` structs.

To avoid those deficiencies, you could create a `class` or a `struct` to carry multiple elements. Unfortunately, that's more work for you, and it obscures your design intent. Making a `struct` or `class` implies that you are defining a type with both data and behavior. Many times, you simply want to store multiple values in a single object.

The language features and the `valueTuple` generic structs enforce the rule that you cannot add any behavior (methods) to these tuple types. All the `valueTuple` types are *mutable structs*. Each member field is a public field. That makes them very lightweight. However, that means tuples should not be used where immutability is important.

Tuples are both simpler and more flexible data containers than `class` and `struct` types. Let's explore those differences.

Named and unnamed tuples

The `valueTuple` struct has fields named `Item1`, `Item2`, `Item3`, and so on, similar to the properties defined in the

existing `Tuple` types. These names are the only names you can use for *unnamed tuples*. When you do not provide any alternative field names to a tuple, you've created an unnamed tuple:

```
var unnamed = ("one", "two");
```

The tuple in the previous example was initialized using literal constants and won't have element names created using *tuple field name projections* in C# 7.1.

However, when you initialize a tuple, you can use new language features that give better names to each field. Doing so creates a *named tuple*. Named tuples still have elements named `Item1`, `Item2`, `Item3` and so on. But they also have synonyms for any of those elements that you have named. You create a named tuple by specifying the names for each element. One way is to specify the names as part of the tuple initialization:

```
var named = (first: "one", second: "two");
```

These synonyms are handled by the compiler and the language so that you can use named tuples effectively. IDEs and editors can read these semantic names using the Roslyn APIs. You can reference the elements of a named tuple by those semantic names anywhere in the same assembly. The compiler replaces the names you've defined with `Item*` equivalents when generating the compiled output. The compiled Microsoft Intermediate Language (MSIL) does not include the names you've given these elements.

Beginning with C# 7.1, the field names for a tuple may be provided from the variables used to initialize the tuple. This is referred to as **tuple projection initializers**. The following code creates a tuple named `accumulation` with elements `count` (an integer), and `sum` (a double).

```
var sum = 12.5;
var count = 5;
var accumulation = (count, sum);
```

The compiler must communicate those names you created for tuples that are returned from public methods or properties. In those cases, the compiler adds a `TupleElementNamesAttribute` attribute on the method. This attribute contains a `TransformNames` list property that contains the names given to each of the elements in the tuple.

NOTE

Development Tools, such as Visual Studio, also read that metadata, and provide IntelliSense and other features using the metadata field names.

It is important to understand these underlying fundamentals of the new tuples and the `ValueTuple` type in order to understand the rules for assigning named tuples to each other.

Tuple projection initializers

In general, tuple projection initializers work by using the variable or field names from the right-hand side of a tuple initialization statement. If an explicit name is given, that takes precedence over any projected name. For example, in the following initializer, the elements are `explicitFieldOne` and `explicitFieldTwo`, not `localVariableOne` and `localVariableTwo`:

```
var localVariableOne = 5;
var localVariableTwo = "some text";

var tuple = (explicitFieldOne: localVariableOne, explicitFieldTwo: localVariableTwo);
```

For any field where an explicit name is not provided, an applicable implicit name is projected. There is no requirement to provide semantic names, either explicitly or implicitly. The following initializer has field names `Item1`, whose value is `42` and `stringContent`, whose value is "The answer to everything":

```
var stringContent = "The answer to everything";
var mixedTuple = (42, stringContent);
```

There are two conditions where candidate field names are not projected onto the tuple field:

1. When the candidate name is a reserved tuple name. Examples include `Item3`, `ToString`. or `Rest`.
2. When the candidate name is a duplicate of another tuple field name, either explicit or implicit.

These conditions avoid ambiguity. These names would cause an ambiguity if they were used as the field names for a field in a tuple. Neither of these conditions cause compile-time errors. Instead, the elements without projected names do not have semantic names projected for them. The following examples demonstrate these conditions:

```
var ToString = "This is some text";
var one = 1;
var Item1 = 5;
var projections = (ToString, one, Item1);
// Accessing the first field:
Console.WriteLine(projections.Item1);
// There is no semantic name 'ToString'
// Accessing the second field:
Console.WriteLine(projections.one);
Console.WriteLine(projections.Item2);
// Accessing the third field:
Console.WriteLine(projections.Item3);
// There is no semantic name 'Item1'.

var pt1 = (X: 3, Y: 0);
var pt2 = (X: 3, Y: 4);

var xCoords = (pt1.X, pt2.X);
// There are no semantic names for the fields
// of xCoords.

// Accessing the first field:
Console.WriteLine(xCoords.Item1);
// Accessing the second field:
Console.WriteLine(xCoords.Item2);
```

These situations do not cause compiler errors because that would be a breaking change for code written with C# 7.0, when tuple field name projections were not available.

Equality and tuples

Beginning with C# 7.3, tuple types support the `==` and `!=` operators. These operators work by comparing each member of the left argument to each member of the right argument in order. These comparisons short-circuit. They will stop evaluating members as soon as one pair is not equal. The following code examples use `==`, but the comparison rules all apply to `!=`. The following code example shows an equality comparison for two pairs of integers:

```
var left = (a: 5, b: 10);
var right = (a: 5, b: 10);
Console.WriteLine(left == right); // displays 'true'
```

There are several rules that make tuple equality tests more convenient. Tuple equality performs [lifted conversions](#) if one of the tuples is a nullable tuple, as shown in the following code:

```
var left = (a: 5, b: 10);
var right = (a: 5, b: 10);
(int a, int b)? nullableTuple = right;
Console.WriteLine(left == nullableTuple); // Also true
```

Tuple equality also performs implicit conversions on each member of both tuples. These include lifted conversions, widening conversions, or other implicit conversions. The following examples show that an integer 2-tuple can be compared to a long 2-tuple because of the implicit conversion from integer to long:

```
// lifted conversions
var left = (a: 5, b: 10);
(int? a, int? b) nullableMembers = (5, 10);
Console.WriteLine(left == nullableMembers); // Also true

// converted type of left is (long, long)
(long a, long b) longTuple = (5, 10);
Console.WriteLine(left == longTuple); // Also true

// comparisons performed on (long, long) tuples
(long a, int b) longFirst = (5, 10);
(int a, long b) longSecond = (5, 10);
Console.WriteLine(longFirst == longSecond); // Also true
```

The names of the tuple members do not participate in tests for equality. However, if one of the operands is a tuple literal with explicit names, the compiler generates warning CS8383 if those names do not match the names of the other operand. In the case where both operands are tuple literals, the warning is on the right operand as shown in the following example:

```
(int a, string b) pair = (1, "Hello");
(int z, string y) another = (1, "Hello");
Console.WriteLine(pair == another); // true. Member names don't participate.
Console.WriteLine(pair == (z: 1, y: "Hello")); // warning: literal contains different member names
```

Finally, tuples may contain nested tuples. Tuple equality compares the "shape" of each operand through nested tuples as shown in the following example:

```
(int, (int, int)) nestedTuple = (1, (2, 3));
Console.WriteLine(nestedTuple == (1, (2, 3)));
```

It's a compile time error to compare two tuples for equality (or inequality) when they have different shapes. The compiler won't attempt any deconstruction of nested tuples in order to compare them.

Assignment and tuples

The language supports assignment between tuple types that have the same number of elements, where each right-hand side element can be implicitly converted to its corresponding left-hand side element. Other conversions aren't considered for assignments. It's a compile time error to assign one tuple to another when they have different shapes. The compiler won't attempt any deconstruction of nested tuples in order to assign them.

Let's look at the kinds of assignments that are allowed between tuple types.

Consider these variables used in the following examples:

```
// The 'arity' and 'shape' of all these tuples are compatible.  
// The only difference is the field names being used.  
var unnamed = (42, "The meaning of life");  
var anonymous = (16, "a perfect square");  
var named = (Answer: 42, Message: "The meaning of life");  
var differentNamed = (SecretConstant: 42, Label: "The meaning of life");
```

The first two variables, `unnamed` and `anonymous` do not have semantic names provided for the elements. The field names are `Item1` and `Item2`. The last two variables, `named` and `differentName` have semantic names given for the elements. These two tuples have different names for the elements.

All four of these tuples have the same number of elements (referred to as 'cardinality') and the types of those elements are identical. Therefore, all of these assignments work:

```
unnamed = named;  
  
named = unnamed;  
// 'named' still has fields that can be referred to  
// as 'answer', and 'message':  
Console.WriteLine($"{named.Answer}, {named.Message}");  
  
// unnamed to unnamed:  
anonymous = unnamed;  
  
// named tuples.  
named = differentNamed;  
// The field names are not assigned. 'named' still has  
// fields that can be referred to as 'answer' and 'message':  
Console.WriteLine($"{named.Answer}, {named.Message}");  
  
// With implicit conversions:  
// int can be implicitly converted to long  
(long, string) conversion = named;
```

Notice that the names of the tuples are not assigned. The values of the elements are assigned following the order of the elements in the tuple.

Tuples of different types or numbers of elements are not assignable:

```
// Does not compile.  
// CS0029: Cannot assign Tuple(int,int,int) to Tuple(int, string)  
var differentShape = (1, 2, 3);  
named = differentShape;
```

Tuples as method return values

One of the most common uses for tuples is as a method return value. Let's walk through one example. Consider this method that computes the standard deviation for a sequence of numbers:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    // Step 1: Compute the Mean:
    var mean = sequence.Average();

    // Step 2: Compute the square of the differences between each number
    // and the mean:
    var squaredMeanDifferences = from n in sequence
                                  select (n - mean) * (n - mean);
    // Step 3: Find the mean of those squared differences:
    var meanOfSquaredDifferences = squaredMeanDifferences.Average();

    // Step 4: Standard Deviation is the square root of that mean:
    var standardDeviation = Math.Sqrt(meanOfSquaredDifferences);
    return standardDeviation;
}

```

NOTE

These examples compute the uncorrected sample standard deviation. The corrected sample standard deviation formula would divide the sum of the squared differences from the mean by $(N-1)$ instead of N , as the `Average` extension method does. Consult a statistics text for more details on the differences between these formulas for standard deviation.

The preceding code follows the textbook formula for the standard deviation. It produces the correct answer, but it's an inefficient implementation. This method enumerates the sequence twice: Once to produce the average, and once to produce the average of the square of the difference of the average. (Remember that LINQ queries are evaluated lazily, so the computation of the differences from the mean and the average of those differences makes only one enumeration.)

There is an alternative formula that computes standard deviation using only one enumeration of the sequence. This computation produces two values as it enumerates the sequence: the sum of all items in the sequence, and the sum of the each value squared:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    double sum = 0;
    double sumOfSquares = 0;
    double count = 0;

    foreach (var item in sequence)
    {
        count++;
        sum += item;
        sumOfSquares += item * item;
    }

    var variance = sumOfSquares - sum * sum / count;
    return Math.Sqrt(variance / count);
}

```

This version enumerates the sequence exactly once. But it's not reusable code. As you keep working, you'll find that many different statistical computations use the number of items in the sequence, the sum of the sequence, and the sum of the squares of the sequence. Let's refactor this method and write a utility method that produces all three of those values. All three values can be returned as a tuple.

Let's update this method so the three values computed during the enumeration are stored in a tuple. That creates this version:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    var computation = (Count: 0, Sum: 0.0, SumOfSquares: 0.0);

    foreach (var item in sequence)
    {
        computation.Count++;
        computation.Sum += item;
        computation.SumOfSquares += item * item;
    }

    var variance = computation.SumOfSquares - computation.Sum * computation.Sum / computation.Count;
    return Math.Sqrt(variance / computation.Count);
}

```

Visual Studio's Refactoring support makes it easy to extract the functionality for the core statistics into a private method. That gives you a `private static` method that returns the tuple type with the three values of `Sum`, `SumOfSquares`, and `Count`:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    (int Count, double Sum, double SumOfSquares) computation = ComputeSumAndSumOfSquares(sequence);

    var variance = computation.SumOfSquares - computation.Sum * computation.Sum / computation.Count;
    return Math.Sqrt(variance / computation.Count);
}

private static (int Count, double Sum, double SumOfSquares) ComputeSumAndSumOfSquares(IEnumerable<double> sequence)
{
    var computation = (count: 0, sum: 0.0, sumOfSquares: 0.0);

    foreach (var item in sequence)
    {
        computation.count++;
        computation.sum += item;
        computation.sumOfSquares += item * item;
    }

    return computation;
}

```

The language enables a couple more options that you can use, if you want to make a few quick edits by hand. First, you can use the `var` declaration to initialize the tuple result from the `ComputeSumAndSumOfSquares` method call. You can also create three discrete variables inside the `ComputeSumAndSumOfSquares` method. The final version is shown in the following code:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    var computation = ComputeSumAndSumOfSquares(sequence);

    var variance = computation.SumOfSquares - computation.Sum * computation.Sum / computation.Count;
    return Math.Sqrt(variance / computation.Count);
}

private static (int Count, double Sum, double SumOfSquares) ComputeSumAndSumOfSquares(IEnumerable<double> sequence)
{
    double sum = 0;
    double sumOfSquares = 0;
    int count = 0;

    foreach (var item in sequence)
    {
        count++;
        sum += item;
        sumOfSquares += item * item;
    }

    return (count, sum, sumOfSquares);
}

```

This final version can be used for any method that needs those three values, or any subset of them.

The language supports other options in managing the names of the elements in these tuple-returning methods.

You can remove the field names from the return value declaration and return an unnamed tuple:

```

private static (double, double, int) ComputeSumAndSumOfSquares(IEnumerable<double> sequence)
{
    double sum = 0;
    double sumOfSquares = 0;
    int count = 0;

    foreach (var item in sequence)
    {
        count++;
        sum += item;
        sumOfSquares += item * item;
    }

    return (sum, sumOfSquares, count);
}

```

The fields of this tuple are named `Item1`, `Item2`, and `Item3`. It's recommended that you provide semantic names to the elements of tuples returned from methods.

Another idiom where tuples can be useful is when you are authoring LINQ queries. The final projected result often contains some, but not all, of the properties of the objects being selected.

You would traditionally project the results of the query into a sequence of objects that were an anonymous type. That presented many limitations, primarily because anonymous types could not conveniently be named in the return type for a method. Alternatives using `object` or `dynamic` as the type of the result came with significant performance costs.

Returning a sequence of a tuple type is easy, and the names and types of the elements are available at compile time and through IDE tools. For example, consider a ToDo application. You might define a class similar to the following to represent a single entry in the ToDo list:

```

public class ToDoItem
{
    public int ID { get; set; }
    public bool IsDone { get; set; }
    public DateTime DueDate { get; set; }
    public string Title { get; set; }
    public string Notes { get; set; }
}

```

Your mobile applications may support a compact form of the current ToDo items that only displays the title. That LINQ query would make a projection that includes only the ID and the title. A method that returns a sequence of tuples expresses that design well:

```

internal IEnumerable<(int ID, string Title)> GetCurrentItemsMobileList()
{
    return from item in AllItems
           where !item.IsDone
           orderby item.DueDate
           select (item.ID, item.Title);
}

```

NOTE

In C# 7.1, tuple projections enable you to create named tuples using elements, in a manner similar to the property naming in anonymous types. In the above code, the `select` statement in the query projection creates a tuple that has elements `ID` and `Title`.

The named tuple can be part of the signature. It lets the compiler and IDE tools provide static checking that you are using the result correctly. The named tuple also carries the static type information so there is no need to use expensive run time features like reflection or dynamic binding to work with the results.

Deconstruction

You can unpack all the items in a tuple by *deconstructing* the tuple returned by a method. There are three different approaches to deconstructing tuples. First, you can explicitly declare the type of each field inside parentheses to create discrete variables for each of the elements in the tuple:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    (int count, double sum, double sumOfSquares) = ComputeSumAndSumOfSquares(sequence);

    var variance = sumOfSquares - sum * sum / count;
    return Math.Sqrt(variance / count);
}

```

You can also declare implicitly typed variables for each field in a tuple by using the `var` keyword outside the parentheses:

```

public static double StandardDeviation(IEnumerable<double> sequence)
{
    var (sum, sumOfSquares, count) = ComputeSumAndSumOfSquares(sequence);

    var variance = sumOfSquares - sum * sum / count;
    return Math.Sqrt(variance / count);
}

```

It is also legal to use the `var` keyword with any, or all of the variable declarations inside the parentheses.

```
(double sum, var sumOfSquares, var count) = ComputeSumAndSumOfSquares(sequence);
```

You cannot use a specific type outside the parentheses, even if every field in the tuple has the same type.

You can deconstruct tuples with existing declarations as well:

```
public class Point
{
    public int X { get; set; }
    public int Y { get; set; }

    public Point(int x, int y) => (X, Y) = (x, y);
}
```

WARNING

You cannot mix existing declarations with declarations inside the parentheses. For instance, the following is not allowed:

```
(var x, y) = MyMethod();
```

This produces error CS8184 because `x` is declared inside the parentheses and `y` is previously declared elsewhere.

Deconstructing user-defined types

Any tuple type can be deconstructed as shown above. It's also easy to enable deconstruction on any user-defined type (classes, structs, or even interfaces).

The type author can define one or more `Deconstruct` methods that assign values to any number of `out` variables representing the data elements that make up the type. For example, the following `Person` type defines a `Deconstruct` method that deconstructs a person object into the elements representing the first name and last name:

```
public class Person
{
    public string FirstName { get; }
    public string LastName { get; }

    public Person(string first, string last)
    {
        FirstName = first;
        LastName = last;
    }

    public void Deconstruct(out string firstName, out string lastName)
    {
        firstName = FirstName;
        lastName = LastName;
    }
}
```

The deconstruct method enables assignment from a `Person` to two strings, representing the `FirstName` and `LastName` properties:

```
var p = new Person("Althea", "Goodwin");
var (first, last) = p;
```

You can enable deconstruction even for types you did not author. The `Deconstruct` method can be an extension

method that unpackages the accessible data members of an object. The example below shows a `Student` type, derived from the `Person` type, and an extension method that deconstructs a `Student` into three variables, representing the `FirstName`, the `LastName`, and the `GPA`:

```
public class Student : Person
{
    public double GPA { get; }
    public Student(string first, string last, double gpa) :
        base(first, last)
    {
        GPA = gpa;
    }
}

public static class Extensions
{
    public static void Deconstruct(this Student s, out string first, out string last, out double gpa)
    {
        first = s.FirstName;
        last = s.LastName;
        gpa = s.GPA;
    }
}
```

A `Student` object now has two accessible `Deconstruct` methods: the extension method declared for `Student` types, and the member of the `Person` type. Both are in scope, and that enables a `Student` to be deconstructed into either two variables or three. If you assign a student to three variables, the first name, last name, and GPA are all returned. If you assign a student to two variables, only the first name and the last name are returned.

```
var s1 = new Student("Cary", "Totten", 4.5);
var (fName, lName, gpa) = s1;
```

You should be careful defining multiple `Deconstruct` methods in a class or a class hierarchy. Multiple `Deconstruct` methods that have the same number of `out` parameters can quickly cause ambiguities. Callers may not be able to easily call the desired `Deconstruct` method.

In this example, there is minimal chance for an ambiguous call because the `Deconstruct` method for `Person` has two output parameters, and the `Deconstruct` method for `Student` has three.

Deconstruction operators do not participate in testing equality. The following example generates compiler error CS0019:

```
Person p = new Person("Althea", "Goodwin");
if (("Althea", "Goodwin") == p)
    Console.WriteLine(p);
```

The `Deconstruct` method could convert the `Person` object `p` to a tuple containing two strings, but it is not applicable in the context of equality tests.

Conclusion

The new language and library support for named tuples makes it much easier to work with designs that use data structures that store multiple elements but do not define behavior, as classes and structs do. It's easy and concise to use tuples for those types. You get all the benefits of static type checking, without needing to author types using the more verbose `class` or `struct` syntax. Even so, they are most useful for utility methods that are `private`, or `internal`. Create user-defined types, either `class` or `struct` types when your public methods

return a value that has multiple elements.

Deconstructing tuples and other types

3/8/2019 • 10 minutes to read • [Edit Online](#)

A tuple provides a light-weight way to retrieve multiple values from a method call. But once you retrieve the tuple, you have to handle its individual elements. Doing this on an element-by-element basis is cumbersome, as the following example shows. The `QueryCityData` method returns a 3-tuple, and each of its elements is assigned to a variable in a separate operation.

```
using System;

public class Example
{
    public static void Main()
    {
        var result = QueryCityData("New York City");

        var city = result.Item1;
        var pop = result.Item2;
        var size = result.Item3;

        // Do something with the data.
    }

    private static (string, int, double) QueryCityData(string name)
    {
        if (name == "New York City")
            return (name, 8175133, 468.48);

        return ("", 0, 0);
    }
}
```

Retrieving multiple field and property values from an object can be equally cumbersome: you have to assign a field or property value to a variable on a member-by-member basis.

Starting with C# 7.0, you can retrieve multiple elements from a tuple or retrieve multiple field, property, and computed values from an object in a single *deconstruct* operation. When you deconstruct a tuple, you assign its elements to individual variables. When you deconstruct an object, you assign selected values to individual variables.

Deconstructing a tuple

C# features built-in support for deconstructing tuples, which lets you unpack all the items in a tuple in a single operation. The general syntax for deconstructing a tuple is similar to the syntax for defining one: you enclose the variables to which each element is to be assigned in parentheses in the left side of an assignment statement. For example, the following statement assigns the elements of a 4-tuple to four separate variables:

```
var (name, address, city, zip) = contact.GetAddressInfo();
```

There are three ways to deconstruct a tuple:

- You can explicitly declare the type of each field inside parentheses. The following example uses this approach to deconstruct the 3-tuple returned by the `QueryCityData` method.

```
public static void Main()
{
    (string city, int population, double area) = QueryCityData("New York City");

    // Do something with the data.
}
```

- You can use the `var` keyword so that C# infers the type of each variable. You place the `var` keyword outside of the parentheses. The following example uses type inference when deconstructing the 3-tuple returned by the `QueryCityData` method.

```
public static void Main()
{
    var (city, population, area) = QueryCityData("New York City");

    // Do something with the data.
}
```

You can also use the `var` keyword individually with any or all of the variable declarations inside the parentheses.

```
public static void Main()
{
    (string city, var population, var area) = QueryCityData("New York City");

    // Do something with the data.
}
```

This is cumbersome and is not recommended.

- Lastly, you may deconstruct the tuple into variables that have already been declared.

```
public static void Main()
{
    string city = "Raleigh";
    int population = 458880;
    double area = 144.8;

    (city, population, area) = QueryCityData("New York City");

    // Do something with the data.
}
```

Note that you cannot specify a specific type outside the parentheses even if every field in the tuple has the same type. This generates compiler error CS8136, "Deconstruction 'var (...)'" form disallows a specific type for 'var'".

Note that you must also assign each element of the tuple to a variable. If you omit any elements, the compiler generates error CS8132, "Cannot deconstruct a tuple of 'x' elements into 'y' variables."

Note that you cannot mix declarations and assignments to existing variables on the left-hand side of a deconstruction. The compiler generates error CS8184, "a deconstruction cannot mix declarations and expressions on the left-hand-side." when the members include newly declared and existing variables.

Deconstructing tuple elements with discards

Often when deconstructing a tuple, you're interested in the values of only some elements. Starting with C# 7.0, you can take advantage of C#'s support for *discards*, which are write-only variables whose values you've chosen to

ignore. A discard is designated by an underscore character ("_") in an assignment. You can discard as many values as you like; all are represented by the single discard, `_`.

The following example illustrates the use of tuples with discards. The `QueryCityDataForYears` method returns a 6-tuple with the name of a city, its area, a year, the city's population for that year, a second year, and the city's population for that second year. The example shows the change in population between those two years. Of the data available from the tuple, we're unconcerned with the city area, and we know the city name and the two dates at design-time. As a result, we're only interested in the two population values stored in the tuple, and can handle its remaining values as discards.

```
using System;
using System.Collections.Generic;

public class Example
{
    public static void Main()
    {
        var (_, _, _, pop1, _, pop2) = QueryCityDataForYears("New York City", 1960, 2010);

        Console.WriteLine($"Population change, 1960 to 2010: {pop2 - pop1:N0}");
    }

    private static (string, double, int, int, int, int) QueryCityDataForYears(string name, int year1, int year2)
    {
        int population1 = 0, population2 = 0;
        double area = 0;

        if (name == "New York City") {
            area = 468.48;
            if (year1 == 1960) {
                population1 = 7781984;
            }
            if (year2 == 2010) {
                population2 = 8175133;
            }
        }
        return (name, area, year1, population1, year2, population2);
    }

    return ("", 0, 0, 0, 0, 0);
}
}

// The example displays the following output:
//      Population change, 1960 to 2010: 393,149
```

Deconstructing user-defined types

Non-tuple types do not offer built-in support for discards. However, as the author of a class, a struct, or an interface, you can allow instances of the type to be deconstructed by implementing one or more `Deconstruct` methods. The method returns void, and each value to be deconstructed is indicated by an `out` parameter in the method signature. For example, the following `Deconstruct` method of a `Person` class returns the first, middle, and last name:

```
public void Deconstruct(out string fname, out string mname, out string lname)
```

You can then deconstruct an instance of the `Person` class named `p` with an assignment like the following:

```
var (fname, mName, lName) = p;
```

The following example overloads the `Deconstruct` method to return various combinations of properties of a

`Person` object. Individual overloads return:

- A first and last name.
- A first, last, and middle name.
- A first name, a last name, a city name, and a state name.

```
using System;

public class Person
{
    public string FirstName { get; set; }
    public string MiddleName { get; set; }
    public string LastName { get; set; }
    public string City { get; set; }
    public string State { get; set; }

    public Person(string fname, string mname, string lname,
                  string cityName, string stateName)
    {
        FirstName = fname;
        MiddleName = mname;
        LastName = lname;
        City = cityName;
        State = stateName;
    }

    // Return the first and last name.
    public void Deconstruct(out string fname, out string lname)
    {
        fname = FirstName;
        lname = LastName;
    }

    public void Deconstruct(out string fname, out string mname, out string lname)
    {
        fname = FirstName;
        mname = MiddleName;
        lname = LastName;
    }

    public void Deconstruct(out string fname, out string lname,
                           out string city, out string state)
    {
        fname = FirstName;
        lname = LastName;
        city = City;
        state = State;
    }
}

public class Example
{
    public static void Main()
    {
        Person p = new Person("John", "Quincy", "Adams", "Boston", "MA");

        // Deconstruct the person object.
        var (fName, lName, city, state) = p;
        Console.WriteLine($"Hello {fName} {lName} of {city}, {state}!");
    }
}

// The example displays the following output:
//      Hello John Adams of Boston, MA!
```

Because you can overload the `Deconstruct` method to reflect groups of data that are commonly extracted from an object, you should be careful to define `Deconstruct` methods with signatures that are distinctive and unambiguous. Multiple `Deconstruct` methods that have the same number of `out` parameters or the same number and type of `out` parameters in a different order can cause confusion.

The overloaded `Deconstruct` method in the following example illustrates one possible source of confusion. The first overload returns the first name, middle name, last name, and age of a `Person` object, in that order. The second overload returns name information only along with annual income, but the first, middle, and last name are in a different order. This makes it easy to confuse the order of arguments when deconstructing a `Person` instance.

```
using System;

public class Person
{
    public string FirstName { get; set; }
    public string MiddleName { get; set; }
    public string LastName { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public DateTime DateOfBirth { get; set; }
    public Decimal AnnualIncome { get; set; }

    public void Deconstruct(out string fname, out string mname, out string lname, out int age)
    {
        fname = FirstName;
        mname = MiddleName;
        lname = LastName;
        age = DateTime.Now.Year - DateOfBirth.Year;

        if (DateTime.Now.DayOfYear - (new DateTime(DateTime.Now.Year, DateOfBirth.Month,
DateOfBirth.Day)).DayOfYear < 0)
            age--;
    }

    public void Deconstruct(out string lname, out string fname, out string mname, out decimal income)
    {
        fname = FirstName;
        mname = MiddleName;
        lname = LastName;
        income = AnnualIncome;
    }
}
```

Deconstructing a user-defined type with discards

Just as you do with [tuples](#), you can use discards to ignore selected items returned by a `Deconstruct` method. Each discard is defined by a variable named `_`, and a single deconstruction operation can include multiple discards.

The following example deconstructs a `Person` object into four strings (the first and last names, the city, and the state) but discards the last name and the state.

```
// Deconstruct the person object.
var (fName, _, city, _) = p;
Console.WriteLine($"Hello {fName} of {city}!");
// The example displays the following output:
//      Hello John of Boston!
```

Deconstructing a user-defined type with an extension method

If you didn't author a class, struct, or interface, you can still deconstruct objects of that type by implementing one or more `Deconstruct` extension methods to return the values in which you're interested.

The following example defines two `Deconstruct` extension methods for the `System.Reflection.PropertyInfo` class. The first returns a set of values that indicate the characteristics of the property, including its type, whether it's static or instance, whether it's read-only, and whether it's indexed. The second indicates the property's accessibility. Because the accessibility of get and set accessors can differ, Boolean values indicate whether the property has separate get and set accessors and, if it does, whether they have the same accessibility. If there is only one accessor or both the get and the set accessor have the same accessibility, the `access` variable indicates the accessibility of the property as a whole. Otherwise, the accessibility of the get and set accessors are indicated by the `getAccess` and `setAccess` variables.

```
using System;
using System.Collections.Generic;
using System.Reflection;

public static class ReflectionExtensions
{
    public static void Deconstruct(this PropertyInfo p, out bool isStatic,
                                  out bool isReadOnly, out bool isIndexed,
                                  out Type propertyType)
    {
        var getter = p.GetMethod();

        // Is the property read-only?
        isReadOnly = !p.CanWrite;

        // Is the property instance or static?
        isStatic = getter.IsStatic;

        // Is the property indexed?
        isIndexed = p.GetIndexParameters().Length > 0;

        // Get the property type.
        propertyType = p.PropertyType;
    }

    public static void Deconstruct(this PropertyInfo p, out bool hasGetAndSet,
                                  out bool sameAccess, out string access,
                                  out string getAccess, out string setAccess)
    {
        hasGetAndSet = sameAccess = false;
        string getAccessTemp = null;
        string setAccessTemp = null;

        MethodInfo getter = null;
        if (p.CanRead)
            getter = p.GetMethod();

        MethodInfo setter = null;
        if (p.CanWrite)
            setter = p.SetMethod();

        if (setter != null && getter != null)
            hasGetAndSet = true;

        if (getter != null) {
            if (getter.IsPublic)
                getAccessTemp = "public";
            else if (getter.IsPrivate)
                getAccessTemp = "private";
            else if (getter.IsAssembly)
                getAccessTemp = "internal";
            else if (getter.IsFamily)
                getAccessTemp = "protected";
        }
    }
}
```

```

        else if (getter.IsFamilyOrAssembly)
            getAccessTemp = "protected internal";
    }

    if (setter != null) {
        if (setter.IsPublic)
            setAccessTemp = "public";
        else if (setter.IsPrivate)
            setAccessTemp = "private";
        else if (setter.IsAssembly)
            setAccessTemp = "internal";
        else if (setter.IsFamily)
            setAccessTemp = "protected";
        else if (setter.IsFamilyOrAssembly)
            setAccessTemp = "protected internal";
    }

    // Are the accessibility of the getter and setter the same?
    if (setAccessTemp == getAccessTemp) {
        sameAccess = true;
        access = getAccessTemp;
        getAccess = setAccess = String.Empty;
    }
    else {
        access = null;
        getAccess = getAccessTemp;
        setAccess = setAccessTemp;
    }
}

public class Example
{
    public static void Main()
    {
        Type dateType = typeof(DateTime);
        PropertyInfo prop = dateType.GetProperty("Now");
        var (isStatic, isRO, isIndexed, propType) = prop;
        Console.WriteLine($"\\nThe {dateType.FullName}.{prop.Name} property:");
        Console.WriteLine($"    PropertyType: {propType.Name}");
        Console.WriteLine($"    Static:      {isStatic}");
        Console.WriteLine($"    Read-only:   {isRO}");
        Console.WriteLine($"    Indexed:     {isIndexed}");

        Type listType = typeof(List<>);
        prop = listType.GetProperty("Item",
                                   BindingFlags.Public | BindingFlags.NonPublic | BindingFlags.Instance |
                                   BindingFlags.Static);
        var (hasGetAndSet, sameAccess, accessibility, getAccessibility, setAccessibility) = prop;
        Console.WriteLine($"\\nAccessibility of the {listType.FullName}.{prop.Name} property: ");

        if (!hasGetAndSet | sameAccess) {
            Console.WriteLine(accessibility);
        }
        else {
            Console.WriteLine($"\\n    The get accessor: {getAccessibility}");
            Console.WriteLine($"    The set accessor: {setAccessibility}");
        }
    }
}

// The example displays the following output:
//     The System.DateTime.Now property:
//         PropertyType: DateTime
//         Static:      True
//         Read-only:   True
//         Indexed:     False
//
//         Accessibility of the System.Collections.Generic.List`1.Item property: public

```

Interfaces (C# Programming Guide)

3/20/2019 • 4 minutes to read • [Edit Online](#)

An interface contains definitions for a group of related functionalities that a [class](#) or a [struct](#) can implement.

By using interfaces, you can, for example, include behavior from multiple sources in a class. That capability is important in C# because the language doesn't support multiple inheritance of classes. In addition, you must use an interface if you want to simulate inheritance for structs, because they can't actually inherit from another struct or class.

You define an interface by using the [interface](#) keyword, as the following example shows.

```
interface IEquatable<T>
{
    bool Equals(T obj);
}
```

The name of the struct must be a valid C# [identifier name](#). By convention, interface names begin with a capital `I`.

Any class or struct that implements the `IEquatable<T>` interface must contain a definition for an [Equals](#) method that matches the signature that the interface specifies. As a result, you can count on a class that implements `IEquatable<T>` to contain an `Equals` method with which an instance of the class can determine whether it's equal to another instance of the same class.

The definition of `IEquatable<T>` doesn't provide an implementation for `Equals`. The interface defines only the signature. In that way, an interface in C# is similar to an abstract class in which all the methods are abstract. However, a class or struct can implement multiple interfaces, but a class can inherit only a single class, abstract or not.

For more information about abstract classes, see [Abstract and Sealed Classes and Class Members](#).

Interfaces can contain methods, properties, events, indexers, or any combination of those four member types. For links to examples, see [Related Sections](#). An interface can't contain constants, fields, operators, instance constructors, finalizers, or types. Interface members are automatically public, and they can't include any access modifiers. Members also can't be [static](#).

To implement an interface member, the corresponding member of the implementing class must be public, non-static, and have the same name and signature as the interface member.

When a class or struct implements an interface, the class or struct must provide an implementation for all of the members that the interface defines. The interface itself provides no functionality that a class or struct can inherit in the way that it can inherit base class functionality. However, if a base class implements an interface, any class that's derived from the base class inherits that implementation.

The following example shows an implementation of the `IEquatable<T>` interface. The implementing class, `Car`, must provide an implementation of the `Equals` method.

```

public class Car : IEquatable<Car>
{
    public string Make {get; set;}
    public string Model { get; set; }
    public string Year { get; set; }

    // Implementation of IEquatable<T> interface
    public bool Equals(Car car)
    {
        return this.Make == car.Make &&
               this.Model == car.Model &&
               this.Year == car.Year;
    }
}

```

Properties and indexers of a class can define extra accessors for a property or indexer that's defined in an interface. For example, an interface might declare a property that has a [get](#) accessor. The class that implements the interface can declare the same property with both a [get](#) and [set](#) accessor. However, if the property or indexer uses explicit implementation, the accessors must match. For more information about explicit implementation, see [Explicit Interface Implementation](#) and [Interface Properties](#).

Interfaces can inherit from other interfaces. A class might include an interface multiple times through base classes that it inherits or through interfaces that other interfaces inherit. However, the class can provide an implementation of an interface only one time and only if the class declares the interface as part of the definition of the class (`class ClassName : InterfaceName`). If the interface is inherited because you inherited a base class that implements the interface, the base class provides the implementation of the members of the interface. However, the derived class can reimplement any virtual interface members instead of using the inherited implementation.

A base class can also implement interface members by using virtual members. In that case, a derived class can change the interface behavior by overriding the virtual members. For more information about virtual members, see [Polymorphism](#).

Interfaces summary

An interface has the following properties:

- An interface is like an abstract base class with only abstract members. Any class or struct that implements the interface must implement all its members.
- An interface can't be instantiated directly. Its members are implemented by any class or struct that implements the interface.
- Interfaces can contain events, indexers, methods, and properties.
- Interfaces contain no implementation of methods.
- A class or struct can implement multiple interfaces. A class can inherit a base class and also implement one or more interfaces.

In this section

[Explicit Interface Implementation](#)

Explains how to create a class member that's specific to an interface.

[How to: Explicitly Implement Interface Members](#)

Provides an example of how to explicitly implement members of interfaces.

[How to: Explicitly Implement Members of Two Interfaces](#)

Provides an example of how to explicitly implement members of interfaces with inheritance.

Methods

3/19/2019 • 21 minutes to read • [Edit Online](#)

A method is a code block that contains a series of statements. A program causes the statements to be executed by calling the method and specifying any required method arguments. In C#, every executed instruction is performed in the context of a method. The `Main` method is the entry point for every C# application and it is called by the common language runtime (CLR) when the program is started.

NOTE

This topic discusses named methods. For information about anonymous functions, see [Anonymous Functions](#).

This topic contains the following sections:

- [Iterators](#)

Method signatures

Methods are declared in a `class` or `struct` by specifying:

- An optional access level, such as `public` or `private`. The default is `private`.
- Optional modifiers such as `abstract` or `sealed`.
- The return value, or `void` if the method has none.
- The method name.
- Any method parameters. Method parameters are enclosed in parentheses and are separated by commas. Empty parentheses indicate that the method requires no parameters.

These parts together form the method signature.

NOTE

A return type of a method is not part of the signature of the method for the purposes of method overloading. However, it is part of the signature of the method when determining the compatibility between a delegate and the method that it points to.

The following example defines a class named `Motorcycle` that contains five methods:

```
using System;

abstract class Motorcycle
{
    // Anyone can call this.
    public void StartEngine() { /* Method statements here */ }

    // Only derived classes can call this.
    protected void AddGas(int gallons) { /* Method statements here */ }

    // Derived classes can override the base class implementation.
    public virtual int Drive(int miles, int speed) { /* Method statements here */ return 1; }

    // Derived classes can override the base class implementation.
    public virtual int Drive(TimeSpan time, int speed) { /* Method statements here */ return 0; }

    // Derived classes must implement this.
    public abstract double GetTopSpeed();
}
```

Note that the `Motorcycle` class includes an overloaded method, `Drive`. Two methods have the same name, but must be differentiated by their parameter types.

Method invocation

Methods can be either *instance* or *static*. Invoking an instance method requires that you instantiate an object and call the method on that object; an instance method operates on that instance and its data. You invoke a static method by referencing the name of the type to which the method belongs; static methods do not operate on instance data. Attempting to call a static method through an object instance generates a compiler error.

Calling a method is like accessing a field. After the object name (if you are calling an instance method) or the type name (if you are calling a `static` method), add a period, the name of the method, and parentheses. Arguments are listed within the parentheses, and are separated by commas.

The method definition specifies the names and types of any parameters that are required. When a caller invokes the method, it provides concrete values, called arguments, for each parameter. The arguments must be compatible with the parameter type, but the argument name, if one is used in the calling code, does not have to be the same as the parameter named defined in the method. In the following example, the `Square` method includes a single parameter of type `int` named `i`. The first method call passes the `Square` method a variable of type `int` named `num`; the second, a numeric constant; and the third, an expression.

```

public class Example
{
    public static void Main()
    {
        // Call with an int variable.
        int num = 4;
        int productA = Square(num);

        // Call with an integer literal.
        int productB = Square(12);

        // Call with an expression that evaluates to int.
        int productC = Square(productA * 3);
    }

    static int Square(int i)
    {
        // Store input argument in a local variable.
        int input = i;
        return input * input;
    }
}

```

The most common form of method invocation used positional arguments; it supplies arguments in the same order as method parameters. The methods of the `Motorcycle` class can therefore be called as in the following example. The call to the `Drive` method, for example, includes two arguments that correspond to the two parameters in the method's syntax. The first becomes the value of the `miles` parameter, the second the value of the `speed` parameter.

```

class TestMotorcycle : Motorcycle
{
    public override double GetTopSpeed()
    {
        return 108.4;
    }

    static void Main()
    {

        TestMotorcycle moto = new TestMotorcycle();

        moto.StartEngine();
        moto.AddGas(15);
        moto.Drive(5, 20);
        double speed = moto.GetTopSpeed();
        Console.WriteLine("My top speed is {0}", speed);
    }
}

```

You can also used *named arguments* instead of positional arguments when invoking a method. When using named arguments, you specify the parameter name followed by a colon (":") and the argument. Arguments to the method can appear in any order, as long as all required arguments are present. The following example uses named arguments to invoke the `TestMotorcycle.Drive` method. In this example, the named arguments are passed in the opposite order from the method's parameter list.

```

using System;

class TestMotorcycle : Motorcycle
{
    public override int Drive(int miles, int speed)
    {
        return (int) Math.Round( ((double)miles) / speed, 0);
    }

    public override double GetTopSpeed()
    {
        return 108.4;
    }

    static void Main()
    {

        TestMotorcycle moto = new TestMotorcycle();
        moto.StartEngine();
        moto.AddGas(15);
        var travelTime = moto.Drive(speed: 60, miles: 170);
        Console.WriteLine("Travel time: approx. {0} hours", travelTime);
    }
}

// The example displays the following output:
//      Travel time: approx. 3 hours

```

You can invoke a method using both positional arguments and named arguments. However, a positional argument cannot follow a named argument. The following example invokes the `TestMotorcycle.Drive` method from the previous example using one positional argument and one named argument.

```
var travelTime = moto.Drive(170, speed: 55);
```

Inherited and overridden methods

In addition to the members that are explicitly defined in a type, a type inherits members defined in its base classes. Since all types in the managed type system inherit directly or indirectly from the `Object` class, all types inherit its members, such as `Equals(Object)`, `GetType()`, and `ToString()`. The following example defines a `Person` class, instantiates two `Person` objects, and calls the `Person.Equals` method to determine whether the two objects are equal. The `Equals` method, however, is not defined in the `Person` class; it is inherited from `Object`.

```

using System;

public class Person
{
    public String FirstName;
}

public class Example
{
    public static void Main()
    {
        var p1 = new Person();
        p1.FirstName = "John";
        var p2 = new Person();
        p2.FirstName = "John";
        Console.WriteLine("p1 = p2: {0}", p1.Equals(p2));
    }
}
// The example displays the following output:
//      p1 = p2: False

```

Types can override inherited members by using the `override` keyword and providing an implementation for the overridden method. The method signature must be the same as that of the overridden method. The following example is like the previous one, except that it overrides the [Equals\(Object\)](#) method. (It also overrides the [GetHashCode\(\)](#) method, since the two methods are intended to provide consistent results.)

```

using System;

public class Person
{
    public String FirstName;

    public override bool Equals(object obj)
    {
        var p2 = obj as Person;
        if (p2 == null)
            return false;
        else
            return FirstName.Equals(p2.FirstName);
    }

    public override int GetHashCode()
    {
        return FirstName.GetHashCode();
    }
}

public class Example
{
    public static void Main()
    {
        var p1 = new Person();
        p1.FirstName = "John";
        var p2 = new Person();
        p2.FirstName = "John";
        Console.WriteLine("p1 = p2: {0}", p1.Equals(p2));
    }
}
// The example displays the following output:
//      p1 = p2: True

```

Passing parameters

Types in C# are either *value types* or *reference types*. For a list of built-in value types, see [Types and variables](#). By default, both value types and reference types are passed to a method by value.

Passing parameters by value

When a value type is passed to a method by value, a copy of the object instead of the object itself is passed to the method. Therefore, changes to the object in the called method have no effect on the original object when control returns to the caller.

The following example passes a value type to a method by value, and the called method attempts to change the value type's value. It defines a variable of type `int`, which is a value type, initializes its value to 20, and passes it to a method named `ModifyValue` that changes the variable's value to 30. When the method returns, however, the variable's value remains unchanged.

```
using System;

public class Example
{
    public static void Main()
    {
        int value = 20;
        Console.WriteLine("In Main, value = {0}", value);
        ModifyValue(value);
        Console.WriteLine("Back in Main, value = {0}", value);
    }

    static void ModifyValue(int i)
    {
        i = 30;
        Console.WriteLine("In ModifyValue, parameter value = {0}", i);
        return;
    }
}

// The example displays the following output:
//      In Main, value = 20
//      In ModifyValue, parameter value = 30
//      Back in Main, value = 20
```

When an object of a reference type is passed to a method by value, a reference to the object is passed by value. That is, the method receives not the object itself, but an argument that indicates the location of the object. If you change a member of the object by using this reference, the change is reflected in the object when control returns to the calling method. However, replacing the object passed to the method has no effect on the original object when control returns to the caller.

The following example defines a class (which is a reference type) named `SampleRefType`. It instantiates a `SampleRefType` object, assigns 44 to its `value` field, and passes the object to the `ModifyObject` method. This example does essentially the same thing as the previous example -- it passes an argument by value to a method. But because a reference type is used, the result is different. The modification that is made in `ModifyObject` to the `obj.value` field also changes the `value` field of the argument, `rt`, in the `Main` method to 33, as the output from the example shows.

```

using System;

public class SampleRefType
{
    public int value;
}

public class Example
{
    public static void Main()
    {
        var rt = new SampleRefType();
        rt.value = 44;
        ModifyObject(rt);
        Console.WriteLine(rt.value);
    }

    static void ModifyObject(SampleRefType obj)
    {
        obj.value = 33;
    }
}

```

Passing parameters by reference

You pass a parameter by reference when you want to change the value of an argument in a method and want to reflect that change when control returns to the calling method. To pass a parameter by reference, you use the `ref` or `out` keyword. You can also pass a value by reference to avoid copying but still prevent modifications using the `in` keyword.

The following example is identical to the previous one, except the value is passed by reference to the `ModifyValue` method. When the value of the parameter is modified in the `ModifyValue` method, the change in value is reflected when control returns to the caller.

```

using System;

public class Example
{
    public static void Main()
    {
        int value = 20;
        Console.WriteLine("In Main, value = {0}", value);
        ModifyValue(ref value);
        Console.WriteLine("Back in Main, value = {0}", value);
    }

    static void ModifyValue(ref int i)
    {
        i = 30;
        Console.WriteLine("In ModifyValue, parameter value = {0}", i);
        return;
    }
}

// The example displays the following output:
//      In Main, value = 20
//      In ModifyValue, parameter value = 30
//      Back in Main, value = 30

```

A common pattern that uses `ref` parameters involves swapping the values of variables. You pass two variables to a method by reference, and the method swaps their contents. The following example swaps integer values.

```

using System;

public class Example
{
    static void Main()
    {
        int i = 2, j = 3;
        System.Console.WriteLine("i = {0}  j = {1}" , i, j);

        Swap(ref i, ref j);

        System.Console.WriteLine("i = {0}  j = {1}" , i, j);
    }

    static void Swap(ref int x, ref int y)
    {
        int temp = x;
        x = y;
        y = temp;
    }
}

// The example displays the following output:
//      i = 2  j = 3
//      i = 3  j = 2

```

Passing a reference-type parameter allows you to change the value of the reference itself, rather than the value of its individual elements or fields.

Parameter arrays

Sometimes, the requirement that you specify the exact number of arguments to your method is restrictive. By using the `params` keyword to indicate that a parameter is a parameter array, you allow your method to be called with a variable number of arguments. The parameter tagged with the `params` keyword must be an array type, and it must be the last parameter in the method's parameter list.

A caller can then invoke the method in either of three ways:

- By passing an array of the appropriate type that contains the desired number of elements.
- By passing a comma-separated list of individual arguments of the appropriate type to the method.
- By not providing an argument to the parameter array.

The following example defines a method named `DoStringOperation` that performs the string operation specified by its first parameter, a `StringOperation` enumeration member. The strings upon which it is to perform the operation are defined by a parameter array. The `Main` method illustrates all three ways of invoking the method. Note that the method tagged with the `params` keyword must be prepared to handle the case in which no argument is supplied for the parameter array, so that its value is `null`.

```

using System;

class Example
{
    static void Main()
    {
        int[] arr = {1, 4, 5};
        Console.WriteLine("In Main, array has {0} elements and starts with {1}",
                          arr.Length, arr[0]);

        Change(ref arr);
        Console.WriteLine("Back in Main, array has {0} elements and starts with {1}",
                          arr.Length, arr[0]);
    }

    static void Change(ref int[] arr)
    {
        // Both of the following changes will affect the original variables:
        arr = new int[5] {-9, -7, -5, -3, -1};
        Console.WriteLine("In Change, array has {0} elements and starts with {1}",
                          arr.Length, arr[0]);
    }
}

// The example displays the following output:
//      In Main, array has 3 elements and starts with 1
//      In Change, array has 5 elements and starts with -9
//      Back in Main, array has 5 elements and starts with -9

```

Optional parameters and arguments

A method definition can specify that its parameters are required or that they are optional. By default, parameters are required. Optional parameters are specified by including the parameter's default value in the method definition. When the method is called, if no argument is supplied for an optional parameter, the default value is used instead.

The parameter's default value must be assigned by one of the following kinds of expressions:

- A constant, such as a literal string or number.
- An expression of the form `new ValType`, where `ValType` is a value type. Note that this invokes the value type's implicit default constructor, which is not an actual member of the type.
- An expression of the form `default(ValType)`, where `ValType` is a value type.

If a method includes both required and optional parameters, optional parameters are defined at the end of the parameter list, after all required parameters.

The following example defines a method, `ExampleMethod`, that has one required and two optional parameters.

```

using System;

public class Options
{
    public void ExampleMethod(int required, int optionalInt = default(int),
                             string description = "Optional Description")
    {
        Console.WriteLine("{0}: {1} + {2} = {3}", description, required,
                         optionalInt, required + optionalInt);
    }
}

```

If a method with multiple optional arguments is invoked using positional arguments, the caller must supply an argument for all optional parameters from the first one to the last one for which an argument is supplied. In the

case of the `ExampleMethod` method, for example, if the caller supplies an argument for the `description` parameter, it must also supply one for the `optionalInt` parameter. `opt.ExampleMethod(2, 2, "Addition of 2 and 2");` is a valid method call; `opt.ExampleMethod(2, , "Addition of 2 and 0");` generates an "Argument missing" compiler error.

If a method is called using named arguments or a combination of positional and named arguments, the caller can omit any arguments that follow the last positional argument in the method call.

The following example calls the `ExampleMethod` method three times. The first two method calls use positional arguments. The first omits both optional arguments, while the second omits the last argument. The third method call supplies a positional argument for the required parameter, but uses a named argument to supply a value to the `description` parameter while omitting the `optionalInt` argument.

```
public class Example
{
    public static void Main()
    {
        var opt = new Options();
        opt.ExampleMethod(10);
        opt.ExampleMethod(10, 2);
        opt.ExampleMethod(12, description: "Addition with zero:");
    }
}
// The example displays the following output:
//      Optional Description: 10 + 0 = 10
//      Optional Description: 10 + 2 = 12
//      Addition with zero:: 12 + 0 = 12
```

The use of optional parameters affects *overload resolution*, or the way in which the C# compiler determines which particular overload should be invoked by a method call, as follows:

- A method, indexer, or constructor is a candidate for execution if each of its parameters either is optional or corresponds, by name or by position, to a single argument in the calling statement, and that argument can be converted to the type of the parameter.
- If more than one candidate is found, overload resolution rules for preferred conversions are applied to the arguments that are explicitly specified. Omitted arguments for optional parameters are ignored.
- If two candidates are judged to be equally good, preference goes to a candidate that does not have optional parameters for which arguments were omitted in the call. This is a consequence of a general preference in overload resolution for candidates that have fewer parameters.

Return values

Methods can return a value to the caller. If the return type (the type listed before the method name) is not `void`, the method can return the value by using the `return` keyword. A statement with the `return` keyword followed by a variable, constant, or expression that matches the return type will return that value to the method caller. Methods with a non-void return type are required to use the `return` keyword to return a value. The `return` keyword also stops the execution of the method.

If the return type is `void`, a `return` statement without a value is still useful to stop the execution of the method. Without the `return` keyword, the method will stop executing when it reaches the end of the code block.

For example, these two methods use the `return` keyword to return integers:

```

class SimpleMath
{
    public int AddTwoNumbers(int number1, int number2)
    {
        return number1 + number2;
    }

    public int SquareANumber(int number)
    {
        return number * number;
    }
}

```

To use a value returned from a method, the calling method can use the method call itself anywhere a value of the same type would be sufficient. You can also assign the return value to a variable. For example, the following two code examples accomplish the same goal:

```

int result = obj.AddTwoNumbers(1, 2);
result = obj.SquareANumber(result);
// The result is 9.
Console.WriteLine(result);

```

```

result = obj.SquareANumber(obj.AddTwoNumbers(1, 2));
// The result is 9.
Console.WriteLine(result);

```

Using a local variable, in this case, `result`, to store a value is optional. It may help the readability of the code, or it may be necessary if you need to store the original value of the argument for the entire scope of the method.

Sometimes, you want your method to return more than a single value. Starting with C# 7.0, you can do this easily by using *tuple types* and *tuple literals*. The tuple type defines the data types of the tuple's elements. Tuple literals provide the actual values of the returned tuple. In the following example, `(string, string, string, int)` defines the tuple type that is returned by the `GetPersonalInfo` method. The expression

`(per.FirstName, per.MiddleName, per.LastName, per.Age)` is the tuple literal; the method returns the first, middle, and last name, along with the age, of a `PersonInfo` object.

```

public (string, string, string, int) GetPersonalInfo(string id)
{
    PersonInfo per = PersonInfo.RetrieveInfoById(id);
    return (per.FirstName, per.MiddleName, per.LastName, per.Age);
}

```

The caller can then consume the returned tuple with code like the following:

```

var person = GetPersonalInfo("111111111")
Console.WriteLine("{person.Item1} {person.Item3}: age = {person.Item4}");

```

Names can also be assigned to the tuple elements in the tuple type definition. The following example shows an alternate version of the `GetPersonalInfo` method that uses named elements:

```

public (string FName, string MName, string LName, int Age) GetPersonalInfo(string id)
{
    PersonInfo per = PersonInfo.RetrieveInfoById(id);
    return (per.FirstName, per.MiddleName, per.LastName, per.Age);
}

```

The previous call to the `GetPersonInfo` method can then be modified as follows:

```

var person = GetPersonalInfo("111111111");
Console.WriteLine("{person.FName} {person.LName}: age = {person.Age}");

```

If a method is passed an array as an argument and modifies the value of individual elements, it is not necessary for the method to return the array, although you may choose to do so for good style or functional flow of values. This is because C# passes all reference types by value, and the value of an array reference is the pointer to the array. In the following example, changes to the contents of the `values` array that are made in the `DoubleValues` method are observable by any code that has a reference to the array.

```

using System;

public class Example
{
    static void Main(string[] args)
    {
        int[] values = { 2, 4, 6, 8 };
        DoubleValues(values);
        foreach (var value in values)
            Console.Write("{0} ", value);
    }

    public static void DoubleValues(int[] arr)
    {
        for (int ctr = 0; ctr <= arr.GetUpperBound(0); ctr++)
            arr[ctr] = arr[ctr] * 2;
    }
}
// The example displays the following output:
//      4 8 12 16

```

Extension methods

Ordinarily, there are two ways to add a method to an existing type:

- Modify the source code for that type. You cannot do this, of course, if you do not own the type's source code. And this becomes a breaking change if you also add any private data fields to support the method.
- Define the new method in a derived class. A method cannot be added in this way using inheritance for other types, such as structures and enumerations. Nor can it be used to "add" a method to a sealed class.

Extension methods let you "add" a method to an existing type without modifying the type itself or implementing the new method in an inherited type. The extension method also does not have to reside in the same assembly as the type it extends. You call an extension method as if it were a defined member of a type.

For more information, see [Extension Methods](#).

Async Methods

By using the `async` feature, you can invoke asynchronous methods without using explicit callbacks or manually splitting your code across multiple methods or lambda expressions.

If you mark a method with the `async` modifier, you can use the `await` operator in the method. When control reaches an `await` expression in the `async` method, control returns to the caller if the awaited task is not completed, and progress in the method with the `await` keyword is suspended until the awaited task completes. When the task is complete, execution can resume in the method.

NOTE

An `async` method returns to the caller when either it encounters the first awaited object that's not yet complete or it gets to the end of the `async` method, whichever occurs first.

An `async` method can have a return type of `Task<TResult>`, `Task`, or `void`. The `void` return type is used primarily to define event handlers, where a `void` return type is required. An `async` method that returns `void` can't be awaited, and the caller of a `void`-returning method can't catch exceptions that the method throws. Starting with C# 7.0, an `async` method can have [any task-like return type](#).

In the following example, `DelayAsync` is an `async` method that has a `return` statement that returns an integer. Because it is an `async` method, its method declaration must have a return type of `Task<int>`. Because the return type is `Task<int>`, the evaluation of the `await` expression in `DoSomethingAsync` produces an integer, as the following `int result = await delayTask` statement demonstrates.

```
using System;
using System.Diagnostics;
using System.Threading.Tasks;

public class Example
{
    // This Click event is marked with the async modifier.
    public static void Main()
    {
        DoSomethingAsync().Wait();
    }

    private static async Task DoSomethingAsync()
    {
        int result = await DelayAsync();
        Console.WriteLine("Result: " + result);
    }

    private static async Task<int> DelayAsync()
    {
        await Task.Delay(100);
        return 5;
    }

    // Output:
    // Result: 5
}

// The example displays the following output:
//      Result: 5
```

An `async` method can't declare any `in`, `ref`, or `out` parameters, but it can call methods that have such parameters.

For more information about `async` methods, see [Asynchronous Programming with Async and Await](#), [Control Flow in Async Programs](#), and [Async Return Types](#).

Expression-bodied members

It is common to have method definitions that simply return immediately with the result of an expression, or that have a single statement as the body of the method. There is a syntax shortcut for defining such methods using `=>`:

```
public Point Move(int dx, int dy) => new Point(x + dx, y + dy);
public void Print() => Console.WriteLine(First + " " + Last);
// Works with operators, properties, and indexers too.
public static Complex operator +(Complex a, Complex b) => a.Add(b);
public string Name => First + " " + Last;
public Customer this[long id] => store.LookupCustomer(id);
```

If the method returns `void` or is an async method, the body of the method must be a statement expression (same as with lambdas). For properties and indexers, they must be read-only, and you do not use the `get` accessor keyword.

Iterators

An iterator performs a custom iteration over a collection, such as a list or an array. An iterator uses the `yield return` statement to return each element one at a time. When a `yield return` statement is reached, the current location is remembered so that the caller can request the next element in the sequence.

The return type of an iterator can be `IEnumerable`, `IEnumerable<T>`, `IEnumerator`, or `IEnumerator<T>`.

For more information, see [Iterators](#).

Lambda expressions (C# Programming Guide)

3/16/2019 • 11 minutes to read • [Edit Online](#)

A *lambda expression* is a block of code (an expression or a statement block) that is treated as an object. It can be passed as an argument to methods, and it can also be returned by method calls. Lambda expressions are used extensively for:

- Passing the code that is to be executed to asynchronous methods, such as [Task.Run\(Action\)](#).
- Writing [LINQ query expressions](#).
- Creating [expression trees](#).

Lambda expressions are code that can be represented either as a delegate, or as an expression tree that compiles to a delegate. The specific delegate type of a lambda expression depends on its parameters and return value.

Lambda expressions that don't return a value correspond to a specific `Action` delegate, depending on its number of parameters. Lambda expressions that return a value correspond to a specific `Func` delegate, depending on its number of parameters. For example, a lambda expression that has two parameters but returns no value corresponds to an `Action<T1,T2>` delegate. A lambda expression that has one parameter and returns a value corresponds to `Func<T,TResult>` delegate.

A lambda expression uses `=>`, the [lambda declaration operator](#), to separate the lambda's parameter list from its executable code. To create a lambda expression, you specify input parameters (if any) on the left side of the lambda operator, and you put the expression or statement block on the other side. For example, the single-line lambda expression `x => x * x` specifies a parameter that's named `x` and returns the value of `x` squared. You can assign this expression to a delegate type, as the following example shows:

```
Func<int, int> square = x => x * x;
Console.WriteLine(square(5));
// Output:
// 25
```

You also can assign a lambda expression to an expression tree type:

```
System.Linq.Expressions.Expression<Func<int, int>> e = x => x * x;
Console.WriteLine(e);
// Output:
// x => (x * x)
```

Or you can pass it directly as a method argument:

```
int[] numbers = { 2, 3, 4, 5 };
var squaredNumbers = numbers.Select(x => x * x);
Console.WriteLine(string.Join(" ", squaredNumbers));
// Output:
// 4 9 16 25
```

When you use method-based syntax to call the `Enumerable.Select` method in the `System.Linq.Enumerable` class (as you do in LINQ to Objects and LINQ to XML) the parameter is a delegate type `System.Func<T,TResult>`. A lambda expression is the most convenient way to create that delegate. When you call the `Queryable.Select` method in the `System.Linq.Queryable` class (as you do in LINQ to SQL) the parameter type is an expression tree

type `Expression<Func<TSource, TResult>>`. Again, a lambda expression is just a very concise way to construct that expression tree. The lambdas allow the `Select` calls to look similar although in fact the type of object created from the lambda is different.

All restrictions that apply to [anonymous methods](#) also apply to lambda expressions.

Expression lambdas

A lambda expression with an expression on the right side of the `=>` operator is called an *expression lambda*.

Expression lambdas are used extensively in the construction of [expression trees](#). An expression lambda returns the result of the expression and takes the following basic form:

```
(input-parameters) => expression
```

The parentheses are optional only if the lambda has one input parameter; otherwise they are required.

Specify zero input parameters with empty parentheses:

```
Action line = () => Console.WriteLine();
```

Two or more input parameters are separated by commas enclosed in parentheses:

```
Func<int, int, bool> testForEquality = (x, y) => x == y;
```

Sometimes it's impossible for the compiler to infer the input types. You can specify the types explicitly as shown in the following example:

```
Func<int, string, bool> isTooLong = (int x, string s) => s.Length > x;
```

Input parameter types must be all explicit or all implicit; otherwise, a [CS0748](#) compiler error occurs.

The body of an expression lambda can consist of a method call. However, if you are creating expression trees that are evaluated outside the context of the .NET common language runtime, such as in SQL Server, you should not use method calls in lambda expressions. The methods will have no meaning outside the context of the .NET common language runtime.

Statement lambdas

A statement lambda resembles an expression lambda except that the statement(s) is enclosed in braces:

```
(input-parameters) => { statement; }
```

The body of a statement lambda can consist of any number of statements; however, in practice there are typically no more than two or three.

```
Action<string> greet = name =>
{
    string greeting = $"Hello {name}!";
    Console.WriteLine(greeting);
};

greet("World");
// Output:
// Hello World!
```

Statement lambdas, like anonymous methods, cannot be used to create expression trees.

Async lambdas

You can easily create lambda expressions and statements that incorporate asynchronous processing by using the `async` and `await` keywords. For example, the following Windows Forms example contains an event handler that calls and awaits an `async` method, `ExampleMethodAsync`.

```
public partial class Form1 : Form
{
    public Form1()
    {
        InitializeComponent();
        button1.Click += button1_Click;
    }

    private async void button1_Click(object sender, EventArgs e)
    {
        await ExampleMethodAsync();
        textBox1.Text += "\r\nControl returned to Click event handler.\n";
    }

    private async Task ExampleMethodAsync()
    {
        // The following line simulates a task-returning asynchronous process.
        await Task.Delay(1000);
    }
}
```

You can add the same event handler by using an `async` lambda. To add this handler, add an `async` modifier before the lambda parameter list, as the following example shows:

```
public partial class Form1 : Form
{
    public Form1()
    {
        InitializeComponent();
        button1.Click += async (sender, e) =>
        {
            await ExampleMethodAsync();
            textBox1.Text += "\r\nControl returned to Click event handler.\n";
        };
    }

    private async Task ExampleMethodAsync()
    {
        // The following line simulates a task-returning asynchronous process.
        await Task.Delay(1000);
    }
}
```

For more information about how to create and use `async` methods, see [Asynchronous Programming with `async`](#)

and await.

Lambda expressions and tuples

Starting with C# 7.0, the C# language provides built-in support for [tuples](#). You can provide a tuple as an argument to a lambda expression, and your lambda expression can also return a tuple. In some cases, the C# compiler uses type inference to determine the types of tuple components.

You define a tuple by enclosing a comma-delimited list of its components in parentheses. The following example uses tuple with three components to pass a sequence of numbers to a lambda expression, which doubles each value and returns a tuple with three components that contains the result of the multiplications.

```
Func<(int, int, int), (int, int, int)> doubleThem = ns => (2 * ns.Item1, 2 * ns.Item2, 2 * ns.Item3);
var numbers = (2, 3, 4);
var doubledNumbers = doubleThem(numbers);
Console.WriteLine($"The set {numbers} doubled: {doubledNumbers}");
// Output:
// The set (2, 3, 4) doubled: (4, 6, 8)
```

Ordinarily, the fields of a tuple are named `Item1`, `Item2`, etc. You can, however, define a tuple with named components, as the following example does.

```
Func<(int n1, int n2, int n3), (int, int, int)> doubleThem = ns => (2 * ns.n1, 2 * ns.n2, 2 * ns.n3);
var numbers = (2, 3, 4);
var doubledNumbers = doubleThem(numbers);
Console.WriteLine($"The set {numbers} doubled: {doubledNumbers}");
```

For more information about C# tuples, see [C# tuple types](#).

Lambdas with the standard query operators

LINQ to Objects, among other implementations, have an input parameter whose type is one of the `Func<TResult>` family of generic delegates. These delegates use type parameters to define the number and type of input parameters, and the return type of the delegate. `Func` delegates are very useful for encapsulating user-defined expressions that are applied to each element in a set of source data. For example, consider the `Func<T,TResult>` delegate type:

```
public delegate TResult Func<in T, out TResult>(T arg)
```

The delegate can be instantiated as a `Func<int, bool>` instance where `int` is an input parameter and `bool` is the return value. The return value is always specified in the last type parameter. For example, `Func<int, string, bool>` defines a delegate with two input parameters, `int` and `string`, and a return type of `bool`. The following `Func` delegate, when it's invoked, returns Boolean value that indicates whether the input parameter is equal to five:

```
Func<int, bool> equalsFive = x => x == 5;
bool result = equalsFive(4);
Console.WriteLine(result); // False
```

You can also supply a lambda expression when the argument type is an `Expression<TDelegate>`, for example in the standard query operators that are defined in the `Queryable` type. When you specify an `Expression<TDelegate>` argument, the lambda is compiled to an expression tree.

The following example uses the `Count` standard query operator:

```
int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };
int oddNumbers = numbers.Count(n => n % 2 == 1);
Console.WriteLine($"There are {oddNumbers} odd numbers in {string.Join(" ", numbers)}");
```

The compiler can infer the type of the input parameter, or you can also specify it explicitly. This particular lambda expression counts those integers (`n`) which when divided by two have a remainder of 1.

The following example produces a sequence that contains all elements in the `numbers` array that precede the 9, because that's the first number in the sequence that doesn't meet the condition:

```
int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };
var firstNumbersLessThanSix = numbers.TakeWhile(n => n < 6);
Console.WriteLine(string.Join(" ", firstNumbersLessThanSix));
// Output:
// 5 4 1 3
```

The following example specifies multiple input parameters by enclosing them in parentheses. The method returns all the elements in the `numbers` array until it encounters a number whose value is less than its ordinal position in the array:

```
int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };
var firstSmallNumbers = numbers.TakeWhile((n, index) => n >= index);
Console.WriteLine(string.Join(" ", firstSmallNumbers));
// Output:
// 5 4
```

Type inference in lambda expressions

When writing lambdas, you often don't have to specify a type for the input parameters because the compiler can infer the type based on the lambda body, the parameter types, and other factors as described in the C# language specification. For most of the standard query operators, the first input is the type of the elements in the source sequence. If you are querying an `IEnumerable<Customer>`, then the input variable is inferred to be a `Customer` object, which means you have access to its methods and properties:

```
customers.Where(c => c.City == "London");
```

The general rules for type inference for lambdas are as follows:

- The lambda must contain the same number of parameters as the delegate type.
- Each input parameter in the lambda must be implicitly convertible to its corresponding delegate parameter.
- The return value of the lambda (if any) must be implicitly convertible to the delegate's return type.

Note that lambda expressions in themselves don't have a type because the common type system has no intrinsic concept of "lambda expression." However, it's sometimes convenient to speak informally of the "type" of a lambda expression. In these cases the type refers to the delegate type or `Expression` type to which the lambda expression is converted.

Variable scope in lambda expressions

Lambdas can refer to *outer variables* (see [Anonymous methods](#)) that are in scope in the method that defines the lambda expression, or in scope in the type that contains the lambda expression. Variables that are captured in this manner are stored for use in the lambda expression even if the variables would otherwise go out of scope and be

garbage collected. An outer variable must be definitely assigned before it can be consumed in a lambda expression. The following example demonstrates these rules:

```
public static class VariableScopeWithLambdas
{
    public class VariableCaptureGame
    {
        internal Action<int> updateCapturedLocalVariable;
        internal Func<int, bool> isEqualToCapturedLocalVariable;

        public void Run(int input)
        {
            int j = 0;

            updateCapturedLocalVariable = x =>
            {
                j = x;
                bool result = j > input;
                Console.WriteLine($"{j} is greater than {input}: {result}");
            };

            isEqualToCapturedLocalVariable = x => x == j;

            Console.WriteLine($"Local variable before lambda invocation: {j}");
            updateCapturedLocalVariable(10);
            Console.WriteLine($"Local variable after lambda invocation: {j}");
        }
    }

    public static void Main()
    {
        var game = new VariableCaptureGame();

        int gameInput = 5;
        game.Run(gameInput);

        int jTry = 10;
        bool result = game.isEqualToCapturedLocalVariable(jTry);
        Console.WriteLine($"Captured local variable is equal to {jTry}: {result}");

        int anotherJ = 3;
        game.updateCapturedLocalVariable(anotherJ);

        bool equalToAnother = game.isEqualToCapturedLocalVariable(anotherJ);
        Console.WriteLine($"Another lambda observes a new value of captured variable: {equalToAnother}");
    }
}

// Output:
// Local variable before lambda invocation: 0
// 10 is greater than 5: True
// Local variable after lambda invocation: 10
// Captured local variable is equal to 10: True
// 3 is greater than 5: False
// Another lambda observes a new value of captured variable: True
```

The following rules apply to variable scope in lambda expressions:

- A variable that is captured will not be garbage-collected until the delegate that references it becomes eligible for garbage collection.
- Variables introduced within a lambda expression are not visible in the enclosing method.
- A lambda expression cannot directly capture an `in`, `ref`, or `out` parameter from the enclosing method.
- A `return` statement in a lambda expression doesn't cause the enclosing method to return.

- A lambda expression cannot contain a [goto](#), [break](#), or [continue](#) statement if the target of that jump statement is outside the lambda expression block. It's also an error to have a jump statement outside the lambda expression block if the target is inside the block.

C# language specification

Properties

5/10/2018 • 9 minutes to read • [Edit Online](#)

Properties are first class citizens in C#. The language defines syntax that enables developers to write code that accurately expresses their design intent.

Properties behave like fields when they are accessed. However, unlike fields, properties are implemented with accessors that define the statements executed when a property is accessed or assigned.

Property syntax

The syntax for properties is a natural extension to fields. A field defines a storage location:

```
public class Person
{
    public string FirstName;
    // remaining implementation removed from listing
}
```

A property definition contains declarations for a `get` and `set` accessor that retrieves and assigns the value of that property:

```
public class Person
{
    public string FirstName { get; set; }

    // remaining implementation removed from listing
}
```

The syntax shown above is the *auto property* syntax. The compiler generates the storage location for the field that backs up the property. The compiler also implements the body of the `get` and `set` accessors.

Sometimes, you need to initialize a property to a value other than the default for its type. C# enables that by setting a value after the closing brace for the property. You may prefer the initial value for the `FirstName` property to be the empty string rather than `null`. You would specify that as shown below:

```
public class Person
{
    public string FirstName { get; set; } = string.Empty;

    // remaining implementation removed from listing
}
```

Specific initialization is most useful for read-only properties, as you'll see later in this article.

You can also define the storage yourself, as shown below:

```
public class Person
{
    public string FirstName
    {
        get { return firstName; }
        set { firstName = value; }
    }
    private string firstName;
    // remaining implementation removed from listing
}
```

When a property implementation is a single expression, you can use *expression-bodied members* for the getter or setter:

```
public class Person
{
    public string FirstName
    {
        get => firstName;
        set => firstName = value;
    }
    private string firstName;
    // remaining implementation removed from listing
}
```

This simplified syntax will be used where applicable throughout this article.

The property definition shown above is a read-write property. Notice the keyword `value` in the set accessor. The `set` accessor always has a single parameter named `value`. The `get` accessor must return a value that is convertible to the type of the property (`string` in this example).

That's the basics of the syntax. There are many different variations that support a variety of different design idioms. Let's explore, and learn the syntax options for each.

Scenarios

The examples above showed one of the simplest cases of property definition: a read-write property with no validation. By writing the code you want in the `get` and `set` accessors, you can create many different scenarios.

Validation

You can write code in the `set` accessor to ensure that the values represented by a property are always valid. For example, suppose one rule for the `Person` class is that the name cannot be blank or white space. You would write that as follows:

```

public class Person
{
    public string FirstName
    {
        get => firstName;
        set
        {
            if (string.IsNullOrWhiteSpace(value))
                throw new ArgumentException("First name must not be blank");
            firstName = value;
        }
    }
    private string firstName;
    // remaining implementation removed from listing
}

```

The preceding example can be simplified by using a `throw` expression as part of the property setter validation:

```

public class Person
{
    public string FirstName
    {
        get => firstName;
        set => firstName = (!string.IsNullOrWhiteSpace(value)) ? value : throw new ArgumentException("First
name must not be blank");
    }
    private string firstName;
    // remaining implementation removed from listing
}

```

The example above enforces the rule that the first name must not be blank or white space. If a developer writes

```
hero.FirstName = "";
```

That assignment throws an `ArgumentException`. Because a property set accessor must have a void return type, you report errors in the set accessor by throwing an exception.

You can extend this same syntax to anything needed in your scenario. You can check the relationships between different properties, or validate against any external conditions. Any valid C# statements are valid in a property accessor.

Read-only

Up to this point, all the property definitions you have seen are read/write properties with public accessors. That's not the only valid accessibility for properties. You can create read-only properties, or give different accessibility to the set and get accessors. Suppose that your `Person` class should only enable changing the value of the `FirstName` property from other methods in that class. You could give the set accessor `private` accessibility instead of `public`:

```

public class Person
{
    public string FirstName { get; private set; }

    // remaining implementation removed from listing
}

```

Now, the `FirstName` property can be accessed from any code, but it can only be assigned from other code in the `Person` class.

You can add any restrictive access modifier to either the set or get accessors. Any access modifier you place on the individual accessor must be more limited than the access modifier on the property definition. The above is legal because the `FirstName` property is `public`, but the set accessor is `private`. You could not declare a `private` property with a `public` accessor. Property declarations can also be declared `protected`, `internal`, `protected internal`, or, even `private`.

It is also legal to place the more restrictive modifier on the `get` accessor. For example, you could have a `public` property, but restrict the `get` accessor to `private`. That scenario is rarely done in practice.

You can also restrict modifications to a property so that it can only be set in a constructor or a property initializer. You can modify the `Person` class so as follows:

```
public class Person
{
    public Person(string firstName) => this.FirstName = firstName;

    public string FirstName { get; }

    // remaining implementation removed from listing
}
```

This feature is most commonly used for initializing collections that are exposed as read-only properties:

```
public class Measurements
{
    public ICollection<DataPoint> points { get; } = new List<DataPoint>();
```

Computed properties

A property does not need to simply return the value of a member field. You can create properties that return a computed value. Let's expand the `Person` object to return the full name, computed by concatenating the first and last names:

```
public class Person
{
    public string FirstName { get; set; }

    public string LastName { get; set; }

    public string FullName { get { return $"{FirstName} {LastName}"; } }
}
```

The example above uses the [string interpolation](#) feature to create the formatted string for the full name.

You can also use an *expression-bodied member*, which provides a more succinct way to create the computed `FullName` property:

```
public class Person
{
    public string FirstName { get; set; }

    public string LastName { get; set; }

    public string FullName => $"{FirstName} {LastName}";
}
```

Expression-bodied members use the [lambda expression](#) syntax to define methods that contain a single expression.

Here, that expression returns the full name for the person object.

Cached evaluated properties

You can mix the concept of a computed property with storage and create a *cached evaluated property*. For example, you could update the `FullName` property so that the string formatting only happened the first time it was accessed:

```
public class Person
{
    public string FirstName { get; set; }

    public string LastName { get; set; }

    private string fullName;
    public string FullName
    {
        get
        {
            if (fullName == null)
                fullName = $"{FirstName} {LastName}";
            return fullName;
        }
    }
}
```

The above code contains a bug though. If code updates the value of either the `FirstName` or `LastName` property, the previously evaluated `fullName` field is invalid. You modify the `set` accessors of the `FirstName` and `LastName` property so that the `fullName` field is calculated again:

```

public class Person
{
    private string firstName;
    public string FirstName
    {
        get => firstName;
        set
        {
            firstName = value;
            fullName = null;
        }
    }

    private string lastName;
    public string LastName
    {
        get => lastName;
        set
        {
            lastName = value;
            fullName = null;
        }
    }

    private string fullName;
    public string FullName
    {
        get
        {
            if (fullName == null)
                fullName = $"{FirstName} {LastName}";
            return fullName;
        }
    }
}

```

This final version evaluates the `FullName` property only when needed. If the previously calculated version is valid, it's used. If another state change invalidates the previously calculated version, it will be recalculated. Developers that use this class do not need to know the details of the implementation. None of these internal changes affect the use of the `Person` object. That's the key reason for using Properties to expose data members of an object.

Attaching attributes to auto-implemented properties

Beginning with C# 7.3, field attributes can be attached to the compiler generated backing field in auto-implemented properties. For example, consider a revision to the `Person` class that adds a unique integer `Id` property. You write the `Id` property using an auto-implemented property, but your design does not call for persisting the `Id` property. The `NonSerializedAttribute` can only be attached to fields, not properties. You can attach the `NonSerializedAttribute` to the backing field for the `Id` property by using the `field:` specifier on the attribute, as shown in the following example:

```

public class Person
{
    public string FirstName { get; set; }

    public string LastName { get; set; }

    [field:NonSerialized]
    public int Id { get; set; }

    public string FullName => $"{FirstName} {LastName}";
}

```

This technique works for any attribute you attach to the backing field on the auto-implemented property.

Implementing `INotifyPropertyChanged`

A final scenario where you need to write code in a property accessor is to support the `INotifyPropertyChanged` interface used to notify data binding clients that a value has changed. When the value of a property changes, the object raises the `INotifyPropertyChanged.PropertyChanged` event to indicate the change. The data binding libraries, in turn, update display elements based on that change. The code below shows how you would implement `INotifyPropertyChanged` for the `FirstName` property of this person class.

```
public class Person : INotifyPropertyChanged
{
    public string FirstName
    {
        get => firstName;
        set
        {
            if (string.IsNullOrWhiteSpace(value))
                throw new ArgumentException("First name must not be blank");
            if (value != firstName)
            {
                PropertyChanged?.Invoke(this,
                    new PropertyChangedEventArgs(nameof(FirstName)));
            }
            firstName = value;
        }
    }
    private string firstName;

    public event PropertyChangedEventHandler PropertyChanged;
    // remaining implementation removed from listing
}
```

The `?.` operator is called the *null conditional operator*. It checks for a null reference before evaluating the right side of the operator. The end result is that if there are no subscribers to the `PropertyChanged` event, the code to raise the event doesn't execute. It would throw a `NullReferenceException` without this check in that case. For more information, see [events](#). This example also uses the new `nameof` operator to convert from the property name symbol to its text representation. Using `nameof` can reduce errors where you have mistyped the name of the property.

Again, implementing `INotifyPropertyChanged` is an example of a case where you can write code in your accessors to support the scenarios you need.

Summing up

Properties are a form of smart fields in a class or object. From outside the object, they appear like fields in the object. However, properties can be implemented using the full palette of C# functionality. You can provide validation, different accessibility, lazy evaluation, or any requirements your scenarios need.

Indexers

10/16/2018 • 9 minutes to read • [Edit Online](#)

Indexers are similar to properties. In many ways indexers build on the same language features as [properties](#). Indexers enable *indexed* properties: properties referenced using one or more arguments. Those arguments provide an index into some collection of values.

Indexer Syntax

You access an indexer through a variable name and square brackets. You place the indexer arguments inside the brackets:

```
var item = someObject["key"];
someObject["AnotherKey"] = item;
```

You declare indexers using the `this` keyword as the property name, and declaring the arguments within square brackets. This declaration would match the usage shown in the previous paragraph:

```
public int this[string key]
{
    get { return storage.Find(key); }
    set { storage.SetAt(key, value); }
}
```

From this initial example, you can see the relationship between the syntax for properties and for indexers. This analogy carries through most of the syntax rules for indexers. Indexers can have any valid access modifiers (public, protected internal, protected, internal, private or private protected). They may be sealed, virtual, or abstract. As with properties, you can specify different access modifiers for the get and set accessors in an indexer. You may also specify read-only indexers (by omitting the set accessor), or write-only indexers (by omitting the get accessor).

You can apply almost everything you learn from working with properties to indexers. The only exception to that rule is *auto implemented properties*. The compiler cannot always generate the correct storage for an indexer.

The presence of arguments to reference an item in a set of items distinguishes indexers from properties. You may define multiple indexers on a type, as long as the argument lists for each indexer is unique. Let's explore different scenarios where you might use one or more indexers in a class definition.

Scenarios

You would define *indexers* in your type when its API models some collection where you define the arguments to that collection. Your indexers may or may not map directly to the collection types that are part of the .NET core framework. Your type may have other responsibilities in addition to modeling a collection. Indexers enable you to provide the API that matches your type's abstraction without exposing the inner details of how the values for that abstraction are stored or computed.

Let's walk through some of the common scenarios for using *indexers*. You can access the [sample folder for indexers](#). For download instructions, see [Samples and Tutorials](#).

Arrays and Vectors

One of the most common scenarios for creating indexers is when your type models an array, or a vector. You can create an indexer to model an ordered list of data.

The advantage of creating your own indexer is that you can define the storage for that collection to suit your needs. Imagine a scenario where your type models historical data that is too large to load into memory at once. You need to load and unload sections of the collection based on usage. The example following models this behavior. It reports on how many data points exist. It creates pages to hold sections of the data on demand. It removes pages from memory to make room for pages needed by more recent requests.

```
public class DataSamples
{
    private class Page
    {
        private readonly List<Measurements> pageData = new List<Measurements>();
        private readonly int startingIndex;
        private readonly int length;
        private bool dirty;
        private DateTime lastAccess;

        public Page(int startingIndex, int length)
        {
            this.startingIndex = startingIndex;
            this.length = length;
            lastAccess = DateTime.Now;

            // This stays as random stuff:
            var generator = new Random();
            for(int i=0; i < length; i++)
            {
                var m = new Measurements
                {
                    HiTemp = generator.Next(50, 95),
                    LoTemp = generator.Next(12, 49),
                    AirPressure = 28.0 + generator.NextDouble() * 4
                };
                pageData.Add(m);
            }
        }

        public bool HasItem(int index) =>
            ((index >= startingIndex) &&
            (index < startingIndex + length));

        public Measurements this[int index]
        {
            get
            {
                lastAccess = DateTime.Now;
                return pageData[index - startingIndex];
            }
            set
            {
                pageData[index - startingIndex] = value;
                dirty = true;
                lastAccess = DateTime.Now;
            }
        }

        public bool Dirty => dirty;
        public DateTime LastAccess => lastAccess;
    }

    private readonly int totalSize;
    private readonly List<Page> pagesInMemory = new List<Page>();

    public DataSamples(int totalSize)
    {
        this.totalSize = totalSize;
    }

    public Measurements this[int index]
```

```

public Measurements this[int index]
{
    get
    {
        if (index < 0)
            throw new IndexOutOfRangeException("Cannot index less than 0");
        if (index >= totalSize)
            throw new IndexOutOfRangeException("Cannot index past the end of storage");

        var page = updateCachedPagesForAccess(index);
        return page[index];
    }
    set
    {
        if (index < 0)
            throw new IndexOutOfRangeException("Cannot index less than 0");
        if (index >= totalSize)
            throw new IndexOutOfRangeException("Cannot index past the end of storage");
        var page = updateCachedPagesForAccess(index);

        page[index] = value;
    }
}

private Page updateCachedPagesForAccess(int index)
{
    foreach (var p in pagesInMemory)
    {
        if (p.HasItem(index))
        {
            return p;
        }
    }
    var startingIndex = (index / 1000) * 1000;
    var nextPage = new Page(startingIndex, 1000);
    addPageToCache(nextPage);
    return nextPage;
}

private void addPageToCache(Page p)
{
    if (pagesInMemory.Count > 4)
    {
        // remove oldest non-dirty page:
        var oldest = pagesInMemory
            .Where(page => !page.Dirty)
            .OrderBy(page => page.LastAccess)
            .FirstOrDefault();
        // Note that this may keep more than 5 pages in memory
        // if too much is dirty
        if (oldest != null)
            pagesInMemory.Remove(oldest);
    }
    pagesInMemory.Add(p);
}
}

```

You can follow this design idiom to model any sort of collection where there are good reasons not to load the entire set of data into an in- memory collection. Notice that the `Page` class is a private nested class that is not part of the public interface. Those details are hidden from any users of this class.

Dictionaries

Another common scenario is when you need to model a dictionary or a map. This scenario is when your type stores values based on key, typically text keys. This example creates a dictionary that maps command line arguments to [lambda expressions](#) that manage those options. The following example shows two classes: an `ArgsActions` class that maps a command line option to an `Action` delegate, and an `ArgsProcessor` that uses the

`ArgsActions` to execute each `Action` when it encounters that option.

```
public class ArgsProcessor
{
    private readonly ArgsActions actions;

    public ArgsProcessor(ArgsActions actions)
    {
        this.actions = actions;
    }

    public void Process(string[] args)
    {
        foreach(var arg in args)
        {
            actions[arg]?.Invoke();
        }
    }
}

public class ArgsActions
{
    readonly private Dictionary<string, Action> argsActions = new Dictionary<string, Action>();

    public Action this[string s]
    {
        get
        {
            Action action;
            Action defaultAction = () => {} ;
            return argsActions.TryGetValue(s, out action) ? action : defaultAction;
        }
    }

    public void SetOption(string s, Action a)
    {
        argsActions[s] = a;
    }
}
```

In this example, the `ArgsAction` collection maps closely to the underlying collection. The `get` determines if a given option has been configured. If so, it returns the `Action` associated with that option. If not, it returns an `Action` that does nothing. The public accessor does not include a `set` accessor. Rather, the design using a public method for setting options.

Multi-Dimensional Maps

You can create indexers that use multiple arguments. In addition, those arguments are not constrained to be the same type. Let's look at two examples.

The first example shows a class that generates values for a Mandelbrot set. For more information on the mathematics behind the set, read [this article](#). The indexer uses two doubles to define a point in the X, Y plane. The `get` accessor computes the number of iterations until a point is determined to be not in the set. If the maximum iterations is reached, the point is in the set, and the class's `maxIterations` value is returned. (The computer generated images popularized for the Mandelbrot set define colors for the number of iterations necessary to determine that a point is outside the set.

```

public class Mandelbrot
{
    readonly private int maxIterations;

    public Mandelbrot(int maxIterations)
    {
        this.maxIterations = maxIterations;
    }

    public int this [double x, double y]
    {
        get
        {
            var iterations = 0;
            var x0 = x;
            var y0 = y;

            while ((x*x + y * y < 4) &&
                   (iterations < maxIterations))
            {
                var newX = x * x - y * y + x0;
                y = 2 * x * y + y0;
                x = newX;
                iterations++;
            }
            return iterations;
        }
    }
}

```

The Mandelbrot Set defines values at every (x,y) coordinate for real number values. That defines a dictionary that could contain an infinite number of values. Therefore, there is no storage behind the set. Instead, this class computes the value for each point when code calls the `get` accessor. There's no underlying storage used.

Let's examine one last use of indexers, where the indexer takes multiple arguments of different types. Consider a program that manages historical temperature data. This indexer uses a city and a date to set or get the high and low temperatures for that location:

```

using DateMeasurements =
    System.Collections.Generic.Dictionary<System.DateTime, IndexersSamples.Common.Measurements>;
using CityDataMeasurements =
    System.Collections.Generic.Dictionary<string, System.Collections.Generic.Dictionary<System.DateTime,
IndexersSamples.Common.Measurements>>;

public class HistoricalWeatherData
{
    readonly CityDataMeasurements storage = new CityDataMeasurements();

    public Measurements this[string city, DateTime date]
    {
        get
        {
            var cityData = default(DateMeasurements);

            if (!storage.TryGetValue(city, out cityData))
                throw new ArgumentOutOfRangeException(nameof(city), "City not found");

            // Strip out any time portion:
            var index = date.Date;
            var measure = default(Measurements);
            if (cityData.TryGetValue(index, out measure))
                return measure;
            throw new ArgumentOutOfRangeException(nameof(date), "Date not found");
        }
        set
        {
            var cityData = default(DateMeasurements);

            if (!storage.TryGetValue(city, out cityData))
            {
                cityData = new DateMeasurements();
                storage.Add(city, cityData);
            }

            // Strip out any time portion:
            var index = date.Date;
            cityData[index] = value;
        }
    }
}

```

This example creates an indexer that maps weather data on two different arguments: a city (represented by a `string`) and a date (represented by a `DateTime`). The internal storage uses two `Dictionary` classes to represent the two-dimensional dictionary. The public API no longer represents the underlying storage. Rather, the language features of indexers enables you to create a public interface that represents your abstraction, even though the underlying storage must use different core collection types.

There are two parts of this code that may be unfamiliar to some developers. These two `using` statements:

```

using DateMeasurements = System.Collections.Generic.Dictionary<System.DateTime,
IndexersSamples.Common.Measurements>;
using CityDataMeasurements = System.Collections.Generic.Dictionary<string,
System.Collections.Generic.Dictionary<System.DateTime, IndexersSamples.Common.Measurements>>;

```

create an *alias* for a constructed generic type. Those statements enable the code later to use the more descriptive `DateMeasurements` and `CityDataMeasurements` names instead of the generic construction of `Dictionary<DateTime, Measurements>` and `Dictionary<string, Dictionary<DateTime, Measurements>>`. This construct does require using the fully qualified type names on the right side of the `=` sign.

The second technique is to strip off the time portions of any `DateTime` object used to index into the collections. The

.NET framework does not include a Date only type. Developers use the `DateTime` type, but use the `Date` property to ensure that any `DateTime` object from that day are equal.

Summing Up

You should create indexers anytime you have a property-like element in your class where that property represents not a single value, but rather a collection of values where each individual item is identified by a set of arguments. Those arguments can uniquely identify which item in the collection should be referenced. Indexers extend the concept of [properties](#), where a member is treated like a data item from outside the class, but like a method on the side. Indexers allow arguments to find a single item in a property that represents a set of items.

Discards - C# Guide

10/16/2018 • 7 minutes to read • [Edit Online](#)

Starting with C# 7.0, C# supports discards, which are temporary, dummy variables that are intentionally unused in application code. Discards are equivalent to unassigned variables; they do not have a value. Because there is only a single discard variable, and that variable may not even be allocated storage, discards can reduce memory allocations. Because they make the intent of your code clear, they enhance its readability and maintainability.

You indicate that a variable is a discard by assigning it the underscore (`_`) as its name. For example, the following method call returns a 3-tuple in which the first and second values are discards and `area` is a previously declared variable to be set to the corresponding third component returned by `GetCityInformation`:

```
(_, _, area) = city.GetCityInformation(cityName);
```

In C# 7.0, discards are supported in assignments in the following contexts:

- Tuple and object [deconstruction](#).
- Pattern matching with `is` and `switch`.
- Calls to methods with `out` parameters.
- A standalone `_` when no `_` is in scope.

When `_` is a valid discard, attempting to retrieve its value or use it in an assignment operation generates compiler error CS0301, "The name '_' does not exist in the current context". This is because `_` is not assigned a value, and may not even be assigned a storage location. If it were an actual variable, you could not discard more than one value, as the previous example did.

Tuple and object deconstruction

Discards are particularly useful in working with tuples when your application code uses some tuple elements but ignores others. For example, the following `QueryCityDataForYears` method returns a 6-tuple with the name of a city, its area, a year, the city's population for that year, a second year, and the city's population for that second year. The example shows the change in population between those two years. Of the data available from the tuple, we're unconcerned with the city area, and we know the city name and the two dates at design-time. As a result, we're only interested in the two population values stored in the tuple, and can handle its remaining values as discards.

```
using System;
using System.Collections.Generic;

public class Example
{
    public static void Main()
    {
        var (_, _, _, pop1, _, pop2) = QueryCityDataForYears("New York City", 1960, 2010);

        Console.WriteLine($"Population change, 1960 to 2010: {pop2 - pop1:N0}");
    }

    private static (string, double, int, int, int, int) QueryCityDataForYears(string name, int year1, int
year2)
    {
        int population1 = 0, population2 = 0;
        double area = 0;

        if (name == "New York City") {
            area = 468.48;
            if (year1 == 1960) {
                population1 = 7781984;
            }
            if (year2 == 2010) {
                population2 = 8175133;
            }
        }
        return (name, area, year1, population1, year2, population2);
    }

    return ("", 0, 0, 0, 0, 0);
}
}

// The example displays the following output:
//      Population change, 1960 to 2010: 393,149
```

For more information on deconstructing tuples with discards, see [Deconstructing tuples and other types](#).

The `Deconstruct` method of a class, structure, or interface also allows you to retrieve and deconstruct a specific set of data from an object. You can use discards when you are interested in working with only a subset of the deconstructed values. The following example deconstructs a `Person` object into four strings (the first and last names, the city, and the state), but discards the last name and the state.

```

using System;

public class Person
{
    public string FirstName { get; set; }
    public string MiddleName { get; set; }
    public string LastName { get; set; }
    public string City { get; set; }
    public string State { get; set; }

    public Person(string fname, string mname, string lname,
                  string cityName, string stateName)
    {
        FirstName = fname;
        MiddleName = mname;
        LastName = lname;
        City = cityName;
        State = stateName;
    }

    // Return the first and last name.
    public void Deconstruct(out string fname, out string lname)
    {
        fname = FirstName;
        lname = LastName;
    }

    public void Deconstruct(out string fname, out string mname, out string lname)
    {
        fname = FirstName;
        mname = MiddleName;
        lname = LastName;
    }

    public void Deconstruct(out string fname, out string lname,
                           out string city, out string state)
    {
        fname = FirstName;
        lname = LastName;
        city = City;
        state = State;
    }
}

public class Example
{
    public static void Main()
    {
        Person p = new Person("John", "Quincy", "Adams", "Boston", "MA");

        // <Snippet1>
        // Deconstruct the person object.
        var (fName, _, city, _) = p;
        Console.WriteLine($"Hello {fName} of {city}!");
        // The example displays the following output:
        //      Hello John of Boston!
        // </Snippet1>
    }
}

// The example displays the following output:
//      Hello John Adams of Boston, MA!

```

For more information on deconstructing user-defined types with discards, see [Deconstructing tuples and other types](#).

Pattern matching with `switch` and `is`

The *discard pattern* can be used in pattern matching with the `is` and `switch` keywords. Every expression always matches the discard pattern.

The following example defines a `ProvidesFormatInfo` method that uses `is` statements to determine whether an object provides an `IFormatProvider` implementation and tests whether the object is `null`. It also uses the discard pattern to handle non-null objects of any other type.

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        object[] objects = { CultureInfo.CurrentCulture,
                            CultureInfo.CurrentCulture.DateTimeFormat,
                            CultureInfo.CurrentCulture.NumberFormat,
                            new ArgumentException(), null };

        foreach (var obj in objects)
            ProvidesFormatInfo(obj);
    }

    private static void ProvidesFormatInfo(object obj)
    {
        if (obj is IFormatProvider fmt)
            Console.WriteLine($"{fmt} object");
        else if (obj is null)
            Console.Write("A null object reference: ");
            Console.WriteLine("Its use could result in a NullReferenceException");
        }
        else
            Console.WriteLine($"Some object type without format information");
    }
}
// The example displays the following output:
//   en-US object
//   System.Globalization.DateTimeFormatInfo object
//   System.Globalization.NumberFormatInfo object
//   Some object type without format information
//   A null object reference: Its use could result in a NullReferenceException
```

Calls to methods with `out` parameters

When calling the `Deconstruct` method to deconstruct a user-defined type (an instance of a class, structure, or interface), you can discard the values of individual `out` arguments. But you can also discard the value of `out` arguments when calling any method with an `out` parameter.

The following example calls the `DateTime.TryParse(String, out DateTime)` method to determine whether the string representation of a date is valid in the current culture. Because the example is concerned only with validating the date string and not with parsing it to extract the date, the `out` argument to the method is a discard.

```

using System;

public class Example
{
    public static void Main()
    {
        string[] dateStrings = {"05/01/2018 14:57:32.8", "2018-05-01 14:57:32.8",
                               "2018-05-01T14:57:32.8375298-04:00", "5/01/2018",
                               "5/01/2018 14:57:32.80 -07:00",
                               "1 May 2018 2:57:32.8 PM", "16-05-2018 1:00:32 PM",
                               "Fri, 15 May 2018 20:10:57 GMT" };

        foreach (string dateString in dateStrings)
        {
            if (DateTime.TryParse(dateString, out _))
                Console.WriteLine($"'{dateString}': valid");
            else
                Console.WriteLine($"'{dateString}': invalid");
        }
    }
}

// The example displays output like the following:
//      '05/01/2018 14:57:32.8': valid
//      '2018-05-01 14:57:32.8': valid
//      '2018-05-01T14:57:32.8375298-04:00': valid
//      '5/01/2018': valid
//      '5/01/2018 14:57:32.80 -07:00': valid
//      '1 May 2018 2:57:32.8 PM': valid
//      '16-05-2018 1:00:32 PM': invalid
//      'Fri, 15 May 2018 20:10:57 GMT': invalid

```

A standalone discard

You can use a standalone discard to indicate any variable that you choose to ignore. The following example uses a standalone discard to ignore the [Task](#) object returned by an asynchronous operation. This has the effect of suppressing the exception that the operation throws as it is about to complete.

```

using System;
using System.Threading.Tasks;

public class Example
{
    public static void Main()
    {
        ExecuteAsyncMethods().Wait();
    }

    private static async Task ExecuteAsyncMethods()
    {
        Console.WriteLine("About to launch a task...");
        _ = Task.Run(() => { var iterations = 0;
            for (int ctr = 0; ctr < int.MaxValue; ctr++)
                iterations++;
            Console.WriteLine("Completed looping operation...");
            throw new InvalidOperationException();
        });
        await Task.Delay(5000);
        Console.WriteLine("Exiting after 5 second delay");
    }
}

// The example displays output like the following:
//      About to launch a task...
//      Completed looping operation...
//      Exiting after 5 second delay

```

Note that `_` is also a valid identifier. When used outside of a supported context, `_` is treated not as a discard but as a valid variable. If an identifier named `_` is already in scope, the use of `_` as a standalone discard can result in:

- Accidental modification of the value of the in-scope `_` variable by assigning it the value of the intended discard. For example:

```

private static void ShowValue(int _)
{
    byte[] arr = { 0, 0, 1, 2 };
    _ = BitConverter.ToInt32(arr, 0);
    Console.WriteLine(_);
}

```

`// The example displays the following output:
// 33619968`

- A compiler error for violating type safety. For example:

```

private static bool RoundTrips(int _)
{
    string value = _.ToString();
    int newValue = 0;
    _ = Int32.TryParse(value, out newValue);
    return _ == newValue;
}

```

`// The example displays the following compiler error:
// error CS0029: Cannot implicitly convert type 'bool' to 'int'`

- Compiler error CS0136, "A local or parameter named '`_`' cannot be declared in this scope because that name is used in an enclosing local scope to define a local or parameter." For example:

```
public void DoSomething(int _)
{
    var _ = GetValue(); // Error: cannot declare local _ when one is already in scope
}
// The example displays the following compiler error:
// error CS0136:
//     A local or parameter named '_' cannot be declared in this scope
//     because that name is used in an enclosing local scope
//     to define a local or parameter
```

Generics (C# Programming Guide)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Generics were added to version 2.0 of the C# language and the common language runtime (CLR). Generics introduce to the .NET Framework the concept of type parameters, which make it possible to design classes and methods that defer the specification of one or more types until the class or method is declared and instantiated by client code. For example, by using a generic type parameter T you can write a single class that other client code can use without incurring the cost or risk of runtime casts or boxing operations, as shown here:

```
// Declare the generic class.
public class GenericList<T>
{
    public void Add(T input) { }

}
class TestGenericList
{
    private class ExampleClass { }

    static void Main()
    {
        // Declare a list of type int.
        GenericList<int> list1 = new GenericList<int>();
        list1.Add(1);

        // Declare a list of type string.
        GenericList<string> list2 = new GenericList<string>();
        list2.Add("");

        // Declare a list of type ExampleClass.
        GenericList<ExampleClass> list3 = new GenericList<ExampleClass>();
        list3.Add(new ExampleClass());
    }
}
```

Generics Overview

- Use generic types to maximize code reuse, type safety, and performance.
- The most common use of generics is to create collection classes.
- The .NET Framework class library contains several new generic collection classes in the [System.Collections.Generic](#) namespace. These should be used whenever possible instead of classes such as [ArrayList](#) in the [System.Collections](#) namespace.
- You can create your own generic interfaces, classes, methods, events and delegates.
- Generic classes may be constrained to enable access to methods on particular data types.
- Information on the types that are used in a generic data type may be obtained at run-time by using reflection.

Iterators

3/16/2019 • 5 minutes to read • [Edit Online](#)

Almost every program you write will have some need to iterate over a collection. You'll write code that examines every item in a collection.

You'll also create iterator methods which are methods that produce an iterator for the elements of that class.

These can be used for:

- Performing an action on each item in a collection.
- Enumerating a custom collection.
- Extending [LINQ](#) or other libraries.
- Creating a data pipeline where data flows efficiently through iterator methods.

The C# language provides features for both these scenarios. This article provides an overview of those features.

This tutorial has multiple steps. After each step, you can run the application and see the progress. You can also [view or download the completed sample](#) for this topic. For download instructions, see [Samples and Tutorials](#).

Iterating with foreach

Enumerating a collection is simple: The `foreach` keyword enumerates a collection, executing the embedded statement once for each element in the collection:

```
foreach (var item in collection)
{
    Console.WriteLine(item.ToString());
}
```

That's all there is to it. To iterate over all the contents of a collection, the `foreach` statement is all you need. The `foreach` statement isn't magic, though. It relies on two generic interfaces defined in the .NET core library in order to generate the code necessary to iterate a collection: `IEnumerable<T>` and `IEnumerator<T>`. This mechanism is explained in more detail below.

Both of these interfaces also have non-generic counterparts: `IEnumerable` and `IEnumerator`. The [generic](#) versions are preferred for modern code.

Enumeration sources with iterator methods

Another great feature of the C# language enables you to build methods that create a source for an enumeration. These are referred to as *iterator methods*. An iterator method defines how to generate the objects in a sequence when requested. You use the `yield return` contextual keywords to define an iterator method.

You could write this method to produce the sequence of integers from 0 through 9:

```

public IEnumerable<int> GetSingleDigitNumbers()
{
    yield return 0;
    yield return 1;
    yield return 2;
    yield return 3;
    yield return 4;
    yield return 5;
    yield return 6;
    yield return 7;
    yield return 8;
    yield return 9;
}

```

The code above shows distinct `yield return` statements to highlight the fact that you can use multiple discrete `yield return` statements in an iterator method. You can (and often do) use other language constructs to simplify the code of an iterator method. The method definition below produces the exact same sequence of numbers:

```

public IEnumerable<int> GetSingleDigitNumbers()
{
    int index = 0;
    while (index++ < 10)
        yield return index;
}

```

You don't have to decide one or the other. You can have as many `yield return` statements as necessary to meet the needs of your method:

```

public IEnumerable<int> GetSingleDigitNumbers()
{
    int index = 0;
    while (index++ < 10)
        yield return index;

    yield return 50;

    index = 100;
    while (index++ < 110)
        yield return index;
}

```

That's the basic syntax. Let's consider a real world example where you would write an iterator method. Imagine you're on an IoT project and the device sensors generate a very large stream of data. To get a feel for the data, you might write a method that samples every Nth data element. This small iterator method does the trick:

```

public static IEnumerable<T> Sample(this IEnumerable<T> sourceSequence, int interval)
{
    int index = 0;
    foreach (T item in sourceSequence)
    {
        if (index++ % interval == 0)
            yield return item;
    }
}

```

There is one important restriction on iterator methods: you can't have both a `return` statement and a `yield return` statement in the same method. The following will not compile:

```

public IEnumerable<int> GetSingleDigitNumbers()
{
    int index = 0;
    while (index++ < 10)
        yield return index;

    yield return 50;

    // generates a compile time error:
    var items = new int[] {100, 101, 102, 103, 104, 105, 106, 107, 108, 109 };
    return items;
}

```

This restriction normally isn't a problem. You have a choice of either using `yield return` throughout the method, or separating the original method into multiple methods, some using `return`, and some using `yield return`.

You can modify the last method slightly to use `yield return` everywhere:

```

public IEnumerable<int> GetSingleDigitNumbers()
{
    int index = 0;
    while (index++ < 10)
        yield return index;

    yield return 50;

    var items = new int[] {100, 101, 102, 103, 104, 105, 106, 107, 108, 109 };
    foreach (var item in items)
        yield return item;
}

```

Sometimes, the right answer is to split an iterator method into two different methods. One that uses `return`, and a second that uses `yield return`. Consider a situation where you might want to return an empty collection, or the first 5 odd numbers, based on a boolean argument. You could write that as these two methods:

```

public IEnumerable<int> GetSingleDigitOddNumbers(bool getCollection)
{
    if (getCollection == false)
        return new int[0];
    else
        return IteratorMethod();
}

private IEnumerable<int> IteratorMethod()
{
    int index = 0;
    while (index++ < 10)
        if (index % 2 == 1)
            yield return index;
}

```

Look at the methods above. The first uses the standard `return` statement to return either an empty collection, or the iterator created by the second method. The second method uses the `yield return` statement to create the requested sequence.

Deeper Dive into `foreach`

The `foreach` statement expands into a standard idiom that uses the `IEnumerable<T>` and `IEnumerator<T>` interfaces to iterate across all elements of a collection. It also minimizes errors developers make by not properly

managing resources.

The compiler translates the `foreach` loop shown in the first example into something similar to this construct:

```
IEnumerator<int> enumerator = collection.GetEnumerator();
while (enumerator.MoveNext())
{
    var item = enumerator.Current;
    Console.WriteLine(item.ToString());
}
```

The construct above represents the code generated by the C# compiler as of version 5 and above. Prior to version 5, the `item` variable had a different scope:

```
// C# versions 1 through 4:
IEnumerator<int> enumerator = collection.GetEnumerator();
int item = default(int);
while (enumerator.MoveNext())
{
    item = enumerator.Current;
    Console.WriteLine(item.ToString());
}
```

This was changed because the earlier behavior could lead to subtle and hard to diagnose bugs involving lambda expressions. For more information about lambda expressions, see [Lambda expressions](#).

The exact code generated by the compiler is somewhat more complicated, and handles situations where the object returned by `GetEnumerator()` implements the `IDisposable` interface. The full expansion generates code more like this:

```
{
    var enumerator = collection.GetEnumerator();
    try
    {
        while (enumerator.MoveNext())
        {
            var item = enumerator.Current;
            Console.WriteLine(item.ToString());
        }
    } finally
    {
        // dispose of enumerator.
    }
}
```

The manner in which the enumerator is disposed of depends on the characteristics of the type of `enumerator`. In the general case, the `finally` clause expands to:

```
finally
{
    (enumerator as IDisposable)?.Dispose();
}
```

However, if the type of `enumerator` is a sealed type and there is no implicit conversion from the type of `enumerator` to `IDisposable`, the `finally` clause expands to an empty block:

```
finally
{
}
```

If there is an implicit conversion from the type of `enumerator` to `IDisposable`, and `enumerator` is a non-nullable value type, the `finally` clause expands to:

```
finally
{
    ((IDisposable)enumerator).Dispose();
}
```

Thankfully, you don't need to remember all these details. The `foreach` statement handles all those nuances for you. The compiler will generate the correct code for any of these constructs.

Delegates & events

6/7/2018 • 2 minutes to read • [Edit Online](#)

This topic will be covered under the following articles:

1. [Overview of Delegates](#)

This article covers an overview of delegates.

8. [Distinguishing Delegates from Events](#)

This article discusses how you should distinguish between using events and delegates in your designs.

You can download the [delegates sample](#) and the [events sample](#) from our GitHub samples repository.

Introduction to Delegates

5/4/2018 • 2 minutes to read • [Edit Online](#)

[Previous](#)

Delegates provide a *late binding* mechanism in .NET. Late Binding means that you create an algorithm where the caller also supplies at least one method that implements part of the algorithm.

For example, consider sorting a list of stars in an astronomy application. You may choose to sort those stars by their distance from the earth, or the magnitude of the star, or their perceived brightness.

In all those cases, the Sort() method does essentially the same thing: arranges the items in the list based on some comparison. The code that compares two stars is different for each of the sort orderings.

These kinds of solutions have been used in software for half a century. The C# language delegate concept provides first class language support, and type safety around the concept.

As you'll see later in this series, the C# code you write for algorithms like this is type safe, and leverages the language and the compiler to ensure that the types match for arguments and return types.

Language Design Goals for Delegates

The language designers enumerated several goals for the feature that eventually became delegates.

The team wanted a common language construct that could be used for any late binding algorithms. That enables developers to learn one concept, and use that same concept across many different software problems.

Second, the team wanted to support both single and multi-cast method calls. (Multicast delegates are delegates where multiple methods have been chained together. You'll see examples [later in this series](#).

The team wanted delegates to support the same type safety that developers expect from all C# constructs.

Finally, the team recognized that an event pattern is one specific pattern where delegates, or any late binding algorithm) is very useful. The team wanted to ensure that the code for delegates could provide the basis for the .NET event pattern.

The result of all that work was the delegate and event support in C# and .NET. The remaining articles in this section will cover the language features, the library support, and the common idioms that are used when you work with delegates.

You'll learn about the `delegate` keyword and what code it generates. You'll learn about the features in the `System.Delegate` class, and how those features are used. You'll learn how to create type safe delegates, and how to create methods that can be invoked through delegates. You'll also learn how to work with delegates and events by using Lambda expressions. You'll see where delegates become one of the building blocks for LINQ. You'll learn how delegates are the basis for the .NET event pattern, and how they are different.

Overall, you'll see how delegates are an integral part of programming in .NET and working with the framework APIs.

Let's get started.

System.Delegate and the `delegate` keyword

3/26/2019 • 6 minutes to read • [Edit Online](#)

[Previous](#)

This article will cover the classes in the .NET framework that support delegates, and how those map to the `delegate` keyword.

Defining Delegate Types

Let's start with the 'delegate' keyword, because that's primarily what you will use as you work with delegates. The code that the compiler generates when you use the `delegate` keyword will map to method calls that invoke members of the [Delegate](#) and [MulticastDelegate](#) classes.

You define a delegate type using syntax that is similar to defining a method signature. You just add the `delegate` keyword to the definition.

Let's continue to use the `List.Sort()` method as our example. The first step is to create a type for the comparison delegate:

```
// From the .NET Core library

// Define the delegate type:
public delegate int Comparison<in T>(T left, T right);
```

The compiler generates a class, derived from `System.Delegate` that matches the signature used (in this case, a method that returns an integer, and has two arguments). The type of that delegate is `Comparison`. The `Comparison` delegate type is a generic type. For details on generics see [here](#).

Notice that the syntax may appear as though it is declaring a variable, but it is actually declaring a *type*. You can define delegate types inside classes, directly inside namespaces, or even in the global namespace.

NOTE

Declaring delegate types (or other types) directly in the global namespace is not recommended.

The compiler also generates add and remove handlers for this new type so that clients of this class can add and remove methods from an instance's invocation list. The compiler will enforce that the signature of the method being added or removed matches the signature used when declaring the method.

Declaring instances of delegates

After defining the delegate, you can create an instance of that type. Like all variables in C#, you cannot declare delegate instances directly in a namespace, or in the global namespace.

```
// inside a class definition:

// Declare an instance of that type:
public Comparison<T> comparator;
```

The type of the variable is `Comparison<T>`, the delegate type defined earlier. The name of the variable is

```
comparator .
```

That code snippet above declared a member variable inside a class. You can also declare delegate variables that are local variables, or arguments to methods.

Invoking Delegates

You invoke the methods that are in the invocation list of a delegate by calling that delegate. Inside the `Sort()` method, the code will call the comparison method to determine which order to place objects:

```
int result = comparator(left, right);
```

In the line above, the code *invokes* the method attached to the delegate. You treat the variable as a method name, and invoke it using normal method call syntax.

That line of code makes an unsafe assumption: There's no guarantee that a target has been added to the delegate. If no targets have been attached, the line above would cause a `NullReferenceException` to be thrown. The idioms used to address this problem are more complicated than a simple null-check, and are covered later in this [series](#).

Assigning, Adding and removing Invocation Targets

That's how a delegate type is defined, and how delegate instances are declared and invoked.

Developers that want to use the `List.Sort()` method need to define a method whose signature matches the delegate type definition, and assign it to the delegate used by the sort method. This assignment adds the method to the invocation list of that delegate object.

Suppose you wanted to sort a list of strings by their length. Your comparison function might be the following:

```
private static int CompareLength(string left, string right) =>
    left.Length.CompareTo(right.Length);
```

The method is declared as a private method. That's fine. You may not want this method to be part of your public interface. It can still be used as the comparison method when attached to a delegate. The calling code will have this method attached to the target list of the delegate object, and can access it through that delegate.

You create that relationship by passing that method to the `List.Sort()` method:

```
phrases.Sort(CompareLength);
```

Notice that the method name is used, without parentheses. Using the method as an argument tells the compiler to convert the method reference into a reference that can be used as a delegate invocation target, and attach that method as an invocation target.

You could also have been explicit by declaring a variable of type `Comparison<string>` and doing an assignment:

```
Comparison<string> comparer = CompareLength;
phrases.Sort(comparer);
```

In uses where the method being used as a delegate target is a small method, it's common to use [lambda expression](#) syntax to perform the assignment:

```
Comparison<string> comparer = (left, right) => left.Length.CompareTo(right.Length);
phrases.Sort(comparer);
```

Using lambda expressions for delegate targets is covered more in a [later section](#).

The Sort() example typically attaches a single target method to the delegate. However, delegate objects do support invocation lists that have multiple target methods attached to a delegate object.

Delegate and MulticastDelegate classes

The language support described above provides the features and support you'll typically need to work with delegates. These features are built on two classes in the .NET Core framework: [Delegate](#) and [MulticastDelegate](#).

The [System.Delegate](#) class, and its single direct sub-class, [System.MulticastDelegate](#), provide the framework support for creating delegates, registering methods as delegate targets, and invoking all methods that are registered as a delegate target.

Interestingly, the [System.Delegate](#) and [System.MulticastDelegate](#) classes are not themselves delegate types. They do provide the basis for all specific delegate types. That same language design process mandated that you cannot declare a class that derives from [Delegate](#) or [MulticastDelegate](#). The C# language rules prohibit it.

Instead, the C# compiler creates instances of a class derived from [MulticastDelegate](#) when you use the C# language keyword to declare delegate types.

This design has its roots in the first release of C# and .NET. One goal for the design team was to ensure that the language enforced type safety when using delegates. That meant ensuring that delegates were invoked with the right type and number of arguments. And, that any return type was correctly indicated at compile time. Delegates were part of the 1.0 .NET release, which was before generics.

The best way to enforce this type safety was for the compiler to create the concrete delegate classes that represented the method signature being used.

Even though you cannot create derived classes directly, you will use the methods defined on these classes. Let's go through the most common methods that you will use when you work with delegates.

The first, most important fact to remember is that every delegate you work with is derived from [MulticastDelegate](#). A multicast delegate means that more than one method target can be invoked when invoking through a delegate. The original design considered making a distinction between delegates where only one target method could be attached and invoked, and delegates where multiple target methods could be attached and invoked. That distinction proved to be less useful in practice than originally thought. The two different classes were already created, and have been in the framework since its initial public release.

The methods that you will use the most with delegates are [Invoke\(\)](#) and [BeginInvoke\(\)](#) / [EndInvoke\(\)](#). [Invoke\(\)](#) will invoke all the methods that have been attached to a particular delegate instance. As you saw above, you typically invoke delegates using the method call syntax on the delegate variable. As you'll see [later in this series](#), there are patterns that work directly with these methods.

Now that you've seen the language syntax and the classes that support delegates, let's examine how strongly typed delegates are used, created and invoked.

[Next](#)

Strongly Typed Delegates

5/4/2018 • 2 minutes to read • [Edit Online](#)

[Previous](#)

In the previous article, you saw that you create specific delegate types using the `delegate` keyword.

The abstract Delegate class provide the infrastructure for loose coupling and invocation. Concrete Delegate types become much more useful by embracing and enforcing type safety for the methods that are added to the invocation list for a delegate object. When you use the `delegate` keyword and define a concrete delegate type, the compiler generates those methods.

In practice, this would lead to creating new delegate types whenever you need a different method signature. This work could get tedious after a time. Every new feature requires new delegate types.

Thankfully, this isn't necessary. The .NET Core framework contains several types that you can reuse whenever you need delegate types. These are `generic` definitions so you can declare customizations when you need new method declarations.

The first of these types is the `Action` type, and several variations:

```
public delegate void Action();
public delegate void Action<in T>(T arg);
public delegate void Action<in T1, in T2>(T1 arg1, T2 arg2);
// Other variations removed for brevity.
```

The `in` modifier on the generic type argument is covered in the article on covariance.

There are variations of the `Action` delegate that contain up to 16 arguments such as `Action<T1,T2,T3,T4,T5,T6,T7,T8,T9,T10,T11,T12,T13,T14,T15,T16>`. It's important that these definitions use different generic arguments for each of the delegate arguments: That gives you maximum flexibility. The method arguments need not be, but may be, the same type.

Use one of the `Action` types for any delegate type that has a void return type.

The framework also includes several generic delegate types that you can use for delegate types that return values:

```
public delegate TResult Func<out TResult>();
public delegate TResult Func<in T1, out TResult>(T1 arg);
public delegate TResult Func<in T1, in T2, out TResult>(T1 arg1, T2 arg2);
// Other variations removed for brevity
```

The `out` modifier on the result generic type argument is covered in the article on covariance.

There are variations of the `Func` delegate with up to 16 input arguments such as `Func<T1,T2,T3,T4,T5,T6,T7,T8,T9,T10,T11,T12,T13,T14,T15,T16,TResult>`. The type of the result is always the last type parameter in all the `Func` declarations, by convention.

Use one of the `Func` types for any delegate type that returns a value.

There's also a specialized `Predicate<T>` type for a delegate that returns a test on a single value:

```
public delegate bool Predicate<in T>(T obj);
```

You may notice that for any `Predicate` type, a structurally equivalent `Func` type exists. For example:

```
Func<string, bool> TestForString;
Predicate<string> AnotherTestForString;
```

You might think these two types are equivalent. They are not. These two variables cannot be used interchangeably. A variable of one type cannot be assigned the other type. The C# type system uses the names of the defined types, not the structure.

All these delegate type definitions in the .NET Core Library should mean that you do not need to define a new delegate type for any new feature you create that requires delegates. These generic definitions should provide all the delegate types you need under most situations. You can simply instantiate one of these types with the required type parameters. In the case of algorithms that can be made generic, these delegates can be used as generic types.

This should save time, and minimize the number of new types that you need to create in order to work with delegates.

In the next article, you'll see several common patterns for working with delegates in practice.

[Next](#)

Common Patterns for Delegates

6/7/2018 • 8 minutes to read • [Edit Online](#)

[Previous](#)

Delegates provide a mechanism that enables software designs involving minimal coupling between components.

One excellent example for this kind of design is LINQ. The LINQ Query Expression Pattern relies on delegates for all of its features. Consider this simple example:

```
var smallNumbers = numbers.Where(n => n < 10);
```

This filters the sequence of numbers to only those less than the value 10. The `Where` method uses a delegate that determines which elements of a sequence pass the filter. When you create a LINQ query, you supply the implementation of the delegate for this specific purpose.

The prototype for the `Where` method is:

```
public static IEnumerable<TSource> Where<TSource> (this IEnumerable<TSource> source, Func<TSource, bool> predicate);
```

This example is repeated with all the methods that are part of LINQ. They all rely on delegates for the code that manages the specific query. This API design pattern is a very powerful one to learn and understand.

This simple example illustrates how delegates require very little coupling between components. You don't need to create a class that derives from a particular base class. You don't need to implement a specific interface. The only requirement is to provide the implementation of one method that is fundamental to the task at hand.

Building Your Own Components with Delegates

Let's build on that example by creating a component using a design that relies on delegates.

Let's define a component that could be used for log messages in a large system. The library components could be used in many different environments, on multiple different platforms. There are a lot of common features in the component that manages the logs. It will need to accept messages from any component in the system. Those messages will have different priorities, which the core component can manage. The messages should have timestamps in their final archived form. For more advanced scenarios, you could filter messages by the source component.

There is one aspect of the feature that will change often: where messages are written. In some environments, they may be written to the error console. In others, a file. Other possibilities include database storage, OS event logs, or other document storage.

There are also combinations of output that might be used in different scenarios. You may want to write messages to the console and to a file.

A design based on delegates will provide a great deal of flexibility, and make it easy to support storage mechanisms that may be added in the future.

Under this design, the primary log component can be a non-virtual, even sealed class. You can plug in any set of delegates to write the messages to different storage media. The built in support for multicast delegates makes it easy to support scenarios where messages must be written to multiple locations (a file, and a console).

A First Implementation

Let's start small: the initial implementation will accept new messages, and write them using any attached delegate. You can start with one delegate that writes messages to the console.

```
public static class Logger
{
    public static Action<string> WriteMessage;

    public static void LogMessage(string msg)
    {
        WriteMessage(msg);
    }
}
```

The static class above is the simplest thing that can work. We need to write the single implementation for the method that writes messages to the console:

```
public static void LogToConsole(string message)
{
    Console.Error.WriteLine(message);
}
```

Finally, you need to hook up the delegate by attaching it to the `WriteMessage` delegate declared in the logger:

```
Logger.WriteMessage += LogToConsole;
```

Practices

Our sample so far is fairly simple, but it still demonstrates some of the important guidelines for designs involving delegates.

Using the delegate types defined in the Core Framework makes it easier for users to work with the delegates. You don't need to define new types, and developers using your library do not need to learn new, specialized delegate types.

The interfaces used are as minimal and as flexible as possible: To create a new output logger, you must create one method. That method may be a static method, or an instance method. It may have any access.

Formatting Output

Let's make this first version a bit more robust, and then start creating other logging mechanisms.

Next, let's add a few arguments to the `LogMessage()` method so that your log class creates more structured messages:

```
public enum Severity
{
    Verbose,
    Trace,
    Information,
    Warning,
    Error,
    Critical
}
```

```

public static class Logger
{
    public static Action<string> WriteMessage;

    public static void LogMessage(Severity s, string component, string msg)
    {
        var outputMsg = $"{DateTime.Now}\t{s}\t{component}\t{msg}";
        WriteMessage(outputMsg);
    }
}

```

Next, let's make use of that `Severity` argument to filter the messages that are sent to the log's output.

```

public static class Logger
{
    public static Action<string> WriteMessage;

    public static Severity LogLevel {get;set;} = Severity.Warning;

    public static void LogMessage(Severity s, string component, string msg)
    {
        if (s < LogLevel)
            return;

        var outputMsg = $"{DateTime.Now}\t{s}\t{component}\t{msg}";
        WriteMessage(outputMsg);
    }
}

```

Practices

You've added new features to the logging infrastructure. Because the logger component is very loosely coupled to any output mechanism, these new features can be added with no impact on any of the code implementing the logger delegate.

As you keep building this, you'll see more examples of how this loose coupling enables greater flexibility in updating parts of the site without any changes to other locations. In fact, in a larger application, the logger output classes might be in a different assembly, and not even need to be rebuilt.

Building a Second Output Engine

The Log component is coming along well. Let's add one more output engine that logs messages to a file. This will be a slightly more involved output engine. It will be a class that encapsulates the file operations, and ensures that the file is always closed after each write. That ensures that all the data is flushed to disk after each message is generated.

Here is that file based logger:

```

public class FileLogger
{
    private readonly string logPath;
    public FileLogger(string path)
    {
        logPath = path;
        Logger.WriteMessage += LogMessage;
    }

    public void DetachLog() => Logger.WriteMessage -= LogMessage;
    // make sure this can't throw.
    private void LogMessage(string msg)
    {
        try
        {
            using (var log = File.AppendText(logPath))
            {
                log.WriteLine(msg);
                log.Flush();
            }
        }
        catch (Exception)
        {
            // Hmm. We caught an exception while
            // logging. We can't really log the
            // problem (since it's the log that's failing).
            // So, while normally, catching an exception
            // and doing nothing isn't wise, it's really the
            // only reasonable option here.
        }
    }
}

```

Once you've created this class, you can instantiate it and it attaches its LogMessage method to the Logger component:

```
var file = new FileLogger("log.txt");
```

These two are not mutually exclusive. You could attach both log methods and generate messages to the console and a file:

```
var fileOutput = new FileLogger("log.txt");
Logger.WriteMessage += LogToConsole;
```

Later, even in the same application, you can remove one of the delegates without any other issues to the system:

```
Logger.WriteMessage -= LogToConsole;
```

Practices

Now, you've added a second output handler for the logging sub-system. This one needs a bit more infrastructure to correctly support the file system. The delegate is an instance method. It's also a private method. There's no need for greater accessibility because the delegate infrastructure can connect the delegates.

Second, the delegate-based design enables multiple output methods without any extra code. You don't need to build any additional infrastructure to support multiple output methods. They simply become another method on the invocation list.

Pay special attention to the code in the file logging output method. It is coded to ensure that it does not throw any exceptions. While this isn't always strictly necessary, it's often a good practice. If either of the delegate methods throws an exception, the remaining delegates that are on the invocation won't be invoked.

As a last note, the file logger must manage its resources by opening and closing the file on each log message. You could choose to keep the file open and implement `IDisposable` to close the file when you are completed. Either method has its advantages and disadvantages. Both do create a bit more coupling between the classes.

None of the code in the `Logger` class would need to be updated in order to support either scenario.

Handling Null Delegates

Finally, let's update the `LogMessage` method so that it is robust for those cases when no output mechanism is selected. The current implementation will throw a `NullReferenceException` when the `WriteMessage` delegate does not have an invocation list attached. You may prefer a design that silently continues when no methods have been attached. This is easy using the null conditional operator, combined with the `Delegate.Invoke()` method:

```
public static void LogMessage(string msg)
{
    WriteMessage?.Invoke(msg);
}
```

The null conditional operator (`?.`) short-circuits when the left operand (`WriteMessage` in this case) is null, which means no attempt is made to log a message.

You won't find the `Invoke()` method listed in the documentation for `System.Delegate` or `System.MulticastDelegate`. The compiler generates a type safe `Invoke` method for any delegate type declared. In this example, that means `Invoke` takes a single `string` argument, and has a void return type.

Summary of Practices

You've seen the beginnings of a log component that could be expanded with other writers, and other features. By using delegates in the design these different components are very loosely coupled. This provides several advantages. It's very easy to create new output mechanisms and attach them to the system. These other mechanisms only need one method: the method that writes the log message. It's a design that is very resilient when new features are added. The contract required for any writer is to implement one method. That method could be a static or instance method. It could be public, private, or any other legal access.

The `Logger` class can make any number of enhancements or changes without introducing breaking changes. Like any class, you cannot modify the public API without the risk of breaking changes. But, because the coupling between the logger and any output engines is only through the delegate, no other types (like interfaces or base classes) are involved. The coupling is as small as possible.

Introduction to Events

9/11/2018 • 3 minutes to read • [Edit Online](#)

[Previous](#)

Events are, like delegates, a *late binding* mechanism. In fact, events are built on the language support for delegates.

Events are a way for an object to broadcast (to all interested components in the system) that something has happened. Any other component can subscribe to the event, and be notified when an event is raised.

You've probably used events in some of your programming. Many graphical systems have an event model to report user interaction. These events would report mouse movement, button presses and similar interactions. That's one of the most common, but certainly not the only scenario where events are used.

You can define events that should be raised for your classes. One important consideration when working with events is that there may not be any object registered for a particular event. You must write your code so that it does not raise events when no listeners are configured.

Subscribing to an event also creates a coupling between two objects (the event source, and the event sink). You need to ensure that the event sink unsubscribes from the event source when no longer interested in events.

Design Goals for Event Support

The language design for events targets these goals.

First, enable very minimal coupling between an event source and an event sink. These two components may not be written by the same organization, and may even be updated on totally different schedules.

Secondly, it should be very simple to subscribe to an event, and to unsubscribe from that same event.

And finally, event sources should support multiple event subscribers. It should also support having no event subscribers attached.

You can see that the goals for events are very similar to the goals for delegates. That's why the event language support is built on the delegate language support.

Language Support for Events

The syntax for defining events, and subscribing or unsubscribing from events is an extension of the syntax for delegates.

To define an event you use the `event` keyword:

```
public event EventHandler<FileListArgs> Progress;
```

The type of the event (`EventHandler<FileListArgs>` in this example) must be a delegate type. There are a number of conventions that you should follow when declaring an event. Typically, the event delegate type has a void return. Event declarations should be a verb, or a verb phrase. Use past tense (as in this example) when the event reports something that has happened. Use a present tense verb (for example, `Closing`) to report something that is about to happen. Often, using present tense indicates that your class supports some kind of customization behavior. One of the most common scenarios is to support cancellation. For example, a `Closing` event may include an argument that would indicate if the close operation should continue, or not. Other scenarios may

enable callers to modify behavior by updating properties of the event arguments. You may raise an event to indicate a proposed next action an algorithm will take. The event handler may mandate a different action by modifying properties of the event argument.

When you want to raise the event, you call the event handlers using the delegate invocation syntax:

```
Progress?.Invoke(this, new FileListArgs(file));
```

As discussed in the section on [delegates](#), the `?.` operator makes it easy to ensure that you do not attempt to raise the event when there are no subscribers to that event.

You subscribe to an event by using the `+=` operator:

```
EventHandler<FileListArgs> onProgress = (sender, eventArgs) =>
    Console.WriteLine(eventArgs.FoundFile);
lister.Progress += onProgress;
```

The handler method typically is the prefix 'On' followed by the event name, as shown above.

You unsubscribe using the `-=` operator:

```
lister.Progress -= onProgress;
```

It's important to note that I declared a local variable for the expression that represents the event handler. That ensures the unsubscribe removes the handler. If, instead, you used the body of the lambda expression, you are attempting to remove a handler that has never been attached, which does nothing.

In the next article, you'll learn more about typical event patterns, and different variations on this example.

[Next](#)

Standard .NET event patterns

3/1/2019 • 8 minutes to read • [Edit Online](#)

[Previous](#)

.NET events generally follow a few known patterns. Standardizing on these patterns means that developers can leverage knowledge of those standard patterns, which can be applied to any .NET event program.

Let's go through these standard patterns so you will have all the knowledge you need to create standard event sources, and subscribe and process standard events in your code.

Event Delegate Signatures

The standard signature for a .NET event delegate is:

```
void OnEventRaised(object sender, EventArgs args);
```

The return type is void. Events are based on delegates and are multicast delegates. That supports multiple subscribers for any event source. The single return value from a method doesn't scale to multiple event subscribers. Which return value does the event source see after raising an event? Later in this article you'll see how to create event protocols that support event subscribers that report information to the event source.

The argument list contains two arguments: the sender, and the event arguments. The compile time type of `sender` is `System.Object`, even though you likely know a more derived type that would always be correct. By convention, use `object`.

The second argument has typically been a type that is derived from `System.EventArgs`. (You'll see in the [next section](#) that this convention is no longer enforced.) If your event type does not need any additional arguments, you will still provide both arguments. There is a special value, `EventArgs.Empty` that you should use to denote that your event does not contain any additional information.

Let's build a class that lists files in a directory, or any of its subdirectories that follow a pattern. This component raises an event for each file found that matches the pattern.

Using an event model provides some design advantages. You can create multiple event listeners that perform different actions when a sought file is found. Combining the different listeners can create more robust algorithms.

Here is the initial event argument declaration for finding a sought file:

```
public class FileFoundArgs : EventArgs
{
    public string FoundFile { get; }
    public bool CancelRequested { get; set; }

    public FileFoundArgs(string fileName)
    {
        FoundFile = fileName;
    }
}
```

Even though this type looks like a small, data-only type, you should follow the convention and make it a reference (`class`) type. That means the argument object will be passed by reference, and any updates to the data will be viewed by all subscribers. The first version is an immutable object. You should prefer to make the properties in

your event argument type immutable. That way, one subscriber cannot change the values before another subscriber sees them. (There are exceptions to this, as you'll see below.)

Next, we need to create the event declaration in the FileSearcher class. Leveraging the `EventHandler<T>` type means that you don't need to create yet another type definition. You simply use a generic specialization.

Let's fill out the FileSearcher class to search for files that match a pattern, and raise the correct event when a match is discovered.

```
public class FileSearcher
{
    public event EventHandler<FileEventArgs> FileFound;

    public void Search(string directory, string searchPattern)
    {
        foreach (var file in Directory.EnumerateFiles(directory, searchPattern))
        {
            FileFound?.Invoke(this, new FileEventArgs(file));
        }
    }
}
```

Defining and Raising Field-Like Events

The simplest way to add an event to your class is to declare that event as a public field, as in the preceding example:

```
public event EventHandler<FileEventArgs> FileFound;
```

This looks like it's declaring a public field, which would appear to be bad object-oriented practice. You want to protect data access through properties, or methods. While this make look like a bad practice, the code generated by the compiler does create wrappers so that the event objects can only be accessed in safe ways. The only operations available on a field-like event are add handler:

```
EventHandler<FileEventArgs> onFileFound = (sender, eventArgs) =>
{
    Console.WriteLine(eventArgs.FoundFile);
    filesFound++;
};

lister.FileFound += onFileFound;
```

and remove handler:

```
lister.FileFound -= onFileFound;
```

Note that there's a local variable for the handler. If you used the body of the lambda, the remove would not work correctly. It would be a different instance of the delegate, and silently do nothing.

Code outside the class cannot raise the event, nor can it perform any other operations.

Returning Values from Event Subscribers

Your simple version is working fine. Let's add another feature: Cancellation.

When you raise the found event, listeners should be able to stop further processing, if this file is that last one

sought.

The event handlers do not return a value, so you need to communicate that in another way. The standard event pattern uses the EventArgs object to include fields that event subscribers can use to communicate cancel.

There are two different patterns that could be used, based on the semantics of the Cancel contract. In both cases, you'll add a boolean field to the EventArguments for the found file event.

One pattern would allow any one subscriber to cancel the operation. For this pattern, the new field is initialized to `false`. Any subscriber can change it to `true`. After all subscribers have seen the event raised, the FileSearcher component examines the boolean value and takes action.

The second pattern would only cancel the operation if all subscribers wanted the operation cancelled. In this pattern, the new field is initialized to indicate the operation should cancel, and any subscriber could change it to indicate the operation should continue. After all subscribers have seen the event raised, the FileSearcher component examines the boolean and takes action. There is one extra step in this pattern: the component needs to know if any subscribers have seen the event. If there are no subscribers, the field would indicate a cancel incorrectly.

Let's implement the first version for this sample. You need to add a boolean field named `CancelRequested` to the `FileFoundArgs` type:

```
public class FileFoundArgs : EventArgs
{
    public string FoundFile { get; }
    public bool CancelRequested { get; set; }

    public FileFoundArgs(string fileName)
    {
        FoundFile = fileName;
    }
}
```

This new Field is automatically initialized to `false`, the default value for a Boolean field, so you don't cancel accidentally. The only other change to the component is to check the flag after raising the event to see if any of the subscribers have requested a cancellation:

```
public void List(string directory, string searchPattern)
{
    foreach (var file in Directory.EnumerateFiles(directory, searchPattern))
    {
        var args = new FileFoundArgs(file);
        FileFound?.Invoke(this, args);
        if (args.CancelRequested)
            break;
    }
}
```

One advantage of this pattern is that it isn't a breaking change. None of the subscribers requested a cancellation before, and they still are not. None of the subscriber code needs updating unless they want to support the new cancel protocol. It's very loosely coupled.

Let's update the subscriber so that it requests a cancellation once it finds the first executable:

```
EventHandler<FileEventArgs> onFileFound = (sender, eventArgs) =>
{
    Console.WriteLine(eventArgs.FoundFile);
    eventArgs.CancelRequested = true;
};
```

Adding Another Event Declaration

Let's add one more feature, and demonstrate other language idioms for events. Let's add an overload of the `Search` method that traverses all subdirectories in search of files.

This could get to be a lengthy operation in a directory with many sub-directories. Let's add an event that gets raised when each new directory search begins. This enables subscribers to track progress, and update the user as to progress. All the samples you've created so far are public. Let's make this one an internal event. That means you can also make the types used for the arguments internal as well.

You'll start by creating the new `EventArgs` derived class for reporting the new directory and progress.

```
internal class SearchDirectoryArgs : EventArgs
{
    internal string CurrentSearchDirectory { get; }
    internal int TotalDirs { get; }
    internal int CompletedDirs { get; }

    internal SearchDirectoryArgs(string dir, int totalDirs, int completedDirs)
    {
        CurrentSearchDirectory = dir;
        TotalDirs = totalDirs;
        CompletedDirs = completedDirs;
    }
}
```

Again, you can follow the recommendations to make an immutable reference type for the event arguments.

Next, define the event. This time, you'll use a different syntax. In addition to using the field syntax, you can explicitly create the property, with add and remove handlers. In this sample, you won't need extra code in those handlers, but this shows how you would create them.

```
internal event EventHandler<SearchDirectoryArgs> DirectoryChanged
{
    add { directoryChanged += value; }
    remove { directoryChanged -= value; }
}
private EventHandler<SearchDirectoryArgs> directoryChanged;
```

In many ways, the code you write here mirrors the code the compiler generates for the field event definitions you've seen earlier. You create the event using syntax very similar to that used for [properties](#). Notice that the handlers have different names: `add` and `remove`. These are called to subscribe to the event, or unsubscribe from the event. Notice that you also must declare a private backing field to store the event variable. It is initialized to null.

Next, let's add the overload of the `Search` method that traverses subdirectories and raises both events. The easiest way to accomplish this is to use a default argument to specify that you want to search all directories:

```

public void Search(string directory, string searchPattern, bool searchSubDirs = false)
{
    if (searchSubDirs)
    {
        var allDirectories = Directory.GetDirectories(directory, "*.*", SearchOption.AllDirectories);
        var completedDirs = 0;
        var totalDirs = allDirectories.Length + 1;
        foreach (var dir in allDirectories)
        {
            directoryChanged?.Invoke(this,
                new SearchDirectoryArgs(dir, totalDirs, completedDirs++));
            // Recursively search this child directory:
            SearchDirectory(dir, searchPattern);
        }
        // Include the Current Directory:
        directoryChanged?.Invoke(this,
            new SearchDirectoryArgs(directory, totalDirs, completedDirs++));
        SearchDirectory(directory, searchPattern);
    }
    else
    {
        SearchDirectory(directory, searchPattern);
    }
}

private void SearchDirectory(string directory, string searchPattern)
{
    foreach (var file in Directory.EnumerateFiles(directory, searchPattern))
    {
        var args = new FileFoundArgs(file);
        FileFound?.Invoke(this, args);
        if (args.CancelRequested)
            break;
    }
}

```

At this point, you can run the application calling the overload for searching all sub-directories. There are no subscribers on the new `ChangeDirectory` event, but using the `??.Invoke()` idiom ensures that this works correctly.

Let's add a handler to write a line that shows the progress in the console window.

```

lister.DirectoryChanged += (sender, eventArgs) =>
{
    Console.WriteLine($"Entering '{eventArgs.CurrentSearchDirectory}'.");
    Console.WriteLine($" {eventArgs.CompletedDirs} of {eventArgs.TotalDirs} completed...");
};

```

You've seen patterns that are followed throughout the .NET ecosystem. By learning these patterns and conventions, you'll be writing idiomatic C# and .NET quickly.

Next, you'll see some changes in these patterns in the most recent release of .NET.

[Next](#)

The Updated .NET Core Event Pattern

10/16/2018 • 3 minutes to read • [Edit Online](#)

[Previous](#)

The previous article discussed the most common event patterns. .NET Core has a more relaxed pattern. In this version, the `EventHandler<TEventArgs>` definition no longer has the constraint that `TEventArgs` must be a class derived from `System.EventArgs`.

This increases flexibility for you, and is backwards compatible. Let's start with the flexibility. The class `System.EventArgs` introduces one method: `MemberwiseClone()`, which creates a shallow copy of the object. That method must use reflection in order to implement its functionality for any class derived from `EventArgs`. That functionality is easier to create in a specific derived class. That effectively means that deriving from `System.EventArgs` is a constraint that limits your designs, but does not provide any additional benefit. In fact, you can change the definitions of `FileEventArgs` and `SearchDirectoryEventArgs` so that they do not derive from `EventArgs`. The program will work exactly the same.

You could also change the `SearchDirectoryEventArgs` to a struct, if you make one more change:

```
internal event EventHandler<SearchDirectoryEventArgs> DirectoryChanged
{
    add { directoryChanged += value; }
    remove { directoryChanged -= value; }
}
private EventHandler<SearchDirectoryEventArgs> directoryChanged;
```

The additional change is to call the default constructor before entering the constructor that initializes all the fields. Without that addition, the rules of C# would report that the properties are being accessed before they have been assigned.

You should not change the `FileEventArgs` from a class (reference type) to a struct (value type). That's because the protocol for handling cancel requires that the event arguments are passed by reference. If you made the same change, the file search class could never observe any changes made by any of the event subscribers. A new copy of the structure would be used for each subscriber, and that copy would be a different copy than the one seen by the file search object.

Next, let's consider how this change can be backwards compatible. The removal of the constraint does not affect any existing code. Any existing event argument types do still derive from `System.EventArgs`. Backwards compatibility is one major reason why they will continue to derive from `System.EventArgs`. Any existing event subscribers will be subscribers to an event that followed the classic pattern.

Following similar logic, any event argument type created now would not have any subscribers in any existing codebases. New event types that do not derive from `System.EventArgs` will not break those codebases.

Events with Async subscribers

You have one final pattern to learn: How to correctly write event subscribers that call async code. The challenge is described in the article on [async and await](#). Async methods can have a void return type, but that is strongly discouraged. When your event subscriber code calls an async method, you have no choice but to create an `async void` method. The event handler signature requires it.

You need to reconcile this opposing guidance. Somehow, you must create a safe `async void` method. The basics

of the pattern you need to implement are below:

```
worker.StartWorking += async (sender, eventArgs) =>
{
    try
    {
        await DoWorkAsync();
    }
    catch (Exception e)
    {
        //Some form of logging.
        Console.WriteLine($"Async task failure: {e.ToString()}");
        // Consider gracefully, and quickly exiting.
    }
};
```

First, notice that the handler is marked as an `async` handler. Because it is being assigned to an event handler delegate type, it will have a void return type. That means you must follow the pattern shown in the handler, and not allow any exceptions to be thrown out of the context of the `async` handler. Because it does not return a task, there is no task that can report the error by entering the faulted state. Because the method is `async`, the method can't simply throw the exception. (The calling method has continued execution because it is `async`.) The actual runtime behavior will be defined differently for different environments. It may terminate the thread, it may terminate the program, or it may leave the program in an undetermined state. None of those are good outcomes.

That's why you should wrap the `await` statement for the `async Task` in your own `try` block. If it does cause a faulted task, you can log the error. If it is an error from which your application cannot recover, you can exit the program quickly and gracefully.

Those are the major updates to the .NET event pattern. You will see many examples of the earlier versions in the libraries you work with. However, you should understand what the latest patterns are as well.

The next article in this series helps you distinguish between using `delegates` and `events` in your designs. They are similar concepts, and that article will help you make the best decision for your programs.

[Next](#)

Distinguishing Delegates and Events

5/4/2018 • 2 minutes to read • [Edit Online](#)

[Previous](#)

Developers that are new to the .NET Core platform often struggle when deciding between a design based on `delegates` and a design based on `events`. This is a difficult concept, because the two language features are very similar. Events are even built using the language support for delegates.

They both offer a late binding scenario: they enable scenarios where a component communicates by calling a method that is only known at runtime. They both support single and multiple subscriber methods. You may find this referred to as singlecast and multicast support. They both support similar syntax for adding and removing handlers. Finally, raising an event and calling a delegate use exactly the same method call syntax. They even both support the same `Invoke()` method syntax for use with the `?.` operator.

With all those similarities, it is easy to have trouble determining when to use which.

Listening to Events is Optional

The most important consideration in determining which language feature to use is whether or not there must be an attached subscriber. If your code must call the code supplied by the subscriber, you should use a design based on delegates. If your code can complete all its work without calling any subscribers, you should use a design based on events.

Consider the examples built during this section. The code you built using `List.Sort()` must be given a comparer function in order to properly sort the elements. LINQ queries must be supplied with delegates in order to determine what elements to return. Both used a design built with delegates.

Consider the `Progress` event. It reports progress on a task. The task continues to proceed whether or not there are any listeners. The `FileSearcher` is another example. It would still search and find all the files that were sought, even with no event subscribers attached. UX controls still work correctly, even when there are no subscribers listening to the events. They both use designs based on events.

Return Values Require Delegates

Another consideration is the method prototype you would want for your delegate method. As you've seen, the delegates used for events all have a void return type. You've also seen that there are idioms to create event handlers that do pass information back to event sources through modifying properties of the event argument object. While these idioms do work, they are not as natural as returning a value from a method.

Notice that these two heuristics may often both be present: If your delegate method returns a value, it will likely impact the algorithm in some way.

Event Listeners Often Have Longer Lifetimes

This is a slightly weaker justification. However, you may find that event-based designs are more natural when the event source will be raising events over a long period of time. You can see examples of this for UX controls on many systems. Once you subscribe to an event, the event source may raise events throughout the lifetime of the program. (You can unsubscribe from events when you no longer need them.)

Contrast that with many delegate-based designs, where a delegate is used as an argument to a method, and the delegate is not used after that method returns.

Evaluate Carefully

The above considerations are not hard and fast rules. Instead, they represent guidance that can help you decide which choice is best for your particular usage. Because they are similar, you can even prototype both, and consider which would be more natural to work with. They both handle late binding scenarios well. Use the one that communicates your design the best.

Language Integrated Query (LINQ)

10/13/2018 • 3 minutes to read • [Edit Online](#)

Language-Integrated Query (LINQ) is the name for a set of technologies based on the integration of query capabilities directly into the C# language. Traditionally, queries against data are expressed as simple strings without type checking at compile time or IntelliSense support. Furthermore, you have to learn a different query language for each type of data source: SQL databases, XML documents, various Web services, and so on. With LINQ, a query is a first-class language construct, just like classes, methods, events.

For a developer who writes queries, the most visible "language-integrated" part of LINQ is the query expression. Query expressions are written in a declarative *query syntax*. By using query syntax, you can perform filtering, ordering, and grouping operations on data sources with a minimum of code. You use the same basic query expression patterns to query and transform data in SQL databases, ADO .NET Datasets, XML documents and streams, and .NET collections.

The following example shows the complete query operation. The complete operation includes creating a data source, defining the query expression, and executing the query in a `foreach` statement.

```
class LINQQueryExpressions
{
    static void Main()
    {

        // Specify the data source.
        int[] scores = new int[] { 97, 92, 81, 60 };

        // Define the query expression.
        IEnumerable<int> scoreQuery =
            from score in scores
            where score > 80
            select score;

        // Execute the query.
        foreach (int i in scoreQuery)
        {
            Console.WriteLine(i + " ");
        }
    }
}
// output: 97 92 81
```

Query expression overview

- Query expressions can be used to query and to transform data from any LINQ-enabled data source. For example, a single query can retrieve data from a SQL database, and produce an XML stream as output.
- Query expressions are easy to master because they use many familiar C# language constructs.
- The variables in a query expression are all strongly typed, although in many cases you do not have to provide the type explicitly because the compiler can infer it. For more information, see [Type relationships in LINQ query operations](#).
- A query is not executed until you iterate over the query variable, for example, in a `foreach` statement. For more information, see [Introduction to LINQ queries](#).

- At compile time, query expressions are converted to Standard Query Operator method calls according to the rules set forth in the C# specification. Any query that can be expressed by using query syntax can also be expressed by using method syntax. However, in most cases query syntax is more readable and concise. For more information, see [C# language specification](#) and [Standard query operators overview](#).
- As a rule when you write LINQ queries, we recommend that you use query syntax whenever possible and method syntax whenever necessary. There is no semantic or performance difference between the two different forms. Query expressions are often more readable than equivalent expressions written in method syntax.
- Some query operations, such as [Count](#) or [Max](#), have no equivalent query expression clause and must therefore be expressed as a method call. Method syntax can be combined with query syntax in various ways. For more information, see [Query syntax and method syntax in LINQ](#).
- Query expressions can be compiled to expression trees or to delegates, depending on the type that the query is applied to. [IEnumerable<T>](#) queries are compiled to delegates. [IQueryable](#) and [IQueryable<T>](#) queries are compiled to expression trees. For more information, see [Expression trees](#).

Next steps

To learn more details about LINQ, start by becoming familiar with some basic concepts in [Query expression basics](#), and then read the documentation for the LINQ technology in which you are interested:

- XML documents: [LINQ to XML](#)
- ADO.NET Entity Framework: [LINQ to entities](#)
- .NET collections, files, strings and so on: [LINQ to objects](#)

To gain a deeper understanding of LINQ in general, see [LINQ in C#](#).

To start working with LINQ in C#, see the tutorial [Working with LINQ](#).

Asynchronous programming

3/19/2019 • 10 minutes to read • [Edit Online](#)

If you have any I/O-bound needs (such as requesting data from a network or accessing a database), you'll want to utilize asynchronous programming. You could also have CPU-bound code, such as performing an expensive calculation, which is also a good scenario for writing async code.

C# has a language-level asynchronous programming model which allows for easily writing asynchronous code without having to juggle callbacks or conform to a library which supports asynchrony. It follows what is known as the [Task-based Asynchronous Pattern \(TAP\)](#).

Basic Overview of the Asynchronous Model

The core of async programming is the `Task` and `Task<T>` objects, which model asynchronous operations. They are supported by the `async` and `await` keywords. The model is fairly simple in most cases:

For I/O-bound code, you `await` an operation which returns a `Task` or `Task<T>` inside of an `async` method.

For CPU-bound code, you `await` an operation which is started on a background thread with the `Task.Run` method.

The `await` keyword is where the magic happens. It yields control to the caller of the method that performed `await`, and it ultimately allows a UI to be responsive or a service to be elastic.

There are other ways to approach async code than `async` and `await` outlined in the TAP article linked above, but this document will focus on the language-level constructs from this point forward.

I/O-Bound Example: Downloading data from a web service

You may need to download some data from a web service when a button is pressed, but don't want to block the UI thread. It can be accomplished simply like this:

```
private readonly HttpClient _httpClient = new HttpClient();

downloadButton.Clicked += async (o, e) =>
{
    // This line will yield control to the UI as the request
    // from the web service is happening.
    //
    // The UI thread is now free to perform other work.
    var stringData = await _httpClient.GetStringAsync(URL);
    DoSomethingWithData(stringData);
};
```

And that's it! The code expresses the intent (downloading some data asynchronously) without getting bogged down in interacting with Task objects.

CPU-bound Example: Performing a Calculation for a Game

Say you're writing a mobile game where pressing a button can inflict damage on many enemies on the screen. Performing the damage calculation can be expensive, and doing it on the UI thread would make the game appear to pause as the calculation is performed!

The best way to handle this is to start a background thread which does the work using `Task.Run`, and `await` its result. This will allow the UI to feel smooth as the work is being done.

```

private DamageResult CalculateDamageDone()
{
    // Code omitted:
    //
    // Does an expensive calculation and returns
    // the result of that calculation.
}

calculateButton.Clicked += async (o, e) =>
{
    // This line will yield control to the UI while CalculateDamageDone()
    // performs its work. The UI thread is free to perform other work.
    var damageResult = await Task.Run(() => CalculateDamageDone());
    DisplayDamage(damageResult);
};

```

And that's it! This code cleanly expresses the intent of the button's click event, it doesn't require managing a background thread manually, and it does so in a non-blocking way.

What happens under the covers

There's a lot of moving pieces where asynchronous operations are concerned. If you're curious about what's happening underneath the covers of `Task` and `Task<T>`, checkout the [Async in-depth](#) article for more information.

On the C# side of things, the compiler transforms your code into a state machine which keeps track of things like yielding execution when an `await` is reached and resuming execution when a background job has finished.

For the theoretically-inclined, this is an implementation of the [Promise Model of asynchrony](#).

Key Pieces to Understand

- Async code can be used for both I/O-bound and CPU-bound code, but differently for each scenario.
- Async code uses `Task<T>` and `Task`, which are constructs used to model work being done in the background.
- The `async` keyword turns a method into an async method, which allows you to use the `await` keyword in its body.
- When the `await` keyword is applied, it suspends the calling method and yields control back to its caller until the awaited task is complete.
- `await` can only be used inside an async method.

Recognize CPU-Bound and I/O-Bound Work

The first two examples of this guide showed how you can use `async` and `await` for I/O-bound and CPU-bound work. It's key that you can identify when a job you need to do is I/O-bound or CPU-bound, because it can greatly affect the performance of your code and could potentially lead to misusing certain constructs.

Here are two questions you should ask before you write any code:

1. Will your code be "waiting" for something, such as data from a database?

If your answer is "yes", then your work is **I/O-bound**.

2. Will your code be performing a very expensive computation?

If you answered "yes", then your work is **CPU-bound**.

If the work you have is **I/O-bound**, use `async` and `await` *without* `Task.Run`. You *should not* use the Task Parallel Library. The reason for this is outlined in the [Async in Depth article](#).

If the work you have is **CPU-bound** and you care about responsiveness, use `async` and `await` but spawn the work off on another thread with `Task.Run`. If the work is appropriate for concurrency and parallelism, you should also consider using the [Task Parallel Library](#).

Additionally, you should always measure the execution of your code. For example, you may find yourself in a situation where your CPU-bound work is not costly enough compared with the overhead of context switches when multithreading. Every choice has its tradeoff, and you should pick the correct tradeoff for your situation.

More Examples

The following examples demonstrate various ways you can write async code in C#. They cover a few different scenarios you may come across.

Extracting Data from a Network

This snippet downloads the HTML from the homepage at www.dotnetfoundation.org and counts the number of times the string ".NET" occurs in the HTML. It uses ASP.NET MVC to define a web controller method which performs this task, returning the number.

NOTE

If you plan on doing HTML parsing in production code, don't use regular expressions. Use a parsing library instead.

```
private readonly HttpClient _httpClient = new HttpClient();

[HttpGet]
[Route("DotNetCount")]
public async Task<int> GetDotNetCountAsync()
{
    // Suspends GetDotNetCountAsync() to allow the caller (the web server)
    // to accept another request, rather than blocking on this one.
    var html = await _httpClient.GetStringAsync("https://dotnetfoundation.org");

    return Regex.Matches(html, @"\.\.NET").Count;
}
```

Here's the same scenario written for a Universal Windows App, which performs the same task when a Button is pressed:

```

private readonly HttpClient _httpClient = new HttpClient();

private async void SeeTheDotNets_Click(object sender, RoutedEventArgs e)
{
    // Capture the task handle here so we can await the background task later.
    var getDotNetFoundationHtmlTask = _httpClient.GetStringAsync("https://www.dotnetfoundation.org");

    // Any other work on the UI thread can be done here, such as enabling a Progress Bar.
    // This is important to do here, before the "await" call, so that the user
    // sees the progress bar before execution of this method is yielded.
    NetworkProgressBar.IsEnabled = true;
    NetworkProgressBar.Visibility = Visibility.Visible;

    // The await operator suspends SeeTheDotNets_Click, returning control to its caller.
    // This is what allows the app to be responsive and not hang on the UI thread.
    var html = await getDotNetFoundationHtmlTask;
    int count = Regex.Matches(html, @"\.\NET").Count;

    DotNetCountLabel.Text = $"Number of .NETs on dotnetfoundation.org: {count}";

    NetworkProgressBar.IsEnabled = false;
    NetworkProgressBar.Visibility = Visibility.Collapsed;
}

```

Waiting for Multiple Tasks to Complete

You may find yourself in a situation where you need to retrieve multiple pieces of data concurrently. The `Task` API contains two methods, `Task.WhenAll` and `Task.WhenAny` which allow you to write asynchronous code which performs a non-blocking wait on multiple background jobs.

This example shows how you might grab `User` data for a set of `userId`s.

```

public async Task<User> GetUserAsync(int userId)
{
    // Code omitted:
    //
    // Given a user Id {userId}, retrieves a User object corresponding
    // to the entry in the database with {userId} as its Id.
}

public static async Task<IEnumerable<User>> GetUsersAsync(IEnumerable<int> userIds)
{
    var getUserTasks = new List<Task<User>>();

    foreach (int userId in userIds)
    {
        getUserTasks.Add(GetUserAsync(userId));
    }

    return await Task.WhenAll(getUserTasks);
}

```

Here's another way to write this a bit more succinctly, using LINQ:

```

public async Task<User> GetUserAsync(int userId)
{
    // Code omitted:
    //
    // Given a user Id {userId}, retrieves a User object corresponding
    // to the entry in the database with {userId} as its Id.
}

public static async Task<User[]> GetUsersAsync(IEnumerable<int> userIds)
{
    var getUserTasks = userIds.Select(id => GetUserAsync(id));
    return await Task.WhenAll(getUserTasks);
}

```

Although it's less code, take care when mixing LINQ with asynchronous code. Because LINQ uses deferred (lazy) execution, `async` calls won't happen immediately as they do in a `foreach()` loop unless you force the generated sequence to iterate with a call to `.ToList()` or `.ToArray()`.

Important Info and Advice

Although `async` programming is relatively straightforward, there are some details to keep in mind which can prevent unexpected behavior.

- `async` methods need to have an `await` keyword in their body or they will never yield!

This is important to keep in mind. If `await` is not used in the body of an `async` method, the C# compiler will generate a warning, but the code will compile and run as if it were a normal method. Note that this would also be incredibly inefficient, as the state machine generated by the C# compiler for the `async` method would not be accomplishing anything.

- You should add "Async" as the suffix of every `async` method name you write.

This is the convention used in .NET to more-easily differentiate synchronous and asynchronous methods. Note that certain methods which aren't explicitly called by your code (such as event handlers or web controller methods) don't necessarily apply. Because these are not explicitly called by your code, being explicit about their naming isn't as important.

- `async void` should only be used for event handlers.

`async void` is the only way to allow asynchronous event handlers to work because events do not have return types (thus cannot make use of `Task` and `Task<T>`). Any other use of `async void` does not follow the TAP model and can be challenging to use, such as:

- Exceptions thrown in an `async void` method can't be caught outside of that method.
- `async void` methods are very difficult to test.
- `async void` methods can cause bad side effects if the caller isn't expecting them to be `async`.
- **Tread carefully when using `async` lambdas in LINQ expressions**

Lambda expressions in LINQ use deferred execution, meaning code could end up executing at a time when you're not expecting it to. The introduction of blocking tasks into this can easily result in a deadlock if not written correctly. Additionally, the nesting of asynchronous code like this can also make it more difficult to reason about the execution of the code. `Async` and LINQ are powerful, but should be used together as carefully and clearly as possible.

- Write code that awaits Tasks in a non-blocking manner

Blocking the current thread as a means to wait for a Task to complete can result in deadlocks and blocked context threads, and can require significantly more complex error-handling. The following table provides guidance on how to deal with waiting for Tasks in a non-blocking way:

USE THIS...	INSTEAD OF THIS...	WHEN WISHING TO DO THIS
<code>await</code>	<code>Task.Wait</code> or <code>Task.Result</code>	Retrieving the result of a background task
<code>await Task.WhenAny</code>	<code>Task.WaitAny</code>	Waiting for any task to complete
<code>await Task.WhenAll</code>	<code>Task.WaitAll</code>	Waiting for all tasks to complete
<code>await Task.Delay</code>	<code>Thread.Sleep</code>	Waiting for a period of time

- **Write less stateful code**

Don't depend on the state of global objects or the execution of certain methods. Instead, depend only on the return values of methods. Why?

- Code will be easier to reason about.
- Code will be easier to test.
- Mixing async and synchronous code is far simpler.
- Race conditions can typically be avoided altogether.
- Depending on return values makes coordinating async code simple.
- (Bonus) it works really well with dependency injection.

A recommended goal is to achieve complete or near-complete [Referential Transparency](#) in your code. Doing so will result in an extremely predictable, testable, and maintainable codebase.

Pattern Matching

2/28/2019 • 13 minutes to read • [Edit Online](#)

Patterns test that a value has a certain *shape*, and can *extract* information from the value when it has the matching shape. Pattern matching provides more concise syntax for algorithms you already use today. You already create pattern matching algorithms using existing syntax. You write `if` or `switch` statements that test values. Then, when those statements match, you extract and use information from that value. The new syntax elements are extensions to statements you are already familiar with: `is` and `switch`. These new extensions combine testing a value and extracting that information.

In this topic, we'll look at the new syntax to show you how it enables readable, concise code. Pattern matching enables idioms where data and the code are separated, unlike object oriented designs where data and the methods that manipulate them are tightly coupled.

To illustrate these new idioms, let's work with structures that represent geometric shapes using pattern matching statements. You are probably familiar with building class hierarchies and creating [virtual methods and overridden methods](#) to customize object behavior based on the runtime type of the object.

Those techniques aren't possible for data that isn't structured in a class hierarchy. When data and methods are separate, you need other tools. The new *pattern matching* constructs enable cleaner syntax to examine data and manipulate control flow based on any condition of that data. You already write `if` statements and `switch` that test a variable's value. You write `is` statements that test a variable's type. *Pattern matching* adds new capabilities to those statements.

In this topic, you'll build a method that computes the area of different geometric shapes. But, you'll do it without resorting to object oriented techniques and building a class hierarchy for the different shapes. You'll use *pattern matching* instead. As you go through this sample, contrast this code with how it would be structured as an object hierarchy. When the data you must query and manipulate is not a class hierarchy, pattern matching enables very elegant designs.

Rather than starting with an abstract shape definition and adding different specific shape classes, let's start instead with simple data only definitions for each of the geometric shapes:

```

public class Square
{
    public double Side { get; }

    public Square(double side)
    {
        Side = side;
    }
}

public class Circle
{
    public double Radius { get; }

    public Circle(double radius)
    {
        Radius = radius;
    }
}

public struct Rectangle
{
    public double Length { get; }
    public double Height { get; }

    public Rectangle(double length, double height)
    {
        Length = length;
        Height = height;
    }
}

public class Triangle
{
    public double Base { get; }
    public double Height { get; }

    public Triangle(double @base, double height)
    {
        Base = @base;
        Height = height;
    }
}

```

From these structures, let's write a method that computes the area of some shape.

The `is` type pattern expression

Before C# 7.0, you'd need to test each type in a series of `if` and `is` statements:

```

public static double ComputeArea(object shape)
{
    if (shape is Square)
    {
        var s = (Square)shape;
        return s.Side * s.Side;
    }
    else if (shape is Circle)
    {
        var c = (Circle)shape;
        return c.Radius * c.Radius * Math.PI;
    }
    // elided
    throw new ArgumentException(
        message: "shape is not a recognized shape",
        paramName: nameof(shape));
}

```

That code above is a classic expression of the *type pattern*: You're testing a variable to determine its type and taking a different action based on that type.

This code becomes simpler using extensions to the `is` expression to assign a variable if the test succeeds:

```

public static double ComputeAreaModernIs(object shape)
{
    if (shape is Square s)
        return s.Side * s.Side;
    else if (shape is Circle c)
        return c.Radius * c.Radius * Math.PI;
    else if (shape is Rectangle r)
        return r.Height * r.Length;
    // elided
    throw new ArgumentException(
        message: "shape is not a recognized shape",
        paramName: nameof(shape));
}

```

In this updated version, the `is` expression both tests the variable and assigns it to a new variable of the proper type. Also, notice that this version includes the `Rectangle` type, which is a `struct`. The new `is` expression works with value types as well as reference types.

Language rules for pattern matching expressions help you avoid misusing the results of a match expression. In the example above, the variables `s`, `c`, and `r` are only in scope and definitely assigned when the respective pattern match expressions have `true` results. If you try to use either variable in another location, your code generates compiler errors.

Let's examine both of those rules in detail, beginning with scope. The variable `c` is in scope only in the `else` branch of the first `if` statement. The variable `s` is in scope in the method `ComputeAreaModernIs`. That's because each branch of an `if` statement establishes a separate scope for variables. However, the `if` statement itself does not. That means variables declared in the `if` statement are in the same scope as the `if` statement (the method in this case.) This behavior is not specific to pattern matching, but is the defined behavior for variable scopes and `if` and `else` statements.

The variables `c` and `s` are assigned when the respective `if` statements are true because of the definitely assigned when true mechanism.

TIP

The samples in this topic use the recommended construct where a pattern match `is` expression definitely assigns the match variable in the `true` branch of the `if` statement. You could reverse the logic by saying `if (!(shape is Square s))` and the variable `s` would be definitely assigned only in the `false` branch. While this is valid C#, it is not recommended because it is more confusing to follow the logic.

These rules mean that you are unlikely to accidentally access the result of a pattern match expression when that pattern was not met.

Using pattern matching `switch` statements

As time goes on, you may need to support other shape types. As the number of conditions you are testing grows, you'll find that using the `is` pattern matching expressions can become cumbersome. In addition to requiring `if` statements on each type you want to check, the `is` expressions are limited to testing if the input matches a single type. In this case, you'll find that the `switch` pattern matching expressions becomes a better choice.

The traditional `switch` statement was a pattern expression: it supported the constant pattern. You could compare a variable to any constant used in a `case` statement:

```
public static string GenerateMessage(params string[] parts)
{
    switch (parts.Length)
    {
        case 0:
            return "No elements to the input";
        case 1:
            return $"One element: {parts[0]}";
        case 2:
            return $"Two elements: {parts[0]}, {parts[1]}";
        default:
            return $"Many elements. Too many to write";
    }
}
```

The only pattern supported by the `switch` statement was the constant pattern. It was further limited to numeric types and the `string` type. Those restrictions have been removed, and you can now write a `switch` statement using the type pattern:

```
public static double ComputeAreaModernSwitch(object shape)
{
    switch (shape)
    {
        case Square s:
            return s.Side * s.Side;
        case Circle c:
            return c.Radius * c.Radius * Math.PI;
        case Rectangle r:
            return r.Height * r.Length;
        default:
            throw new ArgumentException(
                message: "shape is not a recognized shape",
                paramName: nameof(shape));
    }
}
```

The pattern matching `switch` statement uses familiar syntax to developers who have used the traditional C-style

`switch` statement. Each `case` is evaluated and the code beneath the condition that matches the input variable is executed. Code execution cannot "fall through" from one case expression to the next; the syntax of the `case` statement requires that each `case` end with a `break`, `return`, or `goto`.

NOTE

The `goto` statements to jump to another label are valid only for the constant pattern (the classic switch statement).

There are important new rules governing the `switch` statement. The restrictions on the type of the variable in the `switch` expression have been removed. Any type, such as `object` in this example, may be used. The case expressions are no longer limited to constant values. Removing that limitation means that reordering `switch` sections may change a program's behavior.

When limited to constant values, no more than one `case` label could match the value of the `switch` expression. Combine that with the rule that every `switch` section must not fall through to the next section, and it followed that the `switch` sections could be rearranged in any order without affecting behavior. Now, with more generalized `switch` expressions, the order of each section matters. The `switch` expressions are evaluated in textual order. Execution transfers to the first `switch` label that matches the `switch` expression.

Note that the `default` case will only be executed if no other case labels match. The `default` case is evaluated last, regardless of its textual order. If there is no `default` case, and none of the other `case` statements match, execution continues at the statement following the `switch` statement. None of the `case` labels code is executed.

when clauses in case expressions

You can make special cases for those shapes that have 0 area by using a `when` clause on the `case` label. A square with a side length of 0, or a circle with a radius of 0 has a 0 area. You specify that condition using a `when` clause on the `case` label:

```
public static double ComputeArea_Version3(object shape)
{
    switch (shape)
    {
        case Square s when s.Side == 0:
        case Circle c when c.Radius == 0:
            return 0;

        case Square s:
            return s.Side * s.Side;
        case Circle c:
            return c.Radius * c.Radius * Math.PI;
        default:
            throw new ArgumentException(
                message: "shape is not a recognized shape",
                paramName: nameof(shape));
    }
}
```

This change demonstrates a few important points about the new syntax. First, multiple `case` labels can be applied to one `switch` section. The statement block is executed when any of those labels is `true`. In this instance, if the `switch` expression is either a circle or a square with 0 area, the method returns the constant 0.

This example introduces two different variables in the two `case` labels for the first `switch` block. Notice that the statements in this `switch` block do not use either the variables `c` (for the circle) or `s` (for the square). Neither of those variables is definitely assigned in this `switch` block. If either of these cases match, clearly one of the variables has been assigned. However, it is impossible to tell which has been assigned at compile-time, because

either case could match at runtime. For that reason, most times when you use multiple `case` labels for the same block, you won't introduce a new variable in the `case` statement, or you will only use the variable in the `when` clause.

Having added those shapes with 0 area, let's add a couple more shape types: a rectangle and a triangle:

```
public static double ComputeArea_Version4(object shape)
{
    switch (shape)
    {
        case Square s when s.Side == 0:
        case Circle c when c.Radius == 0:
        case Triangle t when t.Base == 0 || t.Height == 0:
        case Rectangle r when r.Length == 0 || r.Height == 0:
            return 0;

        case Square s:
            return s.Side * s.Side;
        case Circle c:
            return c.Radius * c.Radius * Math.PI;
        case Triangle t:
            return t.Base * t.Height / 2;
        case Rectangle r:
            return r.Length * r.Height;
        default:
            throw new ArgumentException(
                message: "shape is not a recognized shape",
                paramName: nameof(shape));
    }
}
```

This set of changes adds `case` labels for the degenerate case, and labels and blocks for each of the new shapes.

Finally, you can add a `null` case to ensure the argument is not `null`:

```
public static double ComputeArea_Version5(object shape)
{
    switch (shape)
    {
        case Square s when s.Side == 0:
        case Circle c when c.Radius == 0:
        case Triangle t when t.Base == 0 || t.Height == 0:
        case Rectangle r when r.Length == 0 || r.Height == 0:
            return 0;

        case Square s:
            return s.Side * s.Side;
        case Circle c:
            return c.Radius * c.Radius * Math.PI;
        case Triangle t:
            return t.Base * t.Height / 2;
        case Rectangle r:
            return r.Length * r.Height;
        case null:
            throw new ArgumentNullException(paramName: nameof(shape), message: "Shape must not be null");
        default:
            throw new ArgumentException(
                message: "shape is not a recognized shape",
                paramName: nameof(shape));
    }
}
```

The special behavior for the `null` pattern is interesting because the constant `null` in the pattern does not have a

type but can be converted to any reference type or nullable type. Rather than convert a `null` to any type, the language defines that a `null` value will not match any type pattern, regardless of the compile-time type of the variable. This behavior makes the new `switch` based type pattern consistent with the `is` statement: `is` statements always return `false` when the value being checked is `null`. It's also simpler: once you have checked the type, you don't need an additional null check. You can see that from the fact that there are no null checks in any of the case blocks of the samples above: they are not necessary, since matching the type pattern guarantees a non-null value.

`var` declarations in `case` expressions

The introduction of `var` as one of the match expressions introduces new rules to the pattern match.

The first rule is that the `var` declaration follows the normal type inference rules: The type is inferred to be the static type of the switch expression. From that rule, the type always matches.

The second rule is that a `var` declaration does not have the null check that other type pattern expressions include. That means the variable may be null, and a null check is necessary in that case.

Those two rules mean that in many instances, a `var` declaration in a `case` expression matches the same conditions as a `default` expression. Because any non-default case is preferred to the `default` case, the `default` case will never execute.

NOTE

The compiler does not emit a warning in those cases where a `default` case has been written but will never execute. This is consistent with current `switch` statement behavior where all possible cases have been listed.

The third rule introduces uses where a `var` case may be useful. Imagine that you are doing a pattern match where the input is a string and you are searching for known command values. You might write something like:

```
static object CreateShape(string shapeDescription)
{
    switch (shapeDescription)
    {
        case "circle":
            return new Circle(2);

        case "square":
            return new Square(4);

        case "large-circle":
            return new Circle(12);

        case var o when (o?.Trim().Length ?? 0) == 0:
            // white space
            return null;
        default:
            return "invalid shape description";
    }
}
```

The `var` case matches `null`, the empty string, or any string that contains only white space. Notice that the preceding code uses the `?.` operator to ensure that it does not accidentally throw a `NullReferenceException`. The `default` case handles any other string values that are not understood by this command parser.

This is one example where you may want to consider a `var` case expression that is distinct from a `default` expression.

Conclusions

Pattern Matching constructs enable you to easily manage control flow among different variables and types that are not related by an inheritance hierarchy. You can also control logic to use any condition you test on the variable. It enables patterns and idioms that you'll need more often as you build more distributed applications, where data and the methods that manipulate that data are separate. You'll notice that the shape structs used in this sample do not contain any methods, just read-only properties. Pattern Matching works with any data type. You write expressions that examine the object, and make control flow decisions based on those conditions.

Compare the code from this sample with the design that would follow from creating a class hierarchy for an abstract `Shape` and specific derived shapes each with their own implementation of a virtual method to calculate the area. You'll often find that pattern matching expressions can be a very useful tool when you are working with data and want to separate the data storage concerns from the behavior concerns.

Write safe and efficient C# code

3/1/2019 • 14 minutes to read • [Edit Online](#)

New features in C# enable you to write verifiable safe code with better performance. If you carefully apply these techniques, fewer scenarios require unsafe code. These features make it easier to use references to value types as method arguments and method returns. When done safely, these techniques minimize copying value types. By using value types, you can minimize the number of allocations and garbage collection passes.

Much of the sample code in this article uses features added in C# 7.2. To use those features, you must configure your project to use C# 7.2 or later. For more information on setting the language version, see [configure the language version](#).

This article focuses on techniques for efficient resource management. One advantage to using value types is that they often avoid heap allocations. The disadvantage is that they're copied by value. This tradeoff makes it harder to optimize algorithms that operate on large amounts of data. New language features in C# 7.2 provide mechanisms that enable safe efficient code using references to value types. Use these features wisely to minimize both allocations and copy operations. This article explores those new features.

This article focuses on the following resource management techniques:

- Declare a `readonly struct` to express that a type is **immutable** and enables the compiler to save copies when using `in` parameters.
- Use a `ref readonly` return when the return value is a `struct` larger than `IntPtr.Size` and the storage lifetime is greater than the method returning the value.
- When the size of a `readonly struct` is bigger than `IntPtr.Size`, you should pass it as an `in` parameter for performance reasons.
- Never pass a `struct` as an `in` parameter unless it's declared with the `readonly` modifier because it may negatively affect performance and could lead to an obscure behavior.
- Use a `ref struct`, or a `readonly ref struct` such as `Span<T>` or `ReadOnlySpan<T>` to work with memory as a sequence of bytes.

These techniques force you to balance two competing goals with regard to **references** and **values**. Variables that are **reference types** hold a reference to the location in memory. Variables that are **value types** directly contain their value. These differences highlight the key differences that are important for managing memory resources. **Value types** are typically copied when passed to a method or returned from a method. This behavior includes copying the value of `this` when calling members of a value type. The cost of the copy is related to the size of the type.

Reference types are allocated on the managed heap. Each new object requires a new allocation, and subsequently must be reclaimed. Both these operations take time. The reference is copied when a reference type is passed as an argument to a method or returned from a method.

This article uses the following example concept of the 3D-point structure to explain these recommendations:

```
public struct Point3D
{
    public double X;
    public double Y;
    public double Z;
}
```

Different examples use different implementations of this concept.

Declare readonly structs for immutable value types

Declaring a `struct` using the `readonly` modifier informs the compiler that your intent is to create an immutable type. The compiler enforces that design decision with the following rules:

- All field members must be `readonly`
- All properties must be read-only, including auto-implemented properties.

These two rules are sufficient to ensure that no member of a `readonly struct` modifies the state of that struct. The `struct` is immutable. The `Point3D` structure could be defined as an immutable struct as shown in the following example:

```
readonly public struct ReadonlyPoint3D
{
    public ReadonlyPoint3D(double x, double y, double z)
    {
        this.X = x;
        this.Y = y;
        this.Z = z;
    }

    public double X { get; }
    public double Y { get; }
    public double Z { get; }
}
```

Follow this recommendation whenever your design intent is to create an immutable value type. Any performance improvements are an added benefit. The `readonly struct` clearly expresses your design intent.

Use `ref readonly return` statements for large structures when possible

You can return values by reference when the value being returned isn't local to the returning method. Returning by reference means that only the reference is copied, not the structure. In the following example, the `Origin` property can't use a `ref` return because the value being returned is a local variable:

```
public Point3D Origin => new Point3D(0,0,0);
```

However, the following property definition can be returned by reference because the returned value is a static member:

```
public struct Point3D
{
    private static Point3D origin = new Point3D(0,0,0);

    // Dangerous! returning a mutable reference to internal storage
    public ref Point3D Origin => ref origin;

    // other members removed for space
}
```

You don't want callers modifying the origin, so you should return the value by `readonly ref`:

```

public struct Point3D
{
    private static Point3D origin = new Point3D(0,0,0);

    public static ref readonly Point3D Origin => ref origin;

    // other members removed for space
}

```

Returning `ref readonly` enables you to save copying larger structures and preserve the immutability of your internal data members.

At the call site, callers make the choice to use the `Origin` property as a `readonly ref` or as a value:

```

var originValue = Point3D.Origin;
ref readonly var originReference = ref Point3D.Origin;

```

The first assignment in the preceding code makes a copy of the `origin` constant and assigns that copy. The second assigns a reference. Notice that the `readonly` modifier must be part of the declaration of the variable. The reference to which it refers can't be modified. Attempts to do so result in a compile-time error.

The `readonly` modifier is required on the declaration of `originReference`.

The compiler enforces that the caller can't modify the reference. Attempts to assign the value directly generate a compile-time error. However, the compiler can't know if any member method modifies the state of the struct. To ensure that the object isn't modified, the compiler creates a copy and calls member references using that copy. Any modifications are to that defensive copy.

Apply the `in` modifier to `readonly struct` parameters larger than `System.IntPtr.Size`

The `in` keyword complements the existing `ref` and `out` keywords to pass arguments by reference. The `in` keyword specifies passing the argument by reference, but the called method doesn't modify the value.

This addition provides a full vocabulary to express your design intent. Value types are copied when passed to a called method when you don't specify any of the following modifiers in the method signature. Each of these modifiers specifies that a variable is passed by reference, avoiding the copy. Each modifier expresses a different intent:

- `out`: This method sets the value of the argument used as this parameter.
- `ref`: This method may set the value of the argument used as this parameter.
- `in`: This method doesn't modify the value of the argument used as this parameter.

Add the `in` modifier to pass an argument by reference and declare your design intent to pass arguments by reference to avoid unnecessary copying. You don't intend to modify the object used as that argument.

This practice often improves performance for readonly value types that are larger than `IntPtr.Size`. For simple types (`sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal` and `bool`, and `enum` types), any potential performance gains are minimal. In fact, performance may degrade by using pass-by-reference for types smaller than `IntPtr.Size`.

The following code shows an example of a method that calculates the distance between two points in 3D space.

```

private static double CalculateDistance(in Point3D point1, in Point3D point2)
{
    double xDifference = point1.X - point2.X;
    double yDifference = point1.Y - point2.Y;
    double zDifference = point1.Z - point2.Z;

    return Math.Sqrt(xDifference * xDifference + yDifference * yDifference + zDifference * zDifference);
}

```

The arguments are two structures that each contain three doubles. A double is 8 bytes, so each argument is 24 bytes. By specifying the `in` modifier, you pass a 4 byte or 8-byte reference to those arguments, depending on the architecture of the machine. The difference in size is small, but it adds up when your application calls this method in a tight loop using many different values.

The `in` modifier complements `out` and `ref` in other ways as well. You can't create overloads of a method that differ only in the presence of `in`, `out`, or `ref`. These new rules extend the same behavior that had always been defined for `out` and `ref` parameters. Like the `out` and `ref` modifiers, value types aren't boxed because the `in` modifier is applied.

The `in` modifier may be applied to any member that takes parameters: methods, delegates, lambdas, local functions, indexers, operators.

Another feature of `in` parameters is that you may use literal values or constants for the argument to an `in` parameter. Also, unlike a `ref` or `out` parameter, you don't need to apply the `in` modifier at the call site. The following code shows you two examples of calling the `CalculateDistance` method. The first uses two local variables passed by reference. The second includes a temporary variable created as part of the method call.

```

var distance = CalculateDistance(pt1, pt2);
var fromOrigin = CalculateDistance(pt1, new Point3D());

```

There are several ways in which the compiler enforces the read-only nature of an `in` argument. First of all, the called method can't directly assign to an `in` parameter. It can't directly assign to any field of an `in` parameter when that value is a `struct` type. In addition, you can't pass an `in` parameter to any method using the `ref` or `out` modifier. These rules apply to any field of an `in` parameter, provided the field is a `struct` type and the parameter is also a `struct` type. In fact, these rules apply for multiple layers of member access provided the types at all levels of member access are `structs`. The compiler enforces that `struct` types passed as `in` arguments and their `struct` members are read-only variables when used as arguments to other methods.

The use of `in` parameters can avoid the potential performance costs of making copies. It doesn't change the semantics of any method call. Therefore, you don't need to specify the `in` modifier at the call site. Omitting the `in` modifier at the call site informs the compiler that it's allowed to make a copy of the argument for the following reasons:

- There exists an implicit conversion but not an identity conversion from the argument type to the parameter type.
- The argument is an expression but doesn't have a known storage variable.
- An overload exists that differs by the presence or absence of `in`. In that case, the by value overload is a better match.

These rules are useful as you update existing code to use read-only reference arguments. Inside the called method, you can call any instance method that uses by value parameters. In those instances, a copy of the `in` parameter is created. Because the compiler may create a temporary variable for any `in` parameter, you can also specify default values for any `in` parameter. The following code specifies the origin (point 0,0) as the default value for the second point:

```

private static double CalculateDistance2(in Point3D point1, in Point3D point2 = default)
{
    double xDifference = point1.X - point2.X;
    double yDifference = point1.Y - point2.Y;
    double zDifference = point1.Z - point2.Z;

    return Math.Sqrt(xDifference * xDifference + yDifference * yDifference + zDifference * zDifference);
}

```

To force the compiler to pass read-only arguments by reference, specify the `in` modifier on the arguments at the call site, as shown in the following code:

```

distance = CalculateDistance(in pt1, in pt2);
distance = CalculateDistance(in pt1, new Point3D());
distance = CalculateDistance(pt1, in Point3D.Origin);

```

This behavior makes it easier to adopt `in` parameters over time in large codebases where performance gains are possible. You add the `in` modifier to method signatures first. Then, you can add the `in` modifier at call sites and create `readonly struct` types to enable the compiler to avoid creating defensive copies of `in` parameters in more locations.

The `in` parameter designation can also be used with reference types or numeric values. However, the benefits in both cases are minimal, if any.

Never use mutable structs as `in` argument

The techniques described above explain how to avoid copies by returning references and passing values by reference. These techniques work best when the argument types are declared as `readonly struct` types.

Otherwise, the compiler must create **defensive copies** in many situations to enforce the readonly-ness of any arguments. Consider the following example that calculates the distance of a 3D point from the origin:

```

private static double CalculateDistance(in Point3D point1, in Point3D point2)
{
    double xDifference = point1.X - point2.X;
    double yDifference = point1.Y - point2.Y;
    double zDifference = point1.Z - point2.Z;

    return Math.Sqrt(xDifference * xDifference + yDifference * yDifference + zDifference * zDifference);
}

```

The `Point3D` structure is *not* a `readonly struct`. There are six different property access calls in the body of this method. On first examination, you may have thought these accesses were safe. After all, a `get` accessor shouldn't modify the state of the object. But there's no language rule that enforces that. It's only a common convention. Any type could implement a `get` accessor that modified the internal state. Without some language guarantee, the compiler must create a temporary copy of the argument before calling any member. The temporary storage is created on the stack, the values of the argument are copied to the temporary storage, and the value is copied to the stack for each member access as the `this` argument. In many situations, these copies harm performance enough that pass-by-value is faster than pass-by-readonly-reference when the argument type isn't a `readonly struct`.

Instead, if the distance calculation uses the immutable struct, `ReadonlyPoint3D`, temporary objects are not needed:

```

private static double CalculateDistance3(in ReadonlyPoint3D point1, in ReadonlyPoint3D point2 = default)
{
    double xDifference = point1.X - point2.X;
    double yDifference = point1.Y - point2.Y;
    double zDifference = point1.Z - point2.Z;

    return Math.Sqrt(xDifference * xDifference + yDifference * yDifference + zDifference * zDifference);
}

```

The compiler generates more efficient code when you call members of a `readonly struct`: The `this` reference, instead of a copy of the receiver, is always an `in` parameter passed by reference to the member method. This optimization saves copying when you use a `readonly struct` as an `in` argument.

You can see an example program that demonstrates the performance differences using [Benchmark.net](#) in our [samples repository](#) on GitHub. It compares passing a mutable struct by value and by reference with passing an immutable struct by value and by reference. The use of the immutable struct and pass by reference is fastest.

Use `ref struct` types to work with blocks or memory on a single stack frame

A related language feature is the ability to declare a value type that must be constrained to a single stack frame. This restriction enables the compiler to make several optimizations. The primary motivation for this feature was `Span<T>` and related structures. You'll achieve performance improvements from these enhancements by using new and updated .NET APIs that make use of the `Span<T>` type.

You may have similar requirements working with memory created using `stackalloc` or when using memory from interop APIs. You can define your own `ref struct` types for those needs.

`readonly ref struct` type

Declaring a struct as `readonly ref` combines the benefits and restrictions of `ref struct` and `readonly struct` declarations. The memory used by the readonly span is restricted to a single stack frame, and the memory used by the readonly span can't be modified.

Conclusions

Using value types minimizes the number of allocation operations:

- Storage for value types is stack allocated for local variables and method arguments.
- Storage for value types that are members of other objects is allocated as part of that object, not as a separate allocation.
- Storage for value type return values is stack allocated.

Contrast that with reference types in those same situations:

- Storage for reference types are heap allocated for local variables and method arguments. The reference is stored on the stack.
- Storage for reference types that are members of other objects are separately allocated on the heap. The containing object stores the reference.
- Storage for reference type return values is heap allocated. The reference to that storage is stored on the stack.

Minimizing allocations comes with tradeoffs. You copy more memory when the size of the `struct` is larger than the size of a reference. A reference is typically 64 bits or 32 bits, and depends on the target machine CPU.

These tradeoffs generally have minimal performance impact. However, for large structs or larger collections, the

performance impact increases. The impact can be large in tight loops and hot paths for programs.

These enhancements to the C# language are designed for performance critical algorithms where minimizing memory allocations is a major factor in achieving the necessary performance. You may find that you don't often use these features in the code you write. However, these enhancements have been adopted throughout .NET. As more and more APIs make use of these features, you'll see the performance of your applications improve.

Expression Trees

3/16/2019 • 2 minutes to read • [Edit Online](#)

If you have used LINQ, you have experience with a rich library where the `Func` types are part of the API set. (If you are not familiar with LINQ, you probably want to read [the LINQ tutorial](#) and the article about [lambda expressions](#) before this one.) *Expression Trees* provide richer interaction with the arguments that are functions.

You write function arguments, typically using Lambda Expressions, when you create LINQ queries. In a typical LINQ query, those function arguments are transformed into a delegate the compiler creates.

When you want to have a richer interaction, you need to use *Expression Trees*. Expression Trees represent code as a structure that you can examine, modify, or execute. These tools give you the power to manipulate code during run time. You can write code that examines running algorithms, or injects new capabilities. In more advanced scenarios, you can modify running algorithms, and even translate C# expressions into another form for execution in another environment.

You've likely already written code that uses Expression Trees. Entity Framework's LINQ APIs accept Expression Trees as the arguments for the LINQ Query Expression Pattern. That enables [Entity Framework](#) to translate the query you wrote in C# into SQL that executes in the database engine. Another example is [Moq](#), which is a popular mocking framework for .NET.

The remaining sections of this tutorial will explore what Expression Trees are, examine the framework classes that support expression trees, and show you how to work with expression trees. You'll learn how to read expression trees, how to create expression trees, how to create modified expression trees, and how to execute the code represented by expression trees. After reading, you will be ready to use these structures to create rich adaptive algorithms.

Expression Trees Explained

5/4/2018 • 4 minutes to read • [Edit Online](#)

[Previous -- Overview](#)

An Expression Tree is a data structure that defines code. They are based on the same structures that a compiler uses to analyze code and generate the compiled output. As you read through this tutorial, you will notice quite a bit of similarity between Expression Trees and the types used in the Roslyn APIs to build [Analyzers and CodeFixes](#). (Analyzers and CodeFixes are NuGet packages that perform static analysis on code and can suggest potential fixes for a developer.) The concepts are similar, and the end result is a data structure that allows examination of the source code in a meaningful way. However, Expression Trees are based on a totally different set of classes and APIs than the Roslyn APIs.

Let's look at a simple example. Here's a line of code:

```
var sum = 1 + 2;
```

If you were to analyze this as an expression tree, the tree contains several nodes. The outermost node is a variable declaration statement with assignment (`var sum = 1 + 2;`) That outermost node contains several child nodes: a variable declaration, an assignment operator, and an expression representing the right hand side of the equals sign. That expression is further subdivided into expressions that represent the addition operation, and left and right operands of the addition.

Let's drill down a bit more into the expressions that make up the right side of the equals sign. The expression is `1 + 2`. That's a binary expression. More specifically, it's a binary addition expression. A binary addition expression has two children, representing the left and right nodes of the addition expression. Here, both nodes are constant expressions: The left operand is the value `1`, and the right operand is the value `2`.

Visually, the entire statement is a tree: You could start at the root node, and travel to each node in the tree to see the code that makes up the statement:

- Variable declaration statement with assignment (`var sum = 1 + 2;`)
 - Implicit variable type declaration (`var sum`)
 - Implicit var keyword (`var`)
 - Variable name declaration (`sum`)
 - Assignment operator (`=`)
 - Binary addition expression (`1 + 2`)
 - Left operand (`1`)
 - Addition operator (`+`)
 - Right operand (`2`)

This may look complicated, but it is very powerful. Following the same process, you can decompose much more complicated expressions. Consider this expression:

```
var finalAnswer = this.SecretSauceFunction(  
    currentState.createInterimResult(), currentState.createSecondValue(1, 2),  
    decisionServer.considerFinalOptions("hello")) +  
    MoreSecretSauce('A', DateTime.Now, true);
```

The expression above is also a variable declaration with an assignment. In this instance, the right hand side of the assignment is a much more complicated tree. I'm not going to decompose this expression, but consider what the different nodes might be. There are method calls using the current object as a receiver, one that has an explicit `this` receiver, one that does not. There are method calls using other receiver objects, there are constant arguments of different types. And finally, there is a binary addition operator. Depending on the return type of `SecretSauceFunction()` or `MoreSecretSauce()`, that binary addition operator may be a method call to an overridden addition operator, resolving to a static method call to the binary addition operator defined for a class.

Despite this perceived complexity, the expression above creates a tree structure that can be navigated as easily as the first sample. You can keep traversing child nodes to find leaf nodes in the expression. Parent nodes will have references to their children, and each node has a property that describes what kind of node it is.

The structure of an expression tree is very consistent. Once you've learned the basics, you can understand even the most complex code when it is represented as an expression tree. The elegance in the data structure explains how the C# compiler can analyze the most complex C# programs and create proper output from that complicated source code.

Once you become familiar with the structure of expression trees, you will find that knowledge you've gained quickly enables you to work with many more and more advanced scenarios. There is incredible power to expression trees.

In addition to translating algorithms to execute in other environments, expression trees can be used to make it easier to write algorithms that inspect code before executing it. You can write a method whose arguments are expressions and then examine those expressions before executing the code. The Expression Tree is a full representation of the code: you can see values of any sub-expression. You can see method and property names. You can see the value of any constant expressions. You can also convert an expression tree into an executable delegate, and execute the code.

The APIs for Expression Trees enable you to create trees that represent almost any valid code construct. However, to keep things as simple as possible, some C# idioms cannot be created in an expression tree. One example is asynchronous expressions (using the `async` and `await` keywords). If your needs require asynchronous algorithms, you would need to manipulate the `Task` objects directly, rather than rely on the compiler support. Another is in creating loops. Typically, you create these by using `for`, `foreach`, `while` or `do` loops. As you'll see [later in this series](#), the APIs for expression trees support a single loop expression, with `break` and `continue` expressions that control repeating the loop.

The one thing you can't do is modify an expression tree. Expression Trees are immutable data structures. If you want to mutate (change) an expression tree, you must create a new tree that is a copy of the original, but with your desired changes.

[Next -- Framework Types Supporting Expression Trees](#)

Framework Types Supporting Expression Trees

8/11/2018 • 3 minutes to read • [Edit Online](#)

[Previous -- Expression Trees Explained](#)

There is a large list of classes in the .NET Core framework that work with Expression Trees. You can see the full list at [System.Linq.Expressions](#). Rather than run through the full list, let's understand how the framework classes have been designed.

In language design, an expression is a body of code that evaluates and returns a value. Expressions may be very simple: the constant expression `1` returns the constant value of 1. They may be more complicated: The expression `(-B + Math.Sqrt(B*B - 4 * A * C)) / (2 * A)` returns one root for a quadratic equation (in the case where the equation has a solution).

It all starts with System.Linq.Expression

One of the complexities of working with expression trees is that many different kinds of expressions are valid in many places in programs. Consider an assignment expression. The right hand side of an assignment could be a constant value, a variable, a method call expression, or others. That language flexibility means that you may encounter many different expression types anywhere in the nodes of a tree when you traverse an expression tree. Therefore, when you can work with the base expression type, that's the simplest way to work. However, sometimes you need to know more. The base Expression class contains a `NodeType` property for this purpose. It returns an `ExpressionType` which is an enumeration of possible expression types. Once you know the type of the node, you can cast it to that type, and perform specific actions knowing the type of the expression node. You can search for certain node types, and then work with the specific properties of that kind of expression.

For example, this code will print the name of a variable for a variable access expression. I've followed the practice of checking the node type, then casting to a variable access expression and then checking the properties of the specific expression type:

```
Expression<Func<int, int>> addFive = (num) => num + 5;

if (addFive.NodeType == ExpressionType.Lambda)
{
    var lambdaExp = (LambdaExpression)addFive;

    var parameter = lambdaExp.Parameters.First();

    Console.WriteLine(parameter.Name);
    Console.WriteLine(parameter.Type);
}
```

Creating Expression Trees

The `System.Linq.Expression` class also contains many static methods to create expressions. These methods create an expression node using the arguments supplied for its children. In this way, you build an expression up from its leaf nodes. For example, this code builds an Add expression:

```
// Addition is an add expression for "1 + 2"
var one = Expression.Constant(1, typeof(int));
var two = Expression.Constant(2, typeof(int));
var addition = Expression.Add(one, two);
```

You can see from this simple example that many types are involved in creating and working with expression trees. That complexity is necessary to provide the capabilities of the rich vocabulary provided by the C# language.

Navigating the APIs

There are Expression node types that map to almost all of the syntax elements of the C# language. Each type has specific methods for that type of language element. It's a lot to keep in your head at one time. Rather than try to memorize everything, here are the techniques I use to work with Expression trees:

1. Look at the members of the `ExpressionType` enum to determine possible nodes you should be examining. This really helps when you want to traverse and understand an expression tree.
2. Look at the static members of the `Expression` class to build an expression. Those methods can build any expression type from a set of its child nodes.
3. Look at the `ExpressionVisitor` class to build a modified expression tree.

You'll find more as you look at each of those three areas. Invariably, you will find what you need when you start with one of those three steps.

[Next -- Executing Expression Trees](#)

Executing Expression Trees

3/1/2019 • 6 minutes to read • [Edit Online](#)

[Previous -- Framework Types Supporting Expression Trees](#)

An *expression tree* is a data structure that represents some code. It is not compiled and executable code. If you want to execute the .NET code that is represented by an expression tree, you must convert it into executable IL instructions.

Lambda Expressions to Functions

You can convert any `LambdaExpression`, or any type derived from `LambdaExpression` into executable IL. Other expression types cannot be directly converted into code. This restriction has little effect in practice. Lambda expressions are the only types of expressions that you would want to execute by converting to executable intermediate language (IL). (Think about what it would mean to directly execute a `ConstantExpression`. Would it mean anything useful?) Any expression tree that is a `LambdaExpression`, or a type derived from `LambdaExpression` can be converted to IL. The expression type `Expression<TDelegate>` is the only concrete example in the .NET Core libraries. It's used to represent an expression that maps to any delegate type. Because this type maps to a delegate type, .NET can examine the expression, and generate IL for an appropriate delegate that matches the signature of the lambda expression.

In most cases, this creates a simple mapping between an expression, and its corresponding delegate. For example, an expression tree that is represented by `Expression<Func<int>>` would be converted to a delegate of the type `Func<int>`. For a lambda expression with any return type and argument list, there exists a delegate type that is the target type for the executable code represented by that lambda expression.

The `LambdaExpression` type contains `Compile` and `CompileToMethod` members that you would use to convert an expression tree to executable code. The `Compile` method creates a delegate. The `CompileToMethod` method updates a `MethodBuilder` object with the IL that represents the compiled output of the expression tree. Note that `CompileToMethod` is only available in the full desktop framework, not in the .NET Core.

Optionally, you can also provide a `DebugInfoGenerator` that will receive the symbol debugging information for the generated delegate object. This enables you to convert the expression tree into a delegate object, and have full debugging information about the generated delegate.

You would convert an expression into a delegate using the following code:

```
Expression<Func<int>> add = () => 1 + 2;
var func = add.Compile(); // Create Delegate
var answer = func(); // Invoke Delegate
Console.WriteLine(answer);
```

Notice that the delegate type is based on the expression type. You must know the return type and the argument list if you want to use the delegate object in a strongly typed manner. The `LambdaExpression.Compile()` method returns the `Delegate` type. You will have to cast it to the correct delegate type to have any compile-time tools check the argument list or return type.

Execution and Lifetimes

You execute the code by invoking the delegate created when you called `LambdaExpression.Compile()`. You can see this above where `add.Compile()` returns a delegate. Invoking that delegate, by calling `func()` executes the code.

That delegate represents the code in the expression tree. You can retain the handle to that delegate and invoke it later. You don't need to compile the expression tree each time you want to execute the code it represents. (Remember that expression trees are immutable, and compiling the same expression tree later will create a delegate that executes the same code.)

I will caution you against trying to create any more sophisticated caching mechanisms to increase performance by avoiding unnecessary compile calls. Comparing two arbitrary expression trees to determine if they represent the same algorithm will also be time consuming to execute. You'll likely find that the compute time you save avoiding any extra calls to `LambdaExpression.Compile()` will be more than consumed by the time executing code that determines of two different expression trees result in the same executable code.

Caveats

Compiling a lambda expression to a delegate and invoking that delegate is one of the simplest operations you can perform with an expression tree. However, even with this simple operation, there are caveats you must be aware of.

Lambda Expressions create closures over any local variables that are referenced in the expression. You must guarantee that any variables that would be part of the delegate are usable at the location where you call `Compile`, and when you execute the resulting delegate.

In general, the compiler will ensure that this is true. However, if your expression accesses a variable that implements `IDisposable`, it's possible that your code might dispose of the object while it is still held by the expression tree.

For example, this code works fine, because `int` does not implement `IDisposable`:

```
private static Func<int, int> CreateBoundFunc()
{
    var constant = 5; // constant is captured by the expression tree
    Expression<Func<int, int>> expression = (b) => constant + b;
    var rVal = expression.Compile();
    return rVal;
}
```

The delegate has captured a reference to the local variable `constant`. That variable is accessed at any time later, when the function returned by `CreateBoundFunc` executes.

However, consider this (rather contrived) class that implements `IDisposable`:

```
public class Resource : IDisposable
{
    private bool isDisposed = false;
    public int Argument
    {
        get
        {
            if (!isDisposed)
                return 5;
            else throw new ObjectDisposedException("Resource");
        }
    }

    public void Dispose()
    {
        isDisposed = true;
    }
}
```

If you use it in an expression as shown below, you'll get an `ObjectDisposedException` when you execute the code referenced by the `Resource.Argument` property:

```
private static Func<int, int> CreateBoundResource()
{
    using (var constant = new Resource()) // constant is captured by the expression tree
    {
        Expression<Func<int, int>> expression = (b) => constant.Argument + b;
        var rVal = expression.Compile();
        return rVal;
    }
}
```

The delegate returned from this method has closed over the `constant` object, which has been disposed of. (It's been disposed, because it was declared in a `using` statement.)

Now, when you execute the delegate returned from this method, you'll have a `ObjectDisposedException` thrown at the point of execution.

It does seem strange to have a runtime error representing a compile-time construct, but that's the world we enter when we work with expression trees.

There are a lot of permutations of this problem, so it's hard to offer general guidance to avoid it. Be careful about accessing local variables when defining expressions, and be careful about accessing state in the current object (represented by `this`) when creating an expression tree that can be returned by a public API.

The code in your expression may reference methods or properties in other assemblies. That assembly must be accessible when the expression is defined, and when it is compiled, and when the resulting delegate is invoked. You'll be met with a `ReferencedAssemblyNotFoundException` in cases where it is not present.

Summary

Expression Trees that represent lambda expressions can be compiled to create a delegate that you can execute. This provides one mechanism to execute the code represented by an expression tree.

The Expression Tree does represent the code that would execute for any given construct you create. As long as the environment where you compile and execute the code matches the environment where you create the expression, everything works as expected. When that doesn't happen, the errors are very predictable, and they will be caught in your first tests of any code using the expression trees.

Interpreting Expressions

3/1/2019 • 14 minutes to read • [Edit Online](#)

[Previous -- Executing Expressions](#)

Now, let's write some code to examine the structure of an *expression tree*. Every node in an expression tree will be an object of a class that is derived from `Expression`.

That design makes visiting all the nodes in an expression tree a relatively straight forward recursive operation. The general strategy is to start at the root node and determine what kind of node it is.

If the node type has children, recursively visit the children. At each child node, repeat the process used at the root node: determine the type, and if the type has children, visit each of the children.

Examining an Expression with No Children

Let's start by visiting each node in a very simple expression tree. Here's the code that creates a constant expression and then examines its properties:

```
var constant = Expression.Constant(24, typeof(int));

Console.WriteLine($"This is a/an {constant.NodeType} expression type");
Console.WriteLine($"The type of the constant value is {constant.Type}");
Console.WriteLine($"The value of the constant value is {constant.Value}");
```

This will print the following:

```
This is an Constant expression type
The type of the constant value is System.Int32
The value of the constant value is 24
```

Now, let's write the code that would examine this expression and write out some important properties about it. Here's that code:

Examining a simple Addition Expression

Let's start with the addition sample from the introduction to this section.

```
Expression<Func<int>> sum = () => 1 + 2;
```

I'm not using `var` to declare this expression tree, as it is not possible because the right-hand side of the assignment is implicitly typed. To understand this more deeply, read [here](#).

The root node is a `LambdaExpression`. In order to get the interesting code on the right hand side of the `=>` operator, you need to find one of the children of the `LambdaExpression`. We'll do that with all the expressions in this section. The parent node does help us find the return type of the `LambdaExpression`.

To examine each node in this expression, we'll need to recursively visit a number of nodes. Here's a simple first implementation:

```

Expression<Func<int, int, int>> addition = (a, b) => a + b;

Console.WriteLine($"This expression is a {addition.NodeType} expression type");
Console.WriteLine($"The name of the lambda is {((addition.Name == null) ? "<null>" : addition.Name)}");
Console.WriteLine($"The return type is {addition.ReturnType.ToString()}");
Console.WriteLine($"The expression has {addition.Parameters.Count} arguments. They are:");
foreach(var argumentExpression in addition.Parameters)
{
    Console.WriteLine($"    \tParameter Type: {argumentExpression.Type.ToString()}, Name: {argumentExpression.Name}");
}

var additionBody = (BinaryExpression)addition.Body;
Console.WriteLine($"The body is a {additionBody.NodeType} expression");
Console.WriteLine($"The left side is a {additionBody.Left.NodeType} expression");
var left = (ParameterExpression)additionBody.Left;
Console.WriteLine($"    \tParameter Type: {left.Type.ToString()}, Name: {left.Name}");
Console.WriteLine($"The right side is a {additionBody.Right.NodeType} expression");
var right= (ParameterExpression)additionBody.Right;
Console.WriteLine($"    \tParameter Type: {right.Type.ToString()}, Name: {right.Name}");

```

This sample prints the following output:

```

This expression is a/an Lambda expression type
The name of the lambda is <null>
The return type is System.Int32
The expression has 2 arguments. They are:
    Parameter Type: System.Int32, Name: a
    Parameter Type: System.Int32, Name: b
The body is a/an Add expression
The left side is a Parameter expression
    Parameter Type: System.Int32, Name: a
The right side is a Parameter expression
    Parameter Type: System.Int32, Name: b

```

You'll notice a lot of repetition in the code sample above. Let's clean that up and build a more general purpose expression node visitor. That's going to require us to write a recursive algorithm. Any node could be of a type that might have children. Any node that has children requires us to visit those children and determine what that node is. Here's the cleaned up version that utilizes recursion to visit the addition operations:

```

// Base Visitor class:
public abstract class Visitor
{
    private readonly Expression node;

    protected Visitor(Expression node)
    {
        this.node = node;
    }

    public abstract void Visit(string prefix);

    public ExpressionType NodeType => this.node.NodeType;
    public static Visitor CreateFromExpression(Expression node)
    {
        switch(node.NodeType)
        {
            case ExpressionType.Constant:
                return new ConstantVisitor((ConstantExpression)node);
            case ExpressionType.Lambda:
                return new LambdaVisitor((LambdaExpression)node);
            case ExpressionType.Parameter:
                return new ParameterVisitor((ParameterExpression)node);
        }
    }
}

```

```

        case ExpressionType.Add:
            return new BinaryVisitor((BinaryExpression)node);
        default:
            Console.Error.WriteLine($"Node not processed yet: {node.NodeType}");
            return default(Visitor);
    }
}

// Lambda Visitor
public class LambdaVisitor : Visitor
{
    private readonly LambdaExpression node;
    public LambdaVisitor(LambdaExpression node) : base(node)
    {
        this.node = node;
    }

    public override void Visit(string prefix)
    {
        Console.WriteLine($"{prefix}This expression is a {NodeType} expression type");
        Console.WriteLine($"{prefix}The name of the lambda is {((node.Name == null) ? "<null>" :
node.Name)}");
        Console.WriteLine($"{prefix}The return type is {node.ReturnType.ToString()}");
        Console.WriteLine($"{prefix}The expression has {node.Parameters.Count} argument(s). They are:");
        // Visit each parameter:
        foreach (var argumentExpression in node.Parameters)
        {
            var argumentVisitor = Visitor.CreateFromExpression(argumentExpression);
            argumentVisitor.Visit(prefix + "\t");
        }
        Console.WriteLine($"{prefix}The expression body is:");
        // Visit the body:
        var bodyVisitor = Visitor.CreateFromExpression(node.Body);
        bodyVisitor.Visit(prefix + "\t");
    }
}

// Binary Expression Visitor:
public class BinaryVisitor : Visitor
{
    private readonly BinaryExpression node;
    public BinaryVisitor(BinaryExpression node) : base(node)
    {
        this.node = node;
    }

    public override void Visit(string prefix)
    {
        Console.WriteLine($"{prefix}This binary expression is a {NodeType} expression");
        var left = Visitor.CreateFromExpression(node.Left);
        Console.WriteLine($"{prefix}The Left argument is:");
        left.Visit(prefix + "\t");
        var right = Visitor.CreateFromExpression(node.Right);
        Console.WriteLine($"{prefix}The Right argument is:");
        right.Visit(prefix + "\t");
    }
}

// Parameter visitor:
public class ParameterVisitor : Visitor
{
    private readonly ParameterExpression node;
    public ParameterVisitor(ParameterExpression node) : base(node)
    {
        this.node = node;
    }

    public override void Visit(string prefix)

```

```

    {
        Console.WriteLine($"{prefix}This is an {NodeType} expression type");
        Console.WriteLine($"{prefix}Type: {node.Type.ToString()}, Name: {node.Name}, ByRef: {node.IsByRef}");
    }
}

// Constant visitor:
public class ConstantVisitor : Visitor
{
    private readonly ConstantExpression node;
    public ConstantVisitor(ConstantExpression node) : base(node)
    {
        this.node = node;
    }

    public override void Visit(string prefix)
    {
        Console.WriteLine($"{prefix}This is an {NodeType} expression type");
        Console.WriteLine($"{prefix}The type of the constant value is {node.Type}");
        Console.WriteLine($"{prefix}The value of the constant value is {node.Value}");
    }
}

```

This algorithm is the basis of an algorithm that can visit any arbitrary `LambdaExpression`. There are a lot of holes, namely that the code I created only looks for a very small sample of the possible sets of expression tree nodes that it may encounter. However, you can still learn quite a bit from what it produces. (The default case in the `Visitor.CreateFromExpression` method prints a message to the error console when a new node type is encountered. That way, you know to add a new expression type.)

When you run this visitor on the addition expression shown above, you get the following output:

```

This expression is a/an Lambda expression type
The name of the lambda is <null>
The return type is System.Int32
The expression has 2 argument(s). They are:
    This is an Parameter expression type
    Type: System.Int32, Name: a, ByRef: False
    This is an Parameter expression type
    Type: System.Int32, Name: b, ByRef: False
The expression body is:
    This binary expression is a Add expression
    The Left argument is:
        This is an Parameter expression type
        Type: System.Int32, Name: a, ByRef: False
    The Right argument is:
        This is an Parameter expression type
        Type: System.Int32, Name: b, ByRef: False

```

Now that you've built a more general visitor implementation, you can visit and process many more different types of expressions.

Examining an Addition Expression with Many Levels

Let's try a more complicated example, yet still limit the node types to addition only:

```
Expression<Func<int>> sum = () => 1 + 2 + 3 + 4;
```

Before you run this on the visitor algorithm, try a thought exercise to work out what the output might be. Remember that the `+` operator is a *binary operator*: it must have two children, representing the left and right operands. There are several possible ways to construct a tree that could be correct:

```

Expression<Func<int>> sum1 = () => 1 + (2 + (3 + 4));
Expression<Func<int>> sum2 = () => ((1 + 2) + 3) + 4;

Expression<Func<int>> sum3 = () => (1 + 2) + (3 + 4);
Expression<Func<int>> sum4 = () => 1 + ((2 + 3) + 4);
Expression<Func<int>> sum5 = () => (1 + (2 + 3)) + 4;

```

You can see the separation into two possible answers to highlight the most promising. The first represents *right associative* expressions. The second represent *left associative* expressions. The advantage of both of those two formats is that the format scales to any arbitrary number of addition expressions.

If you do run this expression through the visitor, you will see this output, verifying that the simple addition expression is *left associative*.

In order to run this sample, and see the full expression tree, I had to make one change to the source expression tree. When the expression tree contains all constants, the resulting tree simply contains the constant value of `10`. The compiler performs all the addition and reduces the expression to its simplest form. Simply adding one variable in the expression is sufficient to see the original tree:

```
Expression<Func<int, int>> sum = (a) => 1 + a + 3 + 4;
```

Create a visitor for this sum and run the visitor you'll see this output:

```

This expression is a/an Lambda expression type
The name of the lambda is <null>
The return type is System.Int32
The expression has 1 argument(s). They are:
    This is an Parameter expression type
    Type: System.Int32, Name: a, ByRef: False
The expression body is:
    This binary expression is a Add expression
        The Left argument is:
            This binary expression is a Add expression
                The Left argument is:
                    This binary expression is a Add expression
                        The Left argument is:
                            This is an Constant expression type
                            The type of the constant value is System.Int32
                            The value of the constant value is 1
                    The Right argument is:
                        This is an Parameter expression type
                        Type: System.Int32, Name: a, ByRef: False
                The Right argument is:
                    This is an Constant expression type
                    The type of the constant value is System.Int32
                    The value of the constant value is 3
            The Right argument is:
                This is an Constant expression type
                The type of the constant value is System.Int32
                The value of the constant value is 4

```

You can also run any of the other samples through the visitor code and see what tree it represents. Here's an example of the `sum3` expression above (with an additional parameter to prevent the compiler from computing the constant):

```
Expression<Func<int, int, int>> sum3 = (a, b) => (1 + a) + (3 + b);
```

Here's the output from the visitor:

```

This expression is a/an Lambda expression type
The name of the lambda is <null>
The return type is System.Int32
The expression has 2 argument(s). They are:
    This is an Parameter expression type
    Type: System.Int32, Name: a, ByRef: False
    This is an Parameter expression type
    Type: System.Int32, Name: b, ByRef: False
The expression body is:
    This binary expression is a Add expression
    The Left argument is:
        This binary expression is a Add expression
        The Left argument is:
            This is an Constant expression type
            The type of the constant value is System.Int32
            The value of the constant value is 1
        The Right argument is:
            This is an Parameter expression type
            Type: System.Int32, Name: a, ByRef: False
    The Right argument is:
        This binary expression is a Add expression
        The Left argument is:
            This is an Constant expression type
            The type of the constant value is System.Int32
            The value of the constant value is 3
        The Right argument is:
            This is an Parameter expression type
            Type: System.Int32, Name: b, ByRef: False

```

Notice that the parentheses are not part of the output. There are no nodes in the expression tree that represent the parentheses in the input expression. The structure of the expression tree contains all the information necessary to communicate the precedence.

Extending from this sample

The sample deals with only the most rudimentary expression trees. The code you've seen in this section only handles constant integers and the binary `+` operator. As a final sample, let's update the visitor to handle a more complicated expression. Let's make it work for this:

```

Expression<Func<int, int>> factorial = (n) =>
    n == 0 ?
    1 :
    Enumerable.Range(1, n).Aggregate((product, factor) => product * factor);

```

This code represents one possible implementation for the mathematical *factorial* function. The way I've written this code highlights two limitations of building expression trees by assigning lambda expressions to Expressions. First, statement lambdas are not allowed. That means I can't use loops, blocks, if / else statements, and other control structures common in C#. I'm limited to using expressions. Second, I can't recursively call the same expression. I could if it were already a delegate, but I can't call it in its expression tree form. In the section on [building expression trees](#) you'll learn techniques to overcome these limitations.

In this expression, you'll encounter nodes of all these types:

1. Equal (binary expression)
2. Multiply (binary expression)
3. Conditional (the `?:` expression)
4. Method Call Expression (calling `Range()` and `Aggregate()`)

One way to modify the visitor algorithm is to keep executing it, and write the node type every time you reach your

`default` clause. After a few iterations, you'll have seen each of the potential nodes. Then, you have all you need. The result would be something like this:

```
public static Visitor CreateFromExpression(Expression node)
{
    switch(node.NodeType)
    {
        case ExpressionType.Constant:
            return new ConstantVisitor((ConstantExpression)node);
        case ExpressionType.Lambda:
            return new LambdaVisitor((LambdaExpression)node);
        case ExpressionType.Parameter:
            return new ParameterVisitor((ParameterExpression)node);
        case ExpressionType.Add:
        case ExpressionType.Equal:
        case ExpressionType.Multiply:
            return new BinaryVisitor((BinaryExpression)node);
        case ExpressionType.Conditional:
            return new ConditionalVisitor((ConditionalExpression)node);
        case ExpressionType.Call:
            return new MethodCallVisitor((MethodCallExpression)node);
        default:
            Console.Error.WriteLine($"Node not processed yet: {node.NodeType}");
            return default(Visitor);
    }
}
```

The `ConditionalVisitor` and `MethodCallVisitor` process those two nodes:

```

public class ConditionalVisitor : Visitor
{
    private readonly ConditionalExpression node;
    public ConditionalVisitor(ConditionalExpression node) : base(node)
    {
        this.node = node;
    }

    public override void Visit(string prefix)
    {
        Console.WriteLine($"{prefix}This expression is a {NodeType} expression");
        var testVisitor = Visitor.CreateFromExpression(node.Test);
        Console.WriteLine($"{prefix}The Test for this expression is:");
        testVisitor.Visit(prefix + "\t");
        var trueVisitor = Visitor.CreateFromExpression(node.IfTrue);
        Console.WriteLine($"{prefix}The True clause for this expression is:");
        trueVisitor.Visit(prefix + "\t");
        var falseVisitor = Visitor.CreateFromExpression(node.IfFalse);
        Console.WriteLine($"{prefix}The False clause for this expression is:");
        falseVisitor.Visit(prefix + "\t");
    }
}

public class MethodCallVisitor : Visitor
{
    private readonly MethodCallExpression node;
    public MethodCallVisitor(MethodCallExpression node) : base(node)
    {
        this.node = node;
    }

    public override void Visit(string prefix)
    {
        Console.WriteLine($"{prefix}This expression is a {NodeType} expression");
        if (node.Object == null)
            Console.WriteLine($"{prefix}This is a static method call");
        else
        {
            Console.WriteLine($"{prefix}The receiver (this) is:");
            var receiverVisitor = Visitor.CreateFromExpression(node.Object);
            receiverVisitor.Visit(prefix + "\t");
        }

        var methodInfo = node.Method;
        Console.WriteLine($"{prefix}The method name is {methodInfo.DeclaringType}.{methodInfo.Name}");
        // There is more here, like generic arguments, and so on.
        Console.WriteLine($"{prefix}The Arguments are:");
        foreach(var arg in node.Arguments)
        {
            var argVisitor = Visitor.CreateFromExpression(arg);
            argVisitor.Visit(prefix + "\t");
        }
    }
}

```

And the output for the expression tree would be:

```

This expression is a/an Lambda expression type
The name of the lambda is <null>
The return type is System.Int32
The expression has 1 argument(s). They are:
    This is an Parameter expression type
    Type: System.Int32, Name: n, ByRef: False
The expression body is:
    This expression is a Conditional expression
    The Test for this expression is:
        This binary expression is a Equal expression
        The Left argument is:
            This is an Parameter expression type
            Type: System.Int32, Name: n, ByRef: False
        The Right argument is:
            This is an Constant expression type
            The type of the constant value is System.Int32
            The value of the constant value is 0
    The True clause for this expression is:
        This is an Constant expression type
        The type of the constant value is System.Int32
        The value of the constant value is 1
    The False clause for this expression is:
        This expression is a Call expression
        This is a static method call
        The method name is System.Linq.Enumerable.Aggregate
        The Arguments are:
            This expression is a Call expression
            This is a static method call
            The method name is System.Linq.Enumerable.Range
            The Arguments are:
                This is an Constant expression type
                The type of the constant value is System.Int32
                The value of the constant value is 1
                This is an Parameter expression type
                Type: System.Int32, Name: n, ByRef: False
        This expression is a Lambda expression type
        The name of the lambda is <null>
        The return type is System.Int32
        The expression has 2 arguments. They are:
            This is an Parameter expression type
            Type: System.Int32, Name: product, ByRef: False
            This is an Parameter expression type
            Type: System.Int32, Name: factor, ByRef: False
        The expression body is:
            This binary expression is a Multiply expression
            The Left argument is:
                This is an Parameter expression type
                Type: System.Int32, Name: product, ByRef: False
            The Right argument is:
                This is an Parameter expression type
                Type: System.Int32, Name: factor, ByRef: False

```

Extending the Sample Library

The samples in this section show the core techniques to visit and examine nodes in an expression tree. I glossed over many actions you might need in order to concentrate on the core tasks of visiting and accessing nodes in an expression tree.

First, the visitors only handle constants that are integers. Constant values could be any other numeric type, and the C# language supports conversions and promotions between those types. A more robust version of this code would mirror all those capabilities.

Even the last example recognizes a subset of the possible node types. You can still feed it many expressions that will cause it to fail. A full implementation is included in the .NET Standard under the name [ExpressionVisitor](#) and

can handle all the possible node types.

Finally, the library I used in this article was built for demonstration and learning. It's not optimized. I wrote it to make the structures used very clear, and to highlight the techniques used to visit the nodes and analyze what's there. A production implementation would pay more attention to performance than I have.

Even with those limitations, you should be well on your way to writing algorithms that read and understand expression trees.

[Next -- Building Expressions](#)

Building Expression Trees

6/19/2018 • 5 minutes to read • [Edit Online](#)

[Previous -- Interpreting Expressions](#)

All the expression trees you've seen so far have been created by the C# compiler. All you had to do was create a lambda expression that was assigned to a variable typed as an `Expression<Func<T>>` or some similar type. That's not the only way to create an expression tree. For many scenarios you may find that you need to build an expression in memory at runtime.

Building Expression Trees is complicated by the fact that those expression trees are immutable. Being immutable means that you must build the tree from the leaves up to the root. The APIs you'll use to build expression trees reflect this fact: The methods you'll use to build a node take all its children as arguments. Let's walk through a few examples to show you the techniques.

Creating Nodes

Let's start relatively simply again. We'll use the addition expression I've been working with throughout these sections:

```
Expression<Func<int>> sum = () => 1 + 2;
```

To construct that expression tree, you must construct the leaf nodes. The leaf nodes are constants, so you can use the `Expression.Constant` method to create the nodes:

```
var one = Expression.Constant(1, typeof(int));
var two = Expression.Constant(2, typeof(int));
```

Next, you'll build the addition expression:

```
var addition = Expression.Add(one, two);
```

Once you've got the addition expression, you can create the lambda expression:

```
var lambda = Expression.Lambda(addition);
```

This is a very simple lambda expression, because it contains no arguments. Later in this section, you'll see how to map arguments to parameters and build more complicated expressions.

For expressions that are as simple as this one, you may combine all the calls into a single statement:

```
var lambda = Expression.Lambda(
    Expression.Add(
        Expression.Constant(1, typeof(int)),
        Expression.Constant(2, typeof(int))
    )
);
```

Building a Tree

That's the basics of building an expression tree in memory. More complex trees generally mean more node types, and more nodes in the tree. Let's run through one more example and show two more node types that you will typically build when you create expression trees: the argument nodes, and method call nodes.

Let's build an expression tree to create this expression:

```
Expression<Func<double, double, double>> distanceCalc =  
    (x, y) => Math.Sqrt(x * x + y * y);
```

You'll start by creating parameter expressions for `x` and `y`:

```
var xParameter = Expression.Parameter(typeof(double), "x");  
var yParameter = Expression.Parameter(typeof(double), "y");
```

Creating the multiplication and addition expressions follows the pattern you've already seen:

```
var xSquared = Expression.Multiply(xParameter, xParameter);  
var ySquared = Expression.Multiply(yParameter, yParameter);  
var sum = Expression.Add(xSquared, ySquared);
```

Next, you need to create a method call expression for the call to `Math.Sqrt`.

```
var sqrtMethod = typeof(Math).GetMethod("Sqrt", new[] { typeof(double) });  
var distance = Expression.Call(sqrtMethod, sum);
```

And then finally, you put the method call into a lambda expression, and make sure to define the arguments to the lambda expression:

```
var distanceLambda = Expression.Lambda(  
    distance,  
    xParameter,  
    yParameter);
```

In this more complicated example, you see a couple more techniques that you will often need to create expression trees.

First, you need to create the objects that represent parameters or local variables before you use them. Once you've created those objects, you can use them in your expression tree wherever you need.

Second, you need to use a subset of the Reflection APIs to create a `MethodInfo` object so that you can create an expression tree to access that method. You must limit yourself to the subset of the Reflection APIs that are available on the .NET Core platform. Again, these techniques will extend to other expression trees.

Building Code In Depth

You aren't limited in what you can build using these APIs. However, the more complicated expression tree that you want to build, the more difficult the code is to manage and to read.

Let's build an expression tree that is the equivalent of this code:

```

Func<int, int> factorialFunc = (n) =>
{
    var res = 1;
    while (n > 1)
    {
        res = res * n;
        n--;
    }
    return res;
};

```

Notice above that I did not build the expression tree, but simply the delegate. Using the `Expression` class, you can't build statement lambdas. Here's the code that is required to build the same functionality. It's complicated by the fact that there isn't an API to build a `while` loop, instead you need to build a loop that contains a conditional test, and a label target to break out of the loop.

```

var nArgument = Expression.Parameter(typeof(int), "n");
var result = Expression.Variable(typeof(int), "result");

// Creating a label that represents the return value
LabelTarget label = Expression.Label(typeof(int));

var initializeResult = Expression.Assign(result, Expression.Constant(1));

// This is the inner block that performs the multiplication,
// and decrements the value of 'n'
var block = Expression.Block(
    Expression.Assign(result,
        Expression.Multiply(result, nArgument)),
    Expression.PostDecrementAssign(nArgument)
);

// Creating a method body.
BlockExpression body = Expression.Block(
    new[] { result },
    initializeResult,
    Expression.Loop(
        Expression.IfThenElse(
            Expression.GreaterThan(nArgument, Expression.Constant(1)),
            block,
            Expression.Break(label, result)
        ),
        label
    )
);

```

The code to build the expression tree for the factorial function is quite a bit longer, more complicated, and it's riddled with labels and break statements and other elements we'd like to avoid in our everyday coding tasks.

For this section, I've also updated the visitor code to visit every node in this expression tree and write out information about the nodes that are created in this sample. You can [view or download the sample code](#) at the dotnet/docs GitHub repository. Experiment for yourself by building and running the samples. For download instructions, see [Samples and Tutorials](#).

Examining the APIs

The expression tree APIs are some of the more difficult to navigate in .NET Core, but that's fine. Their purpose is a rather complex undertaking: writing code that generates code at runtime. They are necessarily complicated to provide a balance between supporting all the control structures available in the C# language and keeping the surface area of the APIs as small as reasonable. This balance means that many control structures are represented

not by their C# constructs, but by constructs that represent the underlying logic that the compiler generates from these higher level constructs.

Also, at this time, there are C# expressions that cannot be built directly using `Expression` class methods. In general, these will be the newest operators and expressions added in C# 5 and C# 6. (For example, `async` expressions cannot be built, and the new `?.` operator cannot be directly created.)

[Next -- Translating Expressions](#)

Translating Expression Trees

3/6/2019 • 6 minutes to read • [Edit Online](#)

[Previous -- Building Expressions](#)

In this final section, you'll learn how to visit each node in an expression tree while building a modified copy of that expression tree. These are the techniques that you will use in two important scenarios. The first is to understand the algorithms expressed by an expression tree so that it can be translated into another environment. The second is when you want to change the algorithm that has been created. This might be to add logging, intercept method calls and track them, or other purposes.

Translating is Visiting

The code you build to translate an expression tree is an extension of what you've already seen to visit all the nodes in a tree. When you translate an expression tree, you visit all the nodes, and while visiting them, build the new tree. The new tree may contain references to the original nodes, or new nodes that you have placed in the tree.

Let's see this in action by visiting an expression tree, and creating a new tree with some replacement nodes. In this example, let's replace any constant with a constant that is ten times larger. Otherwise, we'll leave the expression tree intact. Rather than reading the value of the constant, and replacing it with a new constant, we'll make this replacement by replacing the constant node with a new node that performs the multiplication.

Here, once you find a constant node, you create a new multiplication node whose children are the original constant, and the constant `10`:

```
private static Expression ReplaceNodes(Expression original)
{
    if (original.NodeType == ExpressionType.Constant)
    {
        return Expression.Multiply(original, Expression.Constant(10));
    }
    else if (original.NodeType == ExpressionType.Add)
    {
        var binaryExpression = (BinaryExpression)original;
        return Expression.Add(
            ReplaceNodes(binaryExpression.Left),
            ReplaceNodes(binaryExpression.Right));
    }
    return original;
}
```

By replacing the original node with the substitute, a new tree is formed that contains our modifications. We can verify that by compiling and executing the replaced tree.

```
var one = Expression.Constant(1, typeof(int));
var two = Expression.Constant(2, typeof(int));
var addition = Expression.Add(one, two);
var sum = ReplaceNodes(addition);
var executableFunc = Expression.Lambda(sum);

var func = (Func<int>)executableFunc.Compile();
var answer = func();
Console.WriteLine(answer);
```

Building a new tree is a combination of visiting the nodes in the existing tree, and creating new nodes and inserting them into the tree.

This example shows the importance of expression trees being immutable. Notice that the new tree created above contains a mixture of newly created nodes, and nodes from the existing tree. That's safe, because the nodes in the existing tree cannot be modified. This can result in significant memory efficiencies. The same nodes can be used throughout a tree, or in multiple expression trees. Since nodes can't be modified, the same node can be reused whenever its needed.

Traversing and Executing an Addition

Let's verify this by building a second visitor that walks the tree of addition nodes and computes the result. You can do this by making a couple modifications to the visitor that you've seen so far. In this new version, the visitor will return the partial sum of the addition operation up to this point. For a constant expression, that is simply the value of the constant expression. For an addition expression, the result is the sum of the left and right operands, once those trees have been traversed.

```
var one = Expression.Constant(1, typeof(int));
var two = Expression.Constant(2, typeof(int));
var three = Expression.Constant(3, typeof(int));
var four = Expression.Constant(4, typeof(int));
var addition = Expression.Add(one, two);
var add2 = Expression.Add(three, four);
var sum = Expression.Add(addition, add2);

// Declare the delegate, so we can call it
// from itself recursively:
Func<Expression, int> aggregate = null;
// Aggregate, return constants, or the sum of the left and right operand.
// Major simplification: Assume every binary expression is an addition.
aggregate = (exp) =>
    exp.NodeType == ExpressionType.Constant ?
        (int)((ConstantExpression)exp).Value :
        aggregate(((BinaryExpression)exp).Left) + aggregate(((BinaryExpression)exp).Right);

var theSum = aggregate(sum);
Console.WriteLine(theSum);
```

There's quite a bit of code here, but the concepts are very approachable. This code visits children in a depth first search. When it encounters a constant node, the visitor returns the value of the constant. After the visitor has visited both children, those children will have computed the sum computed for that sub-tree. The addition node can now compute its sum. Once all the nodes in the expression tree have been visited, the sum will have been computed. You can trace the execution by running the sample in the debugger and tracing the execution.

Let's make it easier to trace how the nodes are analyzed and how the sum is computed by traversing the tree. Here's an updated version of the Aggregate method that includes quite a bit of tracing information:

```

private static int Aggregate(Expression exp)
{
    if (exp.NodeType == ExpressionType.Constant)
    {
        var constantExp = (ConstantExpression)exp;
        Console.Error.WriteLine($"Found Constant: {constantExp.Value}");
        return (int)constantExp.Value;
    }
    else if (exp.NodeType == ExpressionType.Add)
    {
        var addExp = (BinaryExpression)exp;
        Console.Error.WriteLine("Found Addition Expression");
        Console.Error.WriteLine("Computing Left node");
        var leftOperand = Aggregate(addExp.Left);
        Console.Error.WriteLine($"Left is: {leftOperand}");
        Console.Error.WriteLine("Computing Right node");
        var rightOperand = Aggregate(addExp.Right);
        Console.Error.WriteLine($"Right is: {rightOperand}");
        var sum = leftOperand + rightOperand;
        Console.Error.WriteLine($"Computed sum: {sum}");
        return sum;
    }
    else throw new NotSupportedException("Haven't written this yet");
}

```

Running it on the same expression yields the following output:

```

10
Found Addition Expression
Computing Left node
Found Addition Expression
Computing Left node
Found Constant: 1
Left is: 1
Computing Right node
Found Constant: 2
Right is: 2
Computed sum: 3
Left is: 3
Computing Right node
Found Addition Expression
Computing Left node
Found Constant: 3
Left is: 3
Computing Right node
Found Constant: 4
Right is: 4
Computed sum: 7
Right is: 7
Computed sum: 10
10

```

Trace the output and follow along in the code above. You should be able to work out how the code visits each node and computes the sum as it goes through the tree and finds the sum.

Now, let's look at a different run, with the expression given by `sum1`:

```
Expression<Func<int>> sum1 = () => 1 + (2 + (3 + 4));
```

Here's the output from examining this expression:

```
Found Addition Expression
Computing Left node
Found Constant: 1
Left is: 1
Computing Right node
Found Addition Expression
Computing Left node
Found Constant: 2
Left is: 2
Computing Right node
Found Addition Expression
Computing Left node
Found Constant: 3
Left is: 3
Computing Right node
Found Constant: 4
Right is: 4
Computed sum: 7
Right is: 7
Computed sum: 9
Right is: 9
Computed sum: 10
10
```

While the final answer is the same, the tree traversal is completely different. The nodes are traveled in a different order, because the tree was constructed with different operations occurring first.

Learning More

This sample shows a small subset of the code you would build to traverse and interpret the algorithms represented by an expression tree. For a complete discussion of all the work necessary to build a general purpose library that translates expression trees into another language, please read [this series](#) by Matt Warren. It goes into great detail on how to translate any of the code you might find in an expression tree.

I hope you've now seen the true power of expression trees. You can examine a set of code, make any changes you'd like to that code, and execute the changed version. Because the expression trees are immutable, you can create new trees by using the components of existing trees. This minimizes the amount of memory needed to create modified expression trees.

[Next -- Summing up](#)

Expression Trees Summary

5/4/2018 • 2 minutes to read • [Edit Online](#)

[Previous -- Translating Expressions](#)

In this series, you've seen how you can use *expression trees* to create dynamic programs that interpret code as data and build new functionality based on that code.

You can examine expression trees to understand the intent of an algorithm. You can not only examine that code. You can build new expression trees that represent modified versions of the original code.

You can also use expression trees to look at an algorithm, and translate that algorithm into another language or environment.

Limitations

There are some newer C# language elements that don't translate well into expression trees. Expression trees cannot contain `await` expressions, or `async` lambda expressions. Many of the features added in the C# 6 release don't appear exactly as written in expression trees. Instead, newer features will be exposed in expressions trees in the equivalent, earlier syntax. This may not be as much of a limitation as you might think. In fact, it means that your code that interprets expression trees will likely still work the same when new language features are introduced.

Even with these limitations, expression trees do enable you to create dynamic algorithms that rely on interpreting and modifying code that is represented as a data structure. It's a powerful tool, and it's one of the features of the .NET ecosystem that enables rich libraries such as Entity Framework to accomplish what they do.

Interoperability (C# Programming Guide)

3/25/2019 • 2 minutes to read • [Edit Online](#)

Interoperability enables you to preserve and take advantage of existing investments in unmanaged code. Code that runs under the control of the common language runtime (CLR) is called *managed code*, and code that runs outside the CLR is called *unmanaged code*. COM, COM+, C++ components, ActiveX components, and Microsoft Windows API are examples of unmanaged code.

The .NET Framework enables interoperability with unmanaged code through platform invoke services, the `System.Runtime.InteropServices` namespace, C++ interoperability, and COM interoperability (COM interop).

In This Section

[Interoperability Overview](#)

Describes methods to interoperate between C# managed code and unmanaged code.

[How to: Access Office Interop Objects by Using Visual C# Features](#)

Describes features that are introduced in Visual C# to facilitate Office programming.

[How to: Use Indexed Properties in COM Interop Programming](#)

Describes how to use indexed properties to access COM properties that have parameters.

[How to: Use Platform Invoke to Play a Wave File](#)

Describes how to use platform invoke services to play a .wav sound file on the Windows operating system.

[Walkthrough: Office Programming](#)

Shows how to create an Excel workbook and a Word document that contains a link to the workbook.

[Example COM Class](#)

Demonstrates how to expose a C# class as a COM object.

C# Language Specification

For more information, see [Basic concepts](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

Documenting your code with XML comments

2/21/2019 • 28 minutes to read • [Edit Online](#)

XML documentation comments are a special kind of comment, added above the definition of any user-defined type or member. They are special because they can be processed by the compiler to generate an XML documentation file at compile time. The compiler generated XML file can be distributed alongside your .NET assembly so that Visual Studio and other IDEs can use IntelliSense to show quick information about types or members. Additionally, the XML file can be run through tools like [DocFX](#) and [Sandcastle](#) to generate API reference websites.

XML documentation comments, like all other comments, are ignored by the compiler.

You can generate the XML file at compile time by doing one of the following:

- If you are developing an application with .NET Core from the command line, you can add a [DocumentationFile element](#) to the `<PropertyGroup>` section of your .csproj project file. The following example generates an XML file in the project directory with the same root filename as the assembly:

```
<DocumentationFile>bin\$(Configuration)\$(TargetFramework)\$(AssemblyName).xml</DocumentationFile>
```

You can also specify the exact absolute or relative path and name of the XML file. The following example generates the XML file in the same directory as the debug version of an application:

```
<DocumentationFile>bin\Debug\netcoreapp2.1\App.xml</DocumentationFile>
```

- If you are developing an application using Visual Studio, right-click on the project and select **Properties**. In the properties dialog, select the **Build** tab, and check **XML documentation file**. You can also change the location to which the compiler writes the file.
- If you are compiling a .NET Framework application from the command line, add the [/doc compiler option](#) when compiling.

XML documentation comments use triple forward slashes (`///`) and an XML formatted comment body. For example:

```
/// <summary>
/// This class does something.
/// </summary>
public class SomeClass
{
}
```

Walkthrough

Let's walk through documenting a very basic math library to make it easy for new developers to understand/contribute and for third party developers to use.

Here's code for the simple math library:

```

/*
The main Math class
Contains all methods for performing basic math functions
*/
public class Math
{
    // Adds two integers and returns the result
    public static int Add(int a, int b)
    {
        // If any parameter is equal to the max value of an integer
        // and the other is greater than zero
        if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }

    // Adds two doubles and returns the result
    public static double Add(double a, double b)
    {
        if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }

    // Subtracts an integer from another and returns the result
    public static int Subtract(int a, int b)
    {
        return a - b;
    }

    // Subtracts a double from another and returns the result
    public static double Subtract(double a, double b)
    {
        return a - b;
    }

    // Multiplies two integers and returns the result
    public static int Multiply(int a, int b)
    {
        return a * b;
    }

    // Multiplies two doubles and returns the result
    public static double Multiply(double a, double b)
    {
        return a * b;
    }

    // Divides an integer by another and returns the result
    public static int Divide(int a, int b)
    {
        return a / b;
    }

    // Divides a double by another and returns the result
    public static double Divide(double a, double b)
    {
        return a / b;
    }
}

```

The sample library supports four major arithmetic operations `add`, `subtract`, `multiply` and `divide` on `int` and `double` data types.

Now you want to be able to create an API reference document from your code for third party developers who use your library but don't have access to the source code. As mentioned earlier XML documentation tags can be used to achieve this. You will now be introduced to the standard XML tags the C# compiler supports.

<summary>

The `<summary>` tag adds brief information about a type or member. I'll demonstrate its use by adding it to the `Math` class definition and the first `Add` method. Feel free to apply it to the rest of your code.

```
/*
 * The main Math class
 * Contains all methods for performing basic math functions
 */
/// <summary>
/// The main Math class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    // Adds two integers and returns the result
    /// <summary>
    /// Adds two integers and returns the result.
    /// </summary>
    public static int Add(int a, int b)
    {
        // If any parameter is equal to the max value of an integer
        // and the other is greater than zero
        if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }
}
```

The `<summary>` tag is very important, and we recommend that you include it because its content is the primary source of type or member information in IntelliSense or an API reference document.

<remarks>

The `<remarks>` tag supplements the information about types or members that the `<summary>` tag provides. In this example, you'll just add it to the class.

```
/*
 * The main Math class
 * Contains all methods for performing basic math functions
 */
/// <summary>
/// The main Math class.
/// Contains all methods for performing basic math functions.
/// </summary>
/// <remarks>
/// This class can add, subtract, multiply and divide.
/// </remarks>
public class Math
{
```

<returns>

The `<returns>` tag describes the return value of a method declaration. As before, the following example illustrates the `<returns>` tag on the first `Add` method. You can do the same on other methods.

```

// Adds two integers and returns the result
/// <summary>
/// Adds two integers and returns the result.
/// </summary>
/// <returns>
/// The sum of two integers.
/// </returns>
public static int Add(int a, int b)
{
    // If any parameter is equal to the max value of an integer
    // and the other is greater than zero
    if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
        throw new System.OverflowException();

    return a + b;
}

```

<value>

The `<value>` tag is similar to the `<returns>` tag, except that you use it for properties. Assuming your `Math` library had a static property called `PI`, here's how you'd use this tag:

```

/*
The main Math class
Contains all methods for performing basic math functions
*/
/// <summary>
/// The main Math class.
/// Contains all methods for performing basic math functions.
/// </summary>
/// <remarks>
/// This class can add, subtract, multiply and divide.
/// These operations can be performed on both integers and doubles
/// </remarks>
public class Math
{
    /// <value>Gets the value of PI.</value>
    public static double PI { get; }
}

```

<example>

You use the `<example>` tag to include an example in your XML documentation. This involves using the child `<code>` tag.

```

// Adds two integers and returns the result
/// <summary>
/// Adds two integers and returns the result.
/// </summary>
/// <returns>
/// The sum of two integers.
/// </returns>
/// <example>
/// <code>
/// int c = Math.Add(4, 5);
/// if (c > 10)
/// {
///     Console.WriteLine(c);
/// }
/// </code>
/// </example>
public static int Add(int a, int b)
{
    // If any parameter is equal to the max value of an integer
    // and the other is greater than zero
    if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
        throw new System.OverflowException();

    return a + b;
}

```

The `code` tag preserves line breaks and indentation for longer examples.

<para>

You use the `<para>` tag to format the content within its parent tag. `<para>` is usually used inside a tag, such as `<remarks>` or `<returns>`, to divide text into paragraphs. You can format the contents of the `<remarks>` tag for your class definition.

```

/*
The main Math class
Contains all methods for performing basic math functions
*/
/// <summary>
/// The main Math class.
/// Contains all methods for performing basic math functions.
/// </summary>
/// <remarks>
/// <para>This class can add, subtract, multiply and divide.</para>
/// <para>These operations can be performed on both integers and doubles.</para>
/// </remarks>
public class Math
{
}
```

<c>

Still on the topic of formatting, you use the `<c>` tag for marking part of text as code. It's like the `<code>` tag but inline. It's useful when you want to show a quick code example as part of a tag's content. Let's update the documentation for the `Math` class.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
}

```

<exception>

By using the `<exception>` tag, you let your developers know that a method can throw specific exceptions. Looking at your `Math` library, you can see that both `Add` methods throw an exception if a certain condition is met. Not so obvious, though, is that integer `Divide` method throws as well if the `b` parameter is zero. Now add exception documentation to this method.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Adds two integers and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two integers.
    /// </returns>
    /// <example>
    /// <code>
    /// int c = Math.Add(4, 5);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than 0.</exception>
    public static int Add(int a, int b)
    {
        if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }

    /// <summary>
    /// Adds two doubles and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two doubles.
    /// </returns>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than zero.</exception>
    public static double Add(double a, double b)
    {
        ...
    }
}
```

```

        if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }

    /// <summary>
    /// Divides an integer by another and returns the result.
    /// </summary>
    /// <returns>
    /// The division of two integers.
    /// </returns>
    /// <exception cref="System.DivideByZeroException">Thrown when a division by zero occurs.</exception>
    public static int Divide(int a, int b)
    {
        return a / b;
    }

    /// <summary>
    /// Divides a double by another and returns the result.
    /// </summary>
    /// <returns>
    /// The division of two doubles.
    /// </returns>
    /// <exception cref="System.DivideByZeroException">Thrown when a division by zero occurs.</exception>
    public static double Divide(double a, double b)
    {
        return a / b;
    }
}

```

The `cref` attribute represents a reference to an exception that is available from the current compilation environment. This can be any type defined in the project or a referenced assembly. The compiler will issue a warning if its value cannot be resolved.

<see>

The `<see>` tag lets you create a clickable link to a documentation page for another code element. In our next example, we'll create a clickable link between the two `Add` methods.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Adds two integers and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two integers.
    /// </returns>
    /// <example>
    /// <code>
    /// int c = Math.Add(4, 5);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than 0.</exception>
    /// See <see cref="Math.Add(double, double)"> to add doubles.
    public static int Add(int a, int b)
    {
        if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }

    /// <summary>
    /// Adds two doubles and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two doubles.
    /// </returns>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than zero.</exception>
    /// See <see cref="Math.Add(int, int)"> to add integers.
    public static double Add(double a, double b)
    {
        if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }
}

```

The `cref` is a **required** attribute that represents a reference to a type or its member that is available from the current compilation environment. This can be any type defined in the project or a referenced assembly.

<seealso>

You use the `<seealso>` tag in the same way you do the `<see>` tag. The only difference is that its content is typically placed in a "See Also" section. Here we'll add a `seealso` tag on the integer `Add` method to reference other methods in the class that accept integer parameters:

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Adds two integers and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two integers.
    /// </returns>
    /// <example>
    /// <code>
    /// int c = Math.Add(4, 5);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than 0.</exception>
    /// See <see cref="Math.Add(double, double)"> to add doubles.
    /// <seealso cref="Math.Subtract(int, int)">
    /// <seealso cref="Math.Multiply(int, int)">
    /// <seealso cref="Math.Divide(int, int)">
    public static int Add(int a, int b)
    {
        if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }
}

```

The `cref` attribute represents a reference to a type or its member that is available from the current compilation environment. This can be any type defined in the project or a referenced assembly.

<param>

You use the `<param>` tag to describe a method's parameters. Here's an example on the `double Add` method: The parameter the tag describes is specified in the **required** `name` attribute.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Adds two doubles and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two doubles.
    /// </returns>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than zero.</exception>
    /// See <see cref="Math.Add(int, int)"> to add integers.
    /// <param name="a">A double precision number.</param>
    /// <param name="b">A double precision number.</param>
    public static double Add(double a, double b)
    {
        if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }
}

```

<typeparam>

You use `<typeparam>` tag just like the `<param>` tag but for generic type or method declarations to describe a generic parameter. Add a quick generic method to your `Math` class to check if one quantity is greater than another.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Checks if an IComparable is greater than another.
    /// </summary>
    /// <typeparam name="T">A type that inherits from the IComparable interface.</typeparam>
    public static bool GreaterThan<T>(T a, T b) where T : IComparable
    {
        return a.CompareTo(b) > 0;
    }
}

```

<paramref>

Sometimes you might be in the middle of describing what a method does in what could be a `<summary>` tag, and you might want to make a reference to a parameter. The `<paramref>` tag is great for just this. Let's update the summary of our double based `Add` method. Like the `<param>` tag the parameter name is specified in the **required** `name` attribute.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Adds two doubles <paramref name="a"/> and <paramref name="b"/> and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two doubles.
    /// </returns>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than zero.</exception>
    /// See <see cref="Math.Add(int, int)"> to add integers.
    /// <param name="a">A double precision number.</param>
    /// <param name="b">A double precision number.</param>
    public static double Add(double a, double b)
    {
        if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }
}

```

<typeparamref>

You use `<typeparamref>` tag just like the `<paramref>` tag but for generic type or method declarations to describe a generic parameter. You can use the same generic method you previously created.

```

/*
    The main Math class
    Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// </summary>
public class Math
{
    /// <summary>
    /// Checks if an IComparable <typeparamref name="T"/> is greater than another.
    /// </summary>
    /// <typeparam name="T">A type that inherits from the IComparable interface.</typeparam>
    public static bool GreaterThan<T>(T a, T b) where T : IComparable
    {
        return a.CompareTo(b) > 0;
    }
}

```

<list>

You use the `<list>` tag to format documentation information as an ordered list, unordered list or table. Make an unordered list of every math operation your `Math` library supports.

```

/*
   The main Math class
   Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// <list type="bullet">
/// <item>
/// <term>Add</term>
/// <description>Addition Operation</description>
/// </item>
/// <item>
/// <term>Subtract</term>
/// <description>Subtraction Operation</description>
/// </item>
/// <item>
/// <term>Multiply</term>
/// <description>Multiplication Operation</description>
/// </item>
/// <item>
/// <term>Divide</term>
/// <description>Division Operation</description>
/// </item>
/// </list>
/// </summary>
public class Math
{
}

```

You can make an ordered list or table by changing the `type` attribute to `number` or `table`, respectively.

Putting it all together

If you've followed this tutorial and applied the tags to your code where necessary, your code should now look similar to the following:

```

/*
   The main Math class
   Contains all methods for performing basic math functions
*/
/// <summary>
/// The main <c>Math</c> class.
/// Contains all methods for performing basic math functions.
/// <list type="bullet">
/// <item>
/// <term>Add</term>
/// <description>Addition Operation</description>
/// </item>
/// <item>
/// <term>Subtract</term>
/// <description>Subtraction Operation</description>
/// </item>
/// <item>
/// <term>Multiply</term>
/// <description>Multiplication Operation</description>
/// </item>
/// <item>
/// <term>Divide</term>
/// <description>Division Operation</description>
/// </item>
/// </list>
/// </summary>
/// <remarks>
/// <para>This class can add, subtract, multiply and divide.</para>

```

```
/// <para>These operations can be performed on both integers and doubles.</para>
/// </remarks>
public class Math
{
    // Adds two integers and returns the result
    /// <summary>
    /// Adds two integers <paramref name="a"/> and <paramref name="b"/> and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two integers.
    /// </returns>
    /// <example>
    /// <code>
    /// int c = Math.Add(4, 5);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than 0.</exception>
    /// See <see cref="Math.Add(double, double)"> to add doubles.
    /// <seealso cref="Math.Subtract(int, int)">
    /// <seealso cref="Math.Multiply(int, int)">
    /// <seealso cref="Math.Divide(int, int)">
    /// <param name="a">An integer.</param>
    /// <param name="b">An integer.</param>
    public static int Add(int a, int b)
    {
        // If any parameter is equal to the max value of an integer
        // and the other is greater than zero
        if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
            throw new System.OverflowException();

        return a + b;
    }

    // Adds two doubles and returns the result
    /// <summary>
    /// Adds two doubles <paramref name="a"/> and <paramref name="b"/> and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two doubles.
    /// </returns>
    /// <example>
    /// <code>
    /// double c = Math.Add(4.5, 5.4);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">Thrown when one parameter is max
    /// and the other is greater than 0.</exception>
    /// See <see cref="Math.Add(int, int)"> to add integers.
    /// <seealso cref="Math.Subtract(double, double)">
    /// <seealso cref="Math.Multiply(double, double)">
    /// <seealso cref="Math.Divide(double, double)">
    /// <param name="a">A double precision number.</param>
    /// <param name="b">A double precision number.</param>
    public static double Add(double a, double b)

public static double Divide(double a, double b)
{
    return a / b;
}
}

```

From your code, you can generate a detailed documentation website complete with clickable cross-references. But you're faced with another problem: your code has become hard to read. There's so much information to sift through that this is going to be a nightmare for any developer who wants to contribute to this code. Thankfully there's an XML tag that can help you deal with this:

<include>

The `<include>` tag lets you refer to comments in a separate XML file that describe the types and members in your source code, as opposed to placing documentation comments directly in your source code file.

Now you're going to move all your XML tags into a separate XML file named `docs.xml`. Feel free to name the file whatever you want.

```

<docs>
<members name="math">
<Math>
    <summary>
        The main <c>Math</c> class.
        Contains all methods for performing basic math functions.
    </summary>
    <remarks>
        <para>This class can add, subtract, multiply and divide.</para>
        <para>These operations can be performed on both integers and doubles.</para>
    </remarks>
</Math>
<AddInt>
    <summary>

<seealso cref="Math.Multiply(double, double)">
<param name="a">A double precision dividend.</param>
<param name="b">A double precision divisor.</param>
</DivideDouble>
</members>
</docs>

```

In the above XML, each member's documentation comments appear directly inside a tag named after what they do. You can choose your own strategy. Now that you have your XML comments in a separate file, let's see how your code can be made more readable by using the `<include>` tag:

```

/*
The main Math class
Contains all methods for performing basic math functions
*/
/// <include file='docs.xml' path='docs/members[@name="math"]/Math/*'>
public class Math
{
    // Adds two integers and returns the result
    /// <include file='docs.xml' path='docs/members[@name="math"]/AddInt/*'>

```

```

public static int Add(int a, int b)
{
    // If any parameter is equal to the max value of an integer
    // and the other is greater than zero
    if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
        throw new System.OverflowException();

    return a + b;
}

// Adds two doubles and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/AddDouble/*'/>
public static double Add(double a, double b)
{
    // If any parameter is equal to the max value of an integer
    // and the other is greater than zero
    if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
        throw new System.OverflowException();

    return a + b;
}

// Subtracts an integer from another and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/SubtractInt/*'/>
public static int Subtract(int a, int b)
{
    return a - b;
}

// Subtracts a double from another and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/SubtractDouble/*'/>
public static double Subtract(double a, double b)
{
    return a - b;
}

// Multiplies two integers and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/MultiplyInt/*'/>
public static int Multiply(int a, int b)
{
    return a * b;
}

// Multiplies two doubles and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/MultiplyDouble/*'/>
public static double Multiply(double a, double b)
{
    return a * b;
}

// Divides an integer by another and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/DivideInt/*'/>
public static int Divide(int a, int b)
{
    return a / b;
}

// Divides a double by another and returns the result
/// <include file='docs.xml' path='docs/members[@name="math"]/DivideDouble/*'/>
public static double Divide(double a, double b)
{
    return a / b;
}
}

```

And there you have it: our code is back to being readable, and no documentation information has been lost.

The `file` attribute represents the name of the XML file containing the documentation.

The `path` attribute represents an [XPath](#) query to the `tag name` present in the specified `file`.

The `name` attribute represents the name specifier in the tag that precedes the comments.

The `id` attribute which can be used in place of `name` represents the ID for the tag that precedes the comments.

User Defined Tags

All the tags outlined above represent those that are recognized by the C# compiler. However, a user is free to define their own tags. Tools like Sandcastle bring support for extra tags like `<event>`, `<note>` and even support [documenting namespaces](#). Custom or in-house documentation generation tools can also be used with the standard tags and multiple output formats from HTML to PDF can be supported.

Recommendations

Documenting code is recommended for many reasons. What follows are some best practices, general use case scenarios, and things that you should know when using XML documentation tags in your C# code.

- For the sake of consistency, all publicly visible types and their members should be documented. If you must do it, do it all.
- Private members can also be documented using XML comments. However, this exposes the inner (potentially confidential) workings of your library.
- At a bare minimum, types and their members should have a `<summary>` tag because its content is needed for IntelliSense.
- Documentation text should be written using complete sentences ending with full stops.
- Partial classes are fully supported, and documentation information will be concatenated into a single entry for that type.
- The compiler verifies the syntax of the `<exception>`, `<include>`, `<param>`, `<see>`, `<seealso>` and `<typeparam>` tags.
- The compiler validates the parameters that contain file paths and references to other parts of the code.

Versioning in C#

2/28/2019 • 5 minutes to read • [Edit Online](#)

In this tutorial you'll learn what versioning means in .NET. You'll also learn the factors to consider when versioning your library as well as upgrading to a new version of a library.

Authoring Libraries

As a developer who has created .NET libraries for public use, you've most likely been in situations where you have to roll out new updates. How you go about this process matters a lot as you need to ensure that there's a seamless transition of existing code to the new version of your library. Here are several things to consider when creating a new release:

Semantic Versioning

[Semantic versioning](#) (SemVer for short) is a naming convention applied to versions of your library to signify specific milestone events. Ideally, the version information you give your library should help developers determine the compatibility with their projects that make use of older versions of that same library.

The most basic approach to SemVer is the 3 component format `MAJOR.MINOR.PATCH`, where:

- `MAJOR` is incremented when you make incompatible API changes
- `MINOR` is incremented when you add functionality in a backwards-compatible manner
- `PATCH` is incremented when you make backwards-compatible bug fixes

There are also ways to specify other scenarios like pre-release versions etc. when applying version information to your .NET library.

Backwards Compatibility

As you release new versions of your library, backwards compatibility with previous versions will most likely be one of your major concerns. A new version of your library is source compatible with a previous version if code that depends on the previous version can, when recompiled, work with the new version. A new version of your library is binary compatible if an application that depended on the old version can, without recompilation, work with the new version.

Here are some things to consider when trying to maintain backwards compatibility with older versions of your library:

- **Virtual methods:** When you make a virtual method non-virtual in your new version it means that projects that override that method will have to be updated. This is a huge breaking change and is strongly discouraged.
- **Method signatures:** When updating a method behaviour requires you to change its signature as well, you should instead create an overload so that code calling into that method will still work. You can always manipulate the old method signature to call into the new method signature so that implementation remains consistent.
- **Obsolete attribute:** You can use this attribute in your code to specify classes or class members that are deprecated and likely to be removed in future versions. This ensures developers utilizing your library are better prepared for breaking changes.
- **Optional Method Arguments:** When you make previously optional method arguments compulsory or change their default value then all code that does not supply those arguments will need to be updated.

NOTE

Making compulsory arguments optional should have very little effect especially if it doesn't change the method's behaviour.

The easier you make it for your users to upgrade to the new version of your library, the more likely that they will upgrade sooner.

Application Configuration File

As a .NET developer there's a very high chance you've encountered the `app.config` file present in most project types. This simple configuration file can go a long way into improving the rollout of new updates. You should generally design your libraries in such a way that information that is likely to change regularly is stored in the `app.config` file, this way when such information is updated the config file of older versions just needs to be replaced with the new one without the need for recompilation of the library.

Consuming Libraries

As a developer that consumes .NET libraries built by other developers you're most likely aware that a new version of a library might not be fully compatible with your project and you might often find yourself having to update your code to work with those changes.

Lucky for you C# and the .NET ecosystem comes with features and techniques that allow us to easily update our app to work with new versions of libraries that might introduce breaking changes.

Assembly Binding Redirection

You can use the `app.config` file to update the version of a library your app uses. By adding what is called a *binding redirect* you can use the new library version without having to recompile your app. The following example shows how you would update your app's `app.config` file to use the `1.0.1` patch version of `ReferencedLibrary` instead of the `1.0.0` version it was originally compiled with.

```
<dependentAssembly>
  <assemblyIdentity name="ReferencedLibrary" publicKeyToken="32ab4ba45e0a69a1" culture="en-us" />
  <bindingRedirect oldVersion="1.0.0" newVersion="1.0.1" />
</dependentAssembly>
```

NOTE

This approach will only work if the new version of `ReferencedLibrary` is binary compatible with your app. See the [Backwards Compatibility](#) section above for changes to look out for when determining compatibility.

new

You use the `new` modifier to hide inherited members of a base class. This is one way derived classes can respond to updates in base classes.

Take the following example:

```

public class BaseClass
{
    public void MyMethod()
    {
        Console.WriteLine("A base method");
    }
}

public class DerivedClass : BaseClass
{
    public new void MyMethod()
    {
        Console.WriteLine("A derived method");
    }
}

public static void Main()
{
    BaseClass b = new BaseClass();
    DerivedClass d = new DerivedClass();

    b.MyMethod();
    d.MyMethod();
}

```

Output

```

A base method
A derived method

```

From the example above you can see how `DerivedClass` hides the `MyMethod` method present in `BaseClass`. This means that when a base class in the new version of a library adds a member that already exists in your derived class, you can simply use the `new` modifier on your derived class member to hide the base class member.

When no `new` modifier is specified, a derived class will by default hide conflicting members in a base class, although a compiler warning will be generated the code will still compile. This means that simply adding new members to an existing class makes that new version of your library both source and binary compatible with code that depends on it.

override

The `override` modifier means a derived implementation extends the implementation of a base class member rather than hides it. The base class member needs to have the `virtual` modifier applied to it.

```
public class MyBaseClass
{
    public virtual string MethodOne()
    {
        return "Method One";
    }
}

public class MyDerivedClass : MyBaseClass
{
    public override string MethodOne()
    {
        return "Derived Method One";
    }
}

public static void Main()
{
    MyBaseClass b = new MyBaseClass();
    MyDerivedClass d = new MyDerivedClass();

    Console.WriteLine("Base Method One: {0}", b.MethodOne());
    Console.WriteLine("Derived Method One: {0}", d.MethodOne());
}
```

Output

```
Base Method One: Method One
Derived Method One: Derived Method One
```

The `override` modifier is evaluated at compile time and the compiler will throw an error if it doesn't find a virtual member to override.

Your knowledge of the discussed techniques as well as your understanding of what situations to use them will go a long way to boost the ease of transition between versions of a library.

How to (C#)

3/1/2019 • 3 minutes to read • [Edit Online](#)

In the How to section of the C# Guide you can find quick answers to common questions. In some cases, articles may be listed in multiple sections. We wanted to make them easy to find for multiple search paths.

General C# concepts

There are several tips and tricks that are common C# developer practices.

- [Initialize objects using an object initializer.](#)
- [Learn the differences between passing a struct and a class to a method.](#)
- [How to use lambda expressions.](#)
- [Resolve type name conflicts by using the `My` namespace from VB.](#)
- [Use operator overloading.](#)
- [Implement and call a custom extension method.](#)
- Even C# programmers may want to [use the `My` namespace from VB.](#)
- [Create a new method for an `enum` type using extension methods.](#)

Class and struct members

You create classes and structs to implement your program. These techniques are commonly used when writing classes or structs.

- [Declare auto implemented properties.](#)
- [Declare and use read/write properties.](#)
- [Define constants.](#)
- [Override the `ToString` method to provide string output.](#)
- [Define abstract properties.](#)
- [Use the xml documentation features to document your code.](#)
- [Explicitly implement interface members](#) to keep your public interface concise.
- [Explicitly implement members of two interfaces.](#)

Working with collections

These articles help you work with collections of data.

- [Initialize a dictionary with a collection initializer.](#)

Working with strings

Strings are the fundamental data type used to display or manipulate text. These articles demonstrate common practices with strings.

- [Compare strings.](#)
- [Modify the contents of a string.](#)
- [Determine if a string represents a number.](#)
- [Use `String.Split` to separate strings.](#)
- [Combine multiple strings into one.](#)
- [Search for text in a string.](#)

Convert between types

You may need to convert an object to a different type.

- Determine if a string represents a number.
- Convert between strings that represent hexadecimal numbers and the number.
- Convert a string to a `DateTime`.
- Convert a byte array to an int.
- Convert a string to a number.
- Use pattern matching, the `as` and `is` operators to safely cast to a different type.
- Define conversion operators for `struct` types.
- Determine if a type is a nullable value type.
- Convert between nullable and non-nullable value types.

Equality and ordering comparisons

You may create types that define their own rules for equality or define a natural ordering among objects of that type.

- Test for reference-based equality.
- Define value-based equality for a type.

Exception handling

.NET programs report that methods did not successfully complete their work by throwing exceptions. In these articles you'll learn to work with exceptions.

- Handle exceptions using `try` and `catch`.
- Cleanup resources using `finally` clauses.
- Recover from non-CLS (Common Language Specification) exceptions.

Delegates and events

Delegates and events provide a capability for strategies that involve loosely coupled blocks of code.

- Declare, instantiate, and use delegates.
- Combine multicast delegates.

Events provide a mechanism to publish or subscribe to notifications.

- Subscribe and unsubscribe from events.
- Implement events declared in interfaces.
- Conform to .NET Framework guidelines when your code publishes events.
- Raise events defined in base classes from derived classes.
- Store event instances in a dictionary.
- Implement custom event accessors.

LINQ practices

LINQ enables you to write code to query any data source that supports the LINQ query expression pattern. These articles help you understand the pattern and work with different data sources.

- Query a collection.

- Use lambda expressions in a query.
- Use `var` in query expressions.
- Return subsets of element properties from a query.
- Write queries with complex filtering.
- Sort elements of a data source.
- Sort elements on multiple keys.
- Control the type of a projection.
- Count occurrences of a value in a source sequence.
- Calculate intermediate values.
- Merge data from multiple sources.
- Find the set difference between two sequences.
- Debug empty query results.
- Add custom methods to LINQ queries.

Multiple threads and async processing

Modern programs often use asynchronous operations. These articles will help you learn to use these techniques.

- Improve async performance using `System.Threading.Tasks.Task.WhenAll`.
- Make multiple web requests in parallel using `async` and `await`.
- Use a thread pool.

Command line args to your program

Typically, C# programs have command line arguments. These articles teach you to access and process those command line arguments.

- Retrieve all command line arguments with `for`.
- Retrieve all command line arguments with `foreach`.

How to: Parse Strings Using String.Split (C# Guide)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The [String.Split](#) method creates an array of substrings by splitting the input string based on one or more delimiters. It is often the easiest way to separate a string on word boundaries. It is also used to split strings on other specific characters or strings.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The following code splits a common phrase into an array of strings for each word.

```
string phrase = "The quick brown fox jumps over the lazy dog.";
string[] words = phrase.Split(' ');

foreach (var word in words)
{
    System.Console.WriteLine($"<{word}>");
}
```

Every instance of a separator character produces a value in the returned array. Consecutive separator characters produce the empty string as a value in the returned array. You can see this in the following example, which uses space as a separator:

```
string phrase = "The quick brown    fox    jumps over the lazy dog.";
string[] words = phrase.Split(' ');

foreach (var word in words)
{
    System.Console.WriteLine($"<{word}>");
}
```

This behavior makes it easier for formats like comma separated values (CSV) files representing tabular data. Consecutive commas represent a blank column.

You can pass an optional [StringSplitOptions.RemoveEmptyEntries](#) parameter to exclude any empty strings in the returned array. For more complicated processing of the returned collection, you can use [LINQ](#) to manipulate the result sequence.

[String.Split](#) can use multiple separator characters. The following example uses spaces, commas, periods, colons, and tabs, all passed in an array containing these separating characters, to [Split](#). The loop at the bottom of the code displays each of the words in the returned array.

```

char[] delimiterChars = { ' ', ',', '.', ':', '\t' };

string text = "one\ttwo three:four,five six seven";
System.Console.WriteLine($"Original text: '{text}'");

string[] words = text.Split(delimiterChars);
System.Console.WriteLine($"{words.Length} words in text:");

foreach (var word in words)
{
    System.Console.WriteLine($"<{word}>");
}

```

Consecutive instances of any separator produce the empty string in the output array:

```

char[] delimiterChars = { ' ', ',', '.', ':', '\t' };

string text = "one\ttwo :,five six seven";
System.Console.WriteLine($"Original text: '{text}'");

string[] words = text.Split(delimiterChars);
System.Console.WriteLine($"{words.Length} words in text:");

foreach (var word in words)
{
    System.Console.WriteLine($"<{word}>");
}

```

[String.Split](#) can take an array of strings (character sequences that act as separators for parsing the target string, instead of single characters).

```

string[] separatingChars = { "<<", "...." };

string text = "one<<two.....three<four";
System.Console.WriteLine("Original text: '{0}'", text);

string[] words = text.Split(separatingChars, System.StringSplitOptions.RemoveEmptyEntries );
System.Console.WriteLine("{0} substrings in text:", words.Length);

foreach (var word in words)
{
    System.Console.WriteLine(word);
}

```

You can try these samples by looking at the code in our [GitHub repository](#). Or you can download the samples [as a zip file](#).

How to: Concatenate Multiple Strings (C# Guide)

1/23/2019 • 3 minutes to read • [Edit Online](#)

Concatenation is the process of appending one string to the end of another string. You concatenate strings by using the `+` operator. For string literals and string constants, concatenation occurs at compile time; no run-time concatenation occurs. For string variables, concatenation occurs only at run time.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The following example uses concatenation to split a long string literal into smaller strings in order to improve readability in the source code. These parts are concatenated into a single string at compile time. There is no run-time performance cost regardless of the number of strings involved.

```
// Concatenation of literals is performed at compile time, not run time.  
string text = "Historically, the world of data and the world of objects " +  
    "have not been well integrated. Programmers work in C# or Visual Basic " +  
    "and also in SQL or XQuery. On the one side are concepts such as classes, " +  
    "objects, fields, inheritance, and .NET Framework APIs. On the other side " +  
    "are tables, columns, rows, nodes, and separate languages for dealing with " +  
    "them. Data types often require translation between the two worlds; there are " +  
    "different standard functions. Because the object world has no notion of query, a " +  
    "query can only be represented as a string without compile-time type checking or " +  
    "IntelliSense support in the IDE. Transferring data from SQL tables or XML trees to " +  
    "objects in memory is often tedious and error-prone.";  
  
System.Console.WriteLine(text);
```

To concatenate string variables, you can use the `+` or `+=` operators, [string interpolation](#) or the [String.Format](#), [String.Concat](#), [String.Join](#) or [StringBuilder.Append](#) methods. The `+` operator is easy to use and makes for intuitive code. Even if you use several `+` operators in one statement, the string content is copied only once. The following code shows examples of using the `+` and `+=` operators to concatenate strings:

```
string userName = "<Type your name here>";  
string dateString = DateTime.Today.ToString("MM dd, yyyy");  
  
// Use the + and += operators for one-time concatenations.  
string str = "Hello " + userName + ". Today is " + dateString + ".  
System.Console.WriteLine(str);  
  
str += " How are you today?";  
System.Console.WriteLine(str);
```

In some expressions, it's easier to concatenate strings using string interpolation, as the following code shows:

```

string userName = "<Type your name here>";
string date = DateTime.Today.ToShortDateString();

// Use string interpolation to concatenate strings.
string str = $"Hello {userName}. Today is {date}.";
System.Console.WriteLine(str);

str = $"{str} How are you today?";
System.Console.WriteLine(str);

```

NOTE

In string concatenation operations, the C# compiler treats a null string the same as an empty string.

Other method to concatenate strings is [String.Format](#). This method works well when you are building a string from a small number of component strings.

In other cases you may be combining strings in a loop, where you don't know how many source strings you are combining, and the actual number of source strings may be quite large. The [StringBuilder](#) class was designed for these scenarios. The following code uses the [Append](#) method of the [StringBuilder](#) class to concatenate strings.

```

// Use StringBuilder for concatenation in tight loops.
var sb = new System.Text.StringBuilder();
for (int i = 0; i < 20; i++)
{
    sb.AppendLine(i.ToString());
}
System.Console.WriteLine(sb.ToString());

```

You can read more about the [reasons to choose string concatenation or the `StringBuilder` class](#)

Another option to join strings from a collection is to use [String.Concat](#) method. Use [String.Join](#) method if source strings should be separated by a delimiter. The following code combines an array of words using both methods:

```

string[] words = { "The", "quick", "brown", "fox", "jumps", "over", "the", "lazy", "dog." };

var unreadablePhrase = string.Concat(words);
System.Console.WriteLine(unreadablePhrase);

var readablePhrase = string.Join(" ", words);
System.Console.WriteLine(readablePhrase);

```

At last, you can use [LINQ](#) and the [Enumerable.Aggregate](#) method to join strings from a collection. This method combines the source strings using a lambda expression. The lambda expression does the work to add each string to the existing accumulation. The following example combines an array of words by adding a space between each word in the array:

```

string[] words = { "The", "quick", "brown", "fox", "jumps", "over", "the", "lazy", "dog." };

var phrase = words.Aggregate((partialPhrase, word) => $"{partialPhrase} {word}");
System.Console.WriteLine(phrase);

```

You can try these samples by looking at the code in our [GitHub repository](#). Or you can download the samples [as a zip file](#).

Parsing Date and Time Strings in .NET

1/23/2019 • 6 minutes to read • [Edit Online](#)

Parsing strings to convert them to [DateTime](#) objects requires you to specify information about how the dates and times are represented as text. Different cultures use different orders for day, month, and year. Some time representations use a 24-hour clock, others specify "AM" and "PM." Some applications need only the date. Others need only the time. Still others need to specify both the date and the time. The methods that convert strings to [DateTime](#) objects enable you to provide detailed information about the formats you expect and the elements of a date and time your application needs. There are three subtasks to correctly converting text into a [DateTime](#):

1. You must specify the expected format of the text representing a date and time.
2. You may specify the culture for the format of a date time.
3. You may specify how missing components in the text representation are set in the date and time.

The [Parse](#) and [TryParse](#) methods convert many common representations of a date and time. The [ParseExact](#) and [TryParseExact](#) methods convert a string representation that conforms to the pattern specified by a date and time format string. (See the articles on [standard date and time format strings](#) and [custom date and time format strings](#) for details.)

The current [DateTimeFormatInfo](#) object provides more control over how text should be interpreted as a date and time. Properties of a [DateTimeFormatInfo](#) describe the date and time separators, and the names of months, days, and eras, and the format for the "AM" and "PM" designations. The current thread culture provides a [DateTimeFormatInfo](#) that represents the current culture. If you want a specific culture or custom settings, you specify the [IFormatProvider](#) parameter of a parsing method. For the [IFormatProvider](#) parameter, specify a [CultureInfo](#) object, which represents a culture, or a [DateTimeFormatInfo](#) object.

The text representing a date or time may be missing some information. For example, most people would assume the date "March 12" represents the current year. Similarly, "March 2018" represents the month of March in the year 2018. Text representing time often does only includes hours, minutes, and an AM/PM designation. Parsing methods handle this missing information by using reasonable defaults:

- When only the time is present, the date portion uses the current date.
- When only the date is present, the time portion is midnight.
- When the year isn't specified in a date, the current year is used.
- When the day of the month isn't specified, the first of the month is used.

If the date is present in the string, it must include the month and one of the day or year. If the time is present, it must include the hour, and either the minutes or the AM/PM designator.

You can specify the [NoCurrentDateDefault](#) constant to override these defaults. When you use that constant, any missing year, month, or day properties are set to the value `1`. The [last example](#) using [Parse](#) demonstrates this behavior.

In addition to a date and a time component, the string representation of a date and time can include an offset that indicates how much the time differs from Coordinated Universal Time (UTC). For example, the string "2/14/2007 5:32:00 -7:00" defines a time that is seven hours earlier than UTC. If an offset is omitted from the string representation of a time, parsing returns a [DateTime](#) object with its [Kind](#) property set to [DateTimeKind.Unspecified](#). If an offset is specified, parsing returns a [DateTime](#) object with its [Kind](#) property set to [DateTimeKind.Local](#) and its value adjusted to the local time zone of your machine. You can modify this behavior by using a [DateTimeStyles](#) value with the parsing method.

The format provider is also used to interpret an ambiguous numeric date. It is not clear which components of the

date represented by the string "02/03/04" are the month, day, and year. The components are interpreted according to the order of similar date formats in the format provider.

Parse

The following example illustrates the use of the `DateTime.Parse` method to convert a `string` into a `DateTime`. This example uses the culture associated with the current thread. If the `CultureInfo` associated with the current culture cannot parse the input string, a `FormatException` is thrown.

TIP

All the C# samples in this article run in your browser. Press the **Run** button to see the output. You can also edit them to experiment yourself.

NOTE

These examples are available in the GitHub docs repo for both [C#](#) and [VB](#). Or you can download the project as a zipfile for [C#](#) or [VB](#).

```
string dateInput = "Jan 1, 2009";
DateTime parsedDate = DateTime.Parse(dateInput);
Console.WriteLine(parsedDate);
// Displays the following output on a system whose culture is en-US:
//      1/1/2009 12:00:00 AM
```

```
Dim MyString As String = "Jan 1, 2009"
Dim MyDateTime As DateTime = DateTime.Parse(MyString)
Console.WriteLine(MyDateTime)
' Displays the following output on a system whose culture is en-US:
'      1/1/2009 12:00:00 AM
```

You can also explicitly define the culture whose formatting conventions are used when you parse a string. You specify one of the standard `DateTimeFormatInfo` objects returned by the `CultureInfo.DateTimeFormat` property. The following example uses a format provider to parse a German string into a `DateTime`. It creates a `CultureInfo` representing the `de-DE` culture. That `CultureInfo` object ensures successful parsing of this particular string. This precludes whatever setting is in the `CurrentCulture` of the `CurrentThread`.

```
CultureInfo MyCultureInfo = new CultureInfo("de-DE");
string MyString = "12 Juni 2008";
DateTime MyDateTime = DateTime.Parse(MyString, MyCultureInfo);
Console.WriteLine(MyDateTime);
// The example displays the following output:
//      6/12/2008 12:00:00 AM
```

```
Dim MyCultureInfo As CultureInfo = New CultureInfo("de-DE")
Dim MyString As String = "12 Juni 2008"
Dim MyDateTime As DateTime = DateTime.Parse(MyString, MyCultureInfo)
Console.WriteLine(MyDateTime)
' The example displays the following output:
'      6/12/2008 12:00:00 AM
```

However, although you can use overloads of the `Parse` method to specify custom format providers, the method does not support parsing non-standard formats. To parse a date and time expressed in a non-standard format, use

the [ParseExact](#) method instead.

The following example uses the [DateTimeStyles](#) enumeration to specify that the current date and time information should not be added to the [DateTime](#) for unspecified fields.

```
CultureInfo MyCultureInfo = new CultureInfo("de-DE");
string MyString = "12 Juni 2008";
DateTime MyDateTime = DateTime.Parse(MyString, MyCultureInfo,
                                     DateTimeStyles.NoCurrentDateDefault);
Console.WriteLine(MyDateTime);
// The example displays the following output if the current culture is en-US:
//       6/12/2008 12:00:00 AM
```

```
Dim MyCultureInfo As CultureInfo = New CultureInfo("de-DE")
Dim MyString As String = "12 Juni 2008"
Dim MyDateTime As DateTime = DateTime.Parse(MyString, MyCultureInfo,
                                             DateTimeStyles.NoCurrentDateDefault)
Console.WriteLine(MyDateTime)
' The example displays the following output if the current culture is en-US:
'       6/12/2008 12:00:00 AM
```

ParseExact

The [DateTime.ParseExact](#) method converts a string to a [DateTime](#) object if it conforms to one of the specified string patterns. When a string that is not one of the forms specified is passed to this method, a [FormatException](#) is thrown. You can specify one of the standard date and time format specifiers or a combination of the custom format specifiers. Using the custom format specifiers, it is possible for you to construct a custom recognition string. For an explanation of the specifiers, see the topics on [standard date and time format strings](#) and [custom date and time format strings](#).

In the following example, the [DateTime.ParseExact](#) method is passed a string object to parse, followed by a format specifier, followed by a [CultureInfo](#) object. This [ParseExact](#) method can only parse strings that follow the long date pattern in the `en-US` culture.

```
CultureInfo MyCultureInfo = new CultureInfo("en-US");
string[] MyString = { " Friday, April 10, 2009", "Friday, April 10, 2009" };
foreach (string dateString in MyString)
{
    try
    {
        DateTime MyDateTime = DateTime.ParseExact(dateString, "D", MyCultureInfo);
        Console.WriteLine(MyDateTime);
    }
    catch (FormatException)
    {
        Console.WriteLine("Unable to parse '{0}'", dateString);
    }
}
// The example displays the following output:
//       Unable to parse ' Friday, April 10, 2009'
//       4/10/2009 12:00:00 AM
```

```

Dim MyCultureInfo As CultureInfo = New CultureInfo("en-US")
Dim MyString() As String = {" Friday, April 10, 2009", "Friday, April 10, 2009"}
For Each dateString As String In MyString
    Try
        Dim MyDateTime As DateTime = DateTime.ParseExact(dateString, "D",
                                                       MyCultureInfo)
        Console.WriteLine(MyDateTime)
    Catch e As FormatException
        Console.WriteLine("Unable to parse '{0}'", dateString)
    End Try
Next
' The example displays the following output:
'     Unable to parse ' Friday, April 10, 2009'
'     4/10/2009 12:00:00 AM

```

Each overload of the [Parse](#) and [ParseExact](#) methods also has an [IFormatProvider](#) parameter that provides culture-specific information about the formatting of the string. This [IFormatProvider](#) object is a [CultureInfo](#) object that represents a standard culture or a [DateTimeFormatInfo](#) object that is returned by the [CultureInfo.DateTimeFormat](#) property. [ParseExact](#) also uses an additional string or string array argument that defines one or more custom date and time formats.

How to: search strings

3/1/2019 • 4 minutes to read • [Edit Online](#)

You can use two main strategies to search for text in strings. Methods of the [String](#) class search for specific text. Regular expressions search for patterns in text.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The [string](#) type, which is an alias for the [System.String](#) class, provides a number of useful methods for searching the contents of a string. Among them are [Contains](#), [StartsWith](#), [EndsWith](#), [IndexOf](#), [LastIndexOf](#). The [System.Text.RegularExpressions.Regex](#) class provides a rich vocabulary to search for patterns in text. In this article, you learn these techniques and how to choose the best method for your needs.

Does a string contain text?

The [String.Contains](#), [String.StartsWith](#) and [String.EndsWith](#) methods search a string for specific text. The following example shows each of these methods and a variation that uses a case insensitive search:

```
string factMessage = "Extension methods have all the capabilities of regular static methods.";

// Write the string and include the quotation marks.
Console.WriteLine($"\"{factMessage}\"");

// Simple comparisons are always case sensitive!
bool containsSearchResult = factMessage.Contains("extension");
Console.WriteLine($"Starts with \"extension\"? {containsSearchResult}");

// For user input and strings that will be displayed to the end user,
// use the StringComparison parameter on methods that have it to specify how to match strings.
bool ignoreCaseSearchResult = factMessage.StartsWith("extension",
    System.StringComparison.CurrentCultureIgnoreCase);
Console.WriteLine($"Starts with \"extension\"? {ignoreCaseSearchResult} (ignoring case)");

bool endsWithSearchResult = factMessage.EndsWith(".", System.StringComparison.CurrentCultureIgnoreCase);
Console.WriteLine($"Ends with '.'? {endsWithSearchResult}");
```

The preceding example demonstrates an important point for using these methods. Searches are **case-sensitive** by default. You use the [StringComparison.CurrentCultureIgnoreCase](#) enum value to specify a case insensitive search.

Where does the sought text occur in a string?

The [IndexOf](#) and [LastIndexOf](#) methods also search for text in strings. These methods return the location of the text being sought. If the text isn't found, they return `-1`. The following example shows a search for the first and last occurrence of the word "methods" and displays the text in between.

```

string factMessage = "Extension methods have all the capabilities of regular static methods.';

// Write the string and include the quotation marks.
Console.WriteLine($"\"{factMessage}\"");

// This search returns the substring between two strings, so
// the first index is moved to the character just after the first string.
int first = factMessage.IndexOf("methods") + "methods".Length;
int last = factMessage.LastIndexOf("methods");
string str2 = factMessage.Substring(first, last - first);
Console.WriteLine($"Substring between \"methods\" and \"methods\": '{str2}'");

```

Finding specific text using regular expressions

The [System.Text.RegularExpressions.Regex](#) class can be used to search strings. These searches can range in complexity from simple to complicated text patterns.

The following code example searches for the word "the" or "their" in a sentence, ignoring case. The static method [Regex.IsMatch](#) performs the search. You give it the string to search and a search pattern. In this case, a third argument specifies case-insensitive search. For more information, see [System.Text.RegularExpressions.RegexOptions](#).

The search pattern describes the text you search for. The following table describes each element of the search pattern. (The table below uses the single `\` which must be escaped as `\\\` in a C# string).

PATTERN	MEANING
the	match the text "the"
(eir)?	match 0 or 1 occurrence of "eir"
\s	match a white-space character

```

string[] sentences =
{
    "Put the water over there.",
    "They're quite thirsty.",
    "Their water bottles broke."
};

string sPattern = "the(ir)?\\s";

foreach (string s in sentences)
{
    Console.WriteLine($"{s,24}");

    if (System.Text.RegularExpressions.Regex.IsMatch(s, sPattern,
System.Text.RegularExpressions.RegexOptions.IgnoreCase))
    {
        Console.WriteLine($"  (match for '{sPattern}' found)");
    }
    else
    {
        Console.WriteLine();
    }
}

```

TIP

The `string` methods are usually better choices when you are searching for an exact string. Regular expressions are better when you are searching for some pattern in a source string.

Does a string follow a pattern?

The following code uses regular expressions to validate the format of each string in an array. The validation requires that each string have the form of a telephone number in which three groups of digits are separated by dashes, the first two groups contain three digits, and the third group contains four digits. The search pattern uses the regular expression `^\d{3}-\d{3}-\d{4}$`. For more information, see [Regular Expression Language - Quick Reference](#).

PATTERN	MEANING
<code>^</code>	matches the beginning of the string
<code>\d{3}</code>	matches exactly 3 digit characters
<code>-</code>	matches the '-' character
<code>\d{3}</code>	matches exactly 3 digit characters
<code>-</code>	matches the '-' character
<code>\d{4}</code>	matches exactly 4 digit characters
<code>\$</code>	matches the end of the string

```

string[] numbers =
{
    "123-555-0190",
    "444-234-22450",
    "690-555-0178",
    "146-893-232",
    "146-555-0122",
    "4007-555-0111",
    "407-555-0111",
    "407-2-5555",
    "407-555-8974",
    "407-2ab-5555",
    "690-555-8148",
    "146-893-232"
};

string sPattern = "^\\d{3}-\\d{3}-\\d{4}$";

foreach (string s in numbers)
{
    Console.WriteLine($"{s,14}");

    if (System.Text.RegularExpressions.Regex.IsMatch(s, sPattern))
    {
        Console.WriteLine(" - valid");
    }
    else
    {
        Console.WriteLine(" - invalid");
    }
}

```

This single search pattern matches many valid strings. Regular expressions are better to search for or validate against a pattern, rather than a single text string.

You can try these samples by looking at the code in our [GitHub repository](#). Or you can download the samples [as a zip file](#).

How to: Modify string contents in C#

1/23/2019 • 5 minutes to read • [Edit Online](#)

This article demonstrates several techniques to produce a `string` by modifying an existing `string`. All the techniques demonstrated return the result of the modifications as a new `string` object. To clearly demonstrate this, the examples all store the result in a new variable. You can then examine both the original `string` and the `string` resulting from the modification when you run each example.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

There are several techniques demonstrated in this article. You can replace existing text. You can search for patterns and replace matching text with other text. You can treat a string as a sequence of characters. You can also use convenience methods that remove white space. You should choose the techniques that most closely match your scenario.

Replace text

The following code creates a new string by replacing existing text with a substitute.

```
string source = "The mountains are behind the clouds today.";  
  
// Replace one substring with another with String.Replace.  
// Only exact matches are supported.  
var replacement = source.Replace("mountains", "peaks");  
Console.WriteLine($"The source string is <{source}>");  
Console.WriteLine($"The updated string is <{replacement}>");
```

The preceding code demonstrates this *immutable* property of strings. You can see in the preceding example that the original string, `source`, is not modified. The [String.Replace](#) method creates a new `string` containing the modifications.

The [Replace](#) method can replace either strings or single characters. In both cases, every occurrence of the sought text is replaced. The following example replaces all `' '` characters with `'_'`:

```
string source = "The mountains are behind the clouds today.";  
  
// Replace all occurrences of one char with another.  
var replacement = source.Replace(' ', '_');  
Console.WriteLine(source);  
Console.WriteLine(replacement);
```

The source string is unchanged, and a new string is returned with the replacement.

Trim white space

You can use the [String.Trim](#), [String.TrimStart](#), and [String.TrimEnd](#) methods to remove any leading or trailing white

space. The following code shows an example of each. The source string does not change; these methods return a new string with the modified contents.

```
// Remove trailing and leading white space.  
string source = "    I'm wider than I need to be.      ";  
// Store the results in a new string variable.  
var trimmedResult = source.Trim();  
var trimLeading = source.TrimStart();  
var trimTrailing = source.TrimEnd();  
Console.WriteLine($"<{source}>");  
Console.WriteLine($"<{trimmedResult}>");  
Console.WriteLine($"<{trimLeading}>");  
Console.WriteLine($"<{trimTrailing}>");
```

Remove text

You can remove text from a string using the [String.Remove](#) method. This method removes a number of characters starting at a specific index. The following example shows how to use [String.IndexOf](#) followed by [Remove](#) to remove text from a string:

```
string source = "Many mountains are behind many clouds today.";  
// Remove a substring from the middle of the string.  
string toRemove = "many ";  
string result = string.Empty;  
int i = source.IndexOf(toRemove);  
if (i >= 0)  
{  
    result = source.Remove(i, toRemove.Length);  
}  
Console.WriteLine(source);  
Console.WriteLine(result);
```

Replace matching patterns

You can use [regular expressions](#) to replace text matching patterns with new text, possibly defined by a pattern. The following example uses the [System.Text.RegularExpressions.Regex](#) class to find a pattern in a source string and replace it with proper capitalization. The [Regex.Replace\(String, String, MatchEvaluator, RegexOptions\)](#) method takes a function that provides the logic of the replacement as one of its arguments. In this example, that function, `LocalReplaceMatchCase` is a **local function** declared inside the sample method. `LocalReplaceMatchCase` uses the [System.Text.StringBuilder](#) class to build the replacement string with proper capitalization.

Regular expressions are most useful for searching and replacing text that follows a pattern, rather than known text. See [How to: search strings](#) for more details. The search pattern, "the\\$\s" searches for the word "the" followed by a white-space character. That part of the pattern ensures that it doesn't match "there" in the source string. For more information on regular expression language elements, see [Regular Expression Language - Quick Reference](#).

```

string source = "The mountains are still there behind the clouds today.";

// Use Regex.Replace for more flexibility.
// Replace "the" or "The" with "many" or "Many".
// using System.Text.RegularExpressions
string replaceWith = "many ";
source = System.Text.RegularExpressions.Regex.Replace(source, "the\\s", LocalReplaceMatchCase,
    System.Text.RegularExpressions.RegexOptions.IgnoreCase);
Console.WriteLine(source);

string LocalReplaceMatchCase(System.Text.RegularExpressions.Match matchExpression)
{
    // Test whether the match is capitalized
    if (Char.IsUpper(matchExpression.Value[0]))
    {
        // Capitalize the replacement string
        System.Text.StringBuilder replacementBuilder = new System.Text.StringBuilder(replaceWith);
        replacementBuilder[0] = Char.ToUpper(replacementBuilder[0]);
        return replacementBuilder.ToString();
    }
    else
    {
        return replaceWith;
    }
}

```

The [StringBuilder.ToString](#) method returns an immutable string with the contents in the [StringBuilder](#) object.

Modifying individual characters

You can produce a character array from a string, modify the contents of the array, and then create a new string from the modified contents of the array.

The following example shows how to replace a set of characters in a string. First, it uses the [ToCharArray\(\)](#) method to create an array of characters. It uses the [IndexOf](#) method to find the starting index of the word "fox." The next three characters are replaced with a different word. Finally, a new string is constructed from the updated character array.

```

string phrase = "The quick brown fox jumps over the fence";
Console.WriteLine(phrase);

char[] phraseAsChars = phrase.ToCharArray();
int animalIndex = phrase.IndexOf("fox");
if (animalIndex != -1)
{
    phraseAsChars[animalIndex++] = 'c';
    phraseAsChars[animalIndex++] = 'a';
    phraseAsChars[animalIndex] = 't';
}

string updatedPhrase = new string(phraseAsChars);
Console.WriteLine(updatedPhrase);

```

Unsafe modifications to string

Using **unsafe** code, you can modify a string "in place" after it has been created. Unsafe code bypasses many of the features of .NET designed to minimize certain types of bugs in code. You need to use unsafe code to modify a string in place because the string class is designed as an **immutable** type. Once it has been created, its value does not change. Unsafe code circumvents this property by accessing and modifying the memory used by a `string` without using normal `string` methods. The following example is provided for those rare situations where you

want to modify a string in-place using unsafe code. The example shows how to use the `fixed` keyword. The `fixed` keyword prevents the garbage collector (GC) from moving the string object in memory while code accesses the memory using the unsafe pointer. It also demonstrates one possible side effect of unsafe operations on strings that results from the way that the C# compiler stores (`interns`) strings internally. In general, you shouldn't use this technique unless it is absolutely necessary. You can learn more in the articles on [unsafe](#) and [fixed](#). The API reference for [Intern](#) includes information on string interning.

```
unsafe
{
    // Compiler will store (intern)
    // these strings in same location.
    string helloOne = "Hello";
    string helloTwo = "Hello";

    // Change one string using unsafe code.
    fixed (char* p = helloOne)
    {
        p[0] = 'C';
    }

    // Both strings have changed.
    Console.WriteLine(helloOne);
    Console.WriteLine(helloTwo);
}
```

You can try these samples by looking at the code in our [GitHub repository](#). Or you can download the samples [as a zip file](#).

How to compare strings in C#

1/23/2019 • 10 minutes to read • [Edit Online](#)

You compare strings to answer one of two questions: "Are these two strings equal?" or "In what order should these strings be placed when sorting them?"

Those two questions are complicated by factors that affect string comparisons:

- You can choose an ordinal or linguistic comparison.
- You can choose if case matters.
- You can choose culture-specific comparisons.
- Linguistic comparisons are culture and platform-dependent.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

When you compare strings, you define an order among them. Comparisons are used to sort a sequence of strings. Once the sequence is in a known order, it is easier to search, both for software and for humans. Other comparisons may check if strings are the same. These sameness checks are similar to equality, but some differences, such as case differences, may be ignored.

Default ordinal comparisons

The most common operations:

- [String.CompareTo](#)
- [String.Equals](#)
- [String.Equality](#)

use an ordinal comparison, a case-sensitive comparison, and use the current culture. The results are shown in the following example:

```
string root = @"C:\users";
string root2 = @"C:\Users";

bool result = root.Equals(root2);
Console.WriteLine($"Ordinal comparison: <{root}> and <{root2}> are {(result ? "equal." : "not equal.")}");

result = root.Equals(root2, StringComparison.OrdinalIgnoreCase);
Console.WriteLine($"Ordinal comparison: <{root}> and <{root2}> are {(result ? "equal." : "not equal.")}");

Console.WriteLine($"Using == says that <{root}> and <{root2}> are {(root == root2 ? "equal" : "not equal")}");

```

The default ordinal comparison does not take linguistic rules into account when comparing strings. It compares the binary value of each [Char](#) object in two strings. As a result, the default ordinal comparison is also case-sensitive.

Note that the test for equality with [String.Equals](#) and [String.Equality](#) differs from string comparison using the

`String.CompareTo` and `Compare(String, String)` methods. While the tests for equality perform a case-sensitive ordinal comparison, the comparison method perform a case-sensitive, culture-sensitive comparison using the current culture. Because the default comparison methods often perform different types of comparisons, we recommend that you always make the intent of your code clear by calling an overload that explicitly specifies the type of comparison to perform.

Case-insensitive ordinal comparisons

The `String.Equals(String, StringComparison)` method enables you to specify a `StringComparison` value of `StringComparison.OrdinalIgnoreCase` for a case-insensitive ordinal comparison. There is also a static `String.Compare(String, String, StringComparison)` method that performs a case-insensitive ordinal comparison if you specify a value of `StringComparison.OrdinalIgnoreCase` for the `StringComparison` argument. These are shown in the following code:

```
string root = @"C:\users";
string root2 = @"C:\Users";

bool result = root.Equals(root2, StringComparison.OrdinalIgnoreCase);
bool areEqual = String.Equals(root, root2, StringComparison.OrdinalIgnoreCase);
int comparison = String.Compare(root, root2, StringComparison.OrdinalIgnoreCase);

Console.WriteLine($"Ordinal ignore case: <{root}> and <{root2}> are {(result ? "equal." : "not equal.")}");
Console.WriteLine($"Ordinal static ignore case: <{root}> and <{root2}> are {(areEqual ? "equal." : "not equal.")}");
if (comparison < 0)
    Console.WriteLine($"<{root}> is less than <{root2}>");
else if (comparison > 0)
    Console.WriteLine($"<{root}> is greater than <{root2}>");
else
    Console.WriteLine($"<{root}> and <{root2}> are equivalent in order");
```

When performing a case-insensitive ordinal comparison, these methods use the casing conventions of the [invariant culture](#).

Linguistic comparisons

Strings can also be ordered using linguistic rules for the current culture. This is sometimes referred to as "word sort order." When you perform a linguistic comparison, some nonalphanumeric Unicode characters might have special weights assigned. For example, the hyphen "-" may have a very small weight assigned to it so that "co-op" and "coop" appear next to each other in sort order. In addition, some Unicode characters may be equivalent to a sequence of `Char` instances. The following example uses the phrase "They dance in the street." in German with the "ss" (U+0073 U+0073) in one string and 'ß' (U+00DF) in another. Linguistically (in Windows), "ss" is equal to the German Essetz: 'ß' character in both the "en-US" and "de-DE" cultures.

```

string first = "Sie tanzen auf der Straße.";
string second = "Sie tanzen auf der Strasse.";

Console.WriteLine($"First sentence is <{first}>");
Console.WriteLine($"Second sentence is <{second}>");

bool equal = String.Equals(first, second, StringComparison.InvariantCulture);
Console.WriteLine($"The two strings {(equal == true ? "are" : "are not")} equal.");
showComparison(first, second);

string word = "coop";
string words = "co-op";
string other = "cop";

showComparison(word, words);
showComparison(word, other);
showComparison(words, other);
void showComparison(string one, string two)
{
    int compareLinguistic = String.Compare(one, two, StringComparison.InvariantCulture);
    int compareOrdinal = String.Compare(one, two, StringComparison.Ordinal);
    if (compareLinguistic < 0)
        Console.WriteLine($"<{one}> is less than <{two}> using invariant culture");
    else if (compareLinguistic > 0)
        Console.WriteLine($"<{one}> is greater than <{two}> using invariant culture");
    else
        Console.WriteLine($"<{one}> and <{two}> are equivalent in order using invariant culture");
    if (compareOrdinal < 0)
        Console.WriteLine($"<{one}> is less than <{two}> using ordinal comparison");
    else if (compareOrdinal > 0)
        Console.WriteLine($"<{one}> is greater than <{two}> using ordinal comparison");
    else
        Console.WriteLine($"<{one}> and <{two}> are equivalent in order using ordinal comparison");
}

```

This sample demonstrates the operating system-dependent nature of linguistic comparisons. The host for the interactive window is a Linux host. The linguistic and ordinal comparisons produce the same results. If you ran this same sample on a Windows host, you would see the following output:

```

<coop> is less than <co-op> using invariant culture
<coop> is greater than <co-op> using ordinal comparison
<coop> is less than <cop> using invariant culture
<coop> is less than <cop> using ordinal comparison
<co-op> is less than <cop> using invariant culture
<co-op> is less than <cop> using ordinal comparison

```

On Windows, the sort order of "cop", "coop", and "co-op" change when you change from a linguistic comparison to an ordinal comparison. The two German sentences also compare differently using the different comparison types.

Comparisons using specific cultures

This sample stores [CultureInfo](#) objects for the en-US and de-DE cultures. The comparisons are performed using a [CultureInfo](#) object to ensure a culture-specific comparison.

The culture used affects linguistic comparisons. The following example shows the results of comparing the two German sentences using the "en-US" culture and the "de-DE" culture:

```

string first = "Sie tanzen auf der Straße.";
string second = "Sie tanzen auf der Strasse.";

Console.WriteLine($"First sentence is <{first}>");
Console.WriteLine($"Second sentence is <{second}>");

var en = new System.Globalization.CultureInfo("en-US");

// For culture-sensitive comparisons, use the String.Compare
// overload that takes a StringComparison value.
int i = String.Compare(first, second, en, System.Globalization.CompareOptions.None);
Console.WriteLine($"Comparing in {en.Name} returns {i}.");

var de = new System.Globalization.CultureInfo("de-DE");
i = String.Compare(first, second, de, System.Globalization.CompareOptions.None);
Console.WriteLine($"Comparing in {de.Name} returns {i}.");

bool b = String.Equals(first, second, StringComparison.CurrentCulture);
Console.WriteLine($"The two strings {(b ? "are" : "are not")} equal.");

string word = "coop";
string words = "co-op";
string other = "cop";

showComparison(word, words, en);
showComparison(word, other, en);
showComparison(words, other, en);
void showComparison(string one, string two, System.Globalization.CultureInfo culture)
{
    int compareLinguistic = String.Compare(one, two, en, System.Globalization.CompareOptions.None);
    int compareOrdinal = String.Compare(one, two, StringComparison.Ordinal);
    if (compareLinguistic < 0)
        Console.WriteLine($"<{one}> is less than <{two}> using en-US culture");
    else if (compareLinguistic > 0)
        Console.WriteLine($"<{one}> is greater than <{two}> using en-US culture");
    else
        Console.WriteLine($"<{one}> and <{two}> are equivalent in order using en-US culture");
    if (compareOrdinal < 0)
        Console.WriteLine($"<{one}> is less than <{two}> using ordinal comparison");
    else if (compareOrdinal > 0)
        Console.WriteLine($"<{one}> is greater than <{two}> using ordinal comparison");
    else
        Console.WriteLine($"<{one}> and <{two}> are equivalent in order using ordinal comparison");
}

```

Culture-sensitive comparisons are typically used to compare and sort strings input by users with other strings input by users. The characters and sorting conventions of these strings might vary depending on the locale of the user's computer. Even strings that contain identical characters might sort differently depending on the culture of the current thread. In addition, try this sample code locally on a Windows machine, and you will see the following results:

```

<coop> is less than <co-op> using en-US culture
<coop> is greater than <co-op> using ordinal comparison
<coop> is less than <cop> using en-US culture
<coop> is less than <cop> using ordinal comparison
<co-op> is less than <cop> using en-US culture
<co-op> is less than <cop> using ordinal comparison

```

Linguistic comparisons are dependent on the current culture, and are OS dependent. You must take that into account when you work with string comparisons.

Linguistic sorting and searching strings in arrays

The following examples show how to sort and search for strings in an array using a linguistic comparison dependent on the current culture. You use the static [Array](#) methods that take a [System.StringComparer](#) parameter.

This example shows how to sort an array of strings using the current culture:

```
string[] lines = new string[]
{
    @"c:\public\textfile.txt",
    @"c:\public\textFile.TXT",
    @"c:\public\Text.txt",
    @"c:\public\testfile2.txt"
};

Console.WriteLine("Non-sorted order:");
foreach (string s in lines)
{
    Console.WriteLine($"    {s}");
}

Console.WriteLine("\n\rSorted order:");

// Specify Ordinal to demonstrate the different behavior.
Array.Sort(lines, StringComparer.CurrentCulture);

foreach (string s in lines)
{
    Console.WriteLine($"    {s}");
}
```

Once the array is sorted, you can search for entries using a binary search. A binary search starts in the middle of the collection to determine which half of the collection would contain the sought string. Each subsequent comparison subdivides the remaining part of the collection in half. The array is sorted using the [StringComparer.CurrentCulture](#). The local function [ShowWhere](#) displays information about where the string was found. If the string was not found, the returned value indicates where it would be if it were found.

```

string[] lines = new string[]
{
    @"c:\public\textfile.txt",
    @"c:\public\textFile.TXT",
    @"c:\public\Text.txt",
    @"c:\public\testfile2.txt"
};

Array.Sort(lines, StringComparer.CurrentCulture);

string searchString = @"c:\public\TEXTFILE.TXT";
Console.WriteLine($"Binary search for <{searchString}>");
int result = Array.BinarySearch(lines, searchString, StringComparer.CurrentCulture);
ShowWhere<string>(lines, result);

Console.WriteLine($"{{(result > 0 ? "Found" : "Did not find")}} {searchString}");
```

```

void ShowWhere<T>(T[] array, int index)
{
    if (index < 0)
    {
        index = ~index;

        Console.Write("Not found. Sorts between: ");

        if (index == 0)
            Console.Write("beginning of sequence and ");
        else
            Console.WriteLine($"{array[index - 1]} and ");

        if (index == array.Length)
            Console.WriteLine("end of sequence.");
        else
            Console.WriteLine($"{array[index]}.");
    }
    else
    {
        Console.WriteLine($"Found at index {index}.");
    }
}
```

Ordinal sorting and searching in collections

The following code uses the [System.Collections.Generic.List<T>](#) collection class to store strings. The strings are sorted using the [List<T>.Sort](#) method. This method needs a delegate that compares and orders two strings. The [String.CompareTo](#) method provides that comparison function. Run the sample and observe the order. This sort operation uses an ordinal case sensitive sort. You would use the static [String.Compare](#) methods to specify different comparison rules.

```
List<string> lines = new List<string>
{
    @"c:\public\textfile.txt",
    @"c:\public\textFile.TXT",
    @"c:\public\Text.txt",
    @"c:\public\testfile2.txt"
};

Console.WriteLine("Non-sorted order:");
foreach (string s in lines)
{
    Console.WriteLine($"    {s}");
}

Console.WriteLine("\n\rSorted order:");

lines.Sort((left, right) => left.CompareTo(right));
foreach (string s in lines)
{
    Console.WriteLine($"    {s}");
}
```

Once sorted, the list of strings can be searched using a binary search. The following sample shows how to search the sorted listed using the same comparison function. The local function `ShowWhere` shows where the sought text is or would be:

```

List<string> lines = new List<string>
{
    @"c:\public\textfile.txt",
    @"c:\public\textFile.TXT",
    @"c:\public\Text.txt",
    @"c:\public\testfile2.txt"
};

lines.Sort((left, right) => left.CompareTo(right));

string searchString = @"c:\public\TEXTFILE.TXT";
Console.WriteLine($"Binary search for <{searchString}>");
int result = lines.BinarySearch(searchString);
ShowWhere<string>(lines, result);

Console.WriteLine($"{{(result > 0 ? "Found" : "Did not find")}} {searchString}"); 

void ShowWhere<T>(IList<T> collection, int index)
{
    if (index < 0)
    {
        index = ~index;

        Console.Write("Not found. Sorts between: ");

        if (index == 0)
            Console.Write("beginning of sequence and ");
        else
            Console.Write($"{collection[index - 1]} and ");

        if (index == collection.Count)
            Console.WriteLine("end of sequence.");
        else
            Console.WriteLine($"{collection[index]}.");
    }
    else
    {
        Console.WriteLine($"Found at index {index}.");
    }
}

```

Always make sure to use the same type of comparison for sorting and searching. Using different comparison types for sorting and searching produces unexpected results.

Collection classes such as [System.Collections.Hashtable](#), [System.Collections.Generic.Dictionary< TKey, TValue >](#), and [System.Collections.Generic.List< T >](#) have constructors that take a [System.StringComparer](#) parameter when the type of the elements or keys is `string`. In general, you should use these constructors whenever possible, and specify either [StringComparer.Ordinal](#) or [StringComparer.OrdinalIgnoreCase](#).

Reference equality and string interning

None of the samples have used [ReferenceEquals](#). This method determines if two strings are the same object. This can lead to inconsistent results in string comparisons. The following example demonstrates the *string interning* feature of C#. When a program declares two or more identical string variables, the compiler stores them all in the same location. By calling the [ReferenceEquals](#) method, you can see that the two strings actually refer to the same object in memory. Use the [String.Copy](#) method to avoid interning. After the copy has been made, the two strings have different storage locations, even though they have the same value. Run the following sample to show that strings `a` and `b` are *interned* meaning they share the same storage. The strings `a` and `c` are not.

```
string a = "The computer ate my source code.";
string b = "The computer ate my source code.";

if (String.ReferenceEquals(a, b))
    Console.WriteLine("a and b are interned.");
else
    Console.WriteLine("a and b are not interned.");

string c = String.Copy(a);

if (String.ReferenceEquals(a, c))
    Console.WriteLine("a and c are interned.");
else
    Console.WriteLine("a and c are not interned.");
```

NOTE

When you test for equality of strings, you should use the methods that explicitly specify what kind of comparison you intend to perform. Your code is much more maintainable and readable. Use the overloads of the methods of the [System.String](#) and [System.Array](#) classes that take a [StringComparison](#) enumeration parameter. You specify which type of comparison to perform. Avoid using the `==` and `!=` operators when you test for equality. The [String.CompareTo](#) instance methods always perform an ordinal case-sensitive comparison. They are primarily suited for ordering strings alphabetically.

You can intern a string or retrieve a reference to an existing interned string by calling the [String.Intern](#) method. To determine whether a string is interned, call the [String.IsInterned](#) method.

How to: safely cast by using pattern matching is and as operators

12/6/2018 • 5 minutes to read • [Edit Online](#)

Because objects are polymorphic, it's possible for a variable of a base class type to hold a derived [type](#). To access the derived type's instance members, it's necessary to [cast](#) the value back to the derived type. However, a cast creates the risk of throwing an [InvalidOperationException](#). C# provides [pattern matching](#) statements that perform a cast conditionally only when it will succeed. C# also provides the [is](#) and [as](#) operators to test if a value is of a certain type.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The following code demonstrates the pattern matching `is` statement. It contains methods that test a method argument to determine if it is one of a possible set of derived types:

```

class Animal
{
    public void Eat() { Console.WriteLine("Eating."); }
    public override string ToString()
    {
        return "I am an animal.";
    }
}
class Mammal : Animal { }
class Giraffe : Mammal { }

class SuperNova { }

class Program
{
    static void Main(string[] args)
    {
        Giraffe g = new Giraffe();
        FeedMammals(g);

        TestForMammals(g);

        SuperNova sn = new SuperNova();
        TestForMammals(sn);
    }

    static void FeedMammals(Animal a)
    {
        // Use the is operator to verify the type
        // before performing a cast.
        if (a is Mammal m)
        {
            m.Eat();
        }
    }

    static void TestForMammals(object o)
    {
        // Alternatively, use the as operator and test for null
        // before referencing the variable.
        if (o is Mammal m)
        {
            Console.WriteLine(m.ToString());
        }
        else
        {
            // variable 'm' is not in scope here, and can't be used.
            Console.WriteLine($"{o.GetType().Name} is not a Mammal");
        }
    }
}

```

The preceding sample demonstrates a few features of pattern matching syntax. The `if (a is Mammal m)` and `if (o is Mammal m)` statements combine the test with an initialization assignment. The assignment occurs only when the test succeeds. The variable `m` is only in scope in the embedded `if` statement where it has been assigned. You cannot access `m` later in the same method. Try it in the interactive window.

You can also use the same syntax for testing if a [nullable type](#) has a value, as shown in the following sample code:

```

class Program
{
    static void Main(string[] args)
    {
        // Use the as operator with a value type.
        // Note the implicit conversion to int? in
        // the method body.
        int i = 5;
        PatternMatchingNullable(i);

        int? j = null;
        PatternMatchingNullable(j);

        double d = 9.78654;
        PatternMatchingNullable(d);

        PatternMatchingSwitch(i);
        PatternMatchingSwitch(j);
        PatternMatchingSwitch(d);
    }

    static void PatternMatchingNullable(System.ValueType val)
    {
        if (val is int j) // Nullable types are not allowed in patterns
        {
            Console.WriteLine(j);
        }
        else if (val is null) // If val is a nullable type with no value, this expression is true
        {
            Console.WriteLine("val is a nullable type with the null value");
        }
        else
        {
            Console.WriteLine("Could not convert " + val.ToString());
        }
    }

    static void PatternMatchingSwitch(System.ValueType val)
    {
        switch (val)
        {
            case int number:
                Console.WriteLine(number);
                break;
            case long number:
                Console.WriteLine(number);
                break;
            case decimal number:
                Console.WriteLine(number);
                break;
            case float number:
                Console.WriteLine(number);
                break;
            case double number:
                Console.WriteLine(number);
                break;
            case null:
                Console.WriteLine("val is a nullable type with the null value");
                break;
            default:
                Console.WriteLine("Could not convert " + val.ToString());
                break;
        }
    }
}

```

The preceding sample demonstrates other features of pattern matching to use with conversions. You can test a variable for the null pattern by checking specifically for the `null` value. When the runtime value of the variable is `null`, an `is` statement checking for a type always returns `false`. The pattern matching `is` statement doesn't allow a nullable value type, such as `int?` or `Nullable<int>`, but you can test for any other value type.

The preceding sample also shows how you use the pattern matching `is` expression in a `switch` statement where the variable may be one of many different types.

If you want to test if a variable is a given type, but not assign it to a new variable, you can use the `is` and `as` operators for reference types and nullable types. The following code shows how to use the `is` and `as` statements that were part of the C# language before pattern matching was introduced to test if a variable is of a given type:

```
class Animal
{
    public void Eat() { Console.WriteLine("Eating."); }
    public override string ToString()
    {
        return "I am an animal.";
    }
}
class Mammal : Animal { }
class Giraffe : Mammal { }

class SuperNova { }

class Program
{
    static void Main(string[] args)
    {
        // Use the is operator to verify the type.
        // before performing a cast.
        Giraffe g = new Giraffe();
        UseIsOperator(g);

        // Use the as operator and test for null
        // before referencing the variable.
        UseAsOperator(g);

        // Use the as operator to test
        // an incompatible type.
        SuperNova sn = new SuperNova();
        UseAsOperator(sn);

        // Use the as operator with a value type.
        // Note the implicit conversion to int? in
        // the method body.
        int i = 5;
        UseAsWithNullable(i);

        double d = 9.78654;
        UseAsWithNullable(d);
    }

    static void UseIsOperator(Animal a)
    {
        if (a is Mammal)
        {
            Mammal m = (Mammal)a;
            m.Eat();
        }
    }

    static void UsePatternMatchingIs(Animal a)
    {
        if (a is Mammal)
        {
            Mammal m = (Mammal)a;
            m.Eat();
        }
    }
}
```

```

    if (a is Mammal m)
    {
        m.Eat();
    }
}

static void UseAsOperator(object o)
{
    Mammal m = o as Mammal;
    if (m != null)
    {
        Console.WriteLine(m.ToString());
    }
    else
    {
        Console.WriteLine($"{o.GetType().Name} is not a Mammal");
    }
}

static void UseAsWithNullable(System.ValueType val)
{
    int? j = val as int?;
    if (j != null)
    {
        Console.WriteLine(j);
    }
    else
    {
        Console.WriteLine("Could not convert " + val.ToString());
    }
}
}

```

As you can see by comparing this code with the pattern matching code, the pattern matching syntax provides more robust features by combining the test and the assignment in a single statement. Use the pattern matching syntax whenever possible.

You can try these samples by looking at the code in our [GitHub repository](#). Or you can download the samples [as a zip file](#).

The .NET Compiler Platform SDK

3/19/2019 • 6 minutes to read • [Edit Online](#)

Compilers build a detailed model of application code as they validate the syntax and semantics of that code. They use this model to build the executable output from the source code. The .NET Compiler Platform SDK provides access to this model. Increasingly, we rely on integrated development environment (IDE) features such as IntelliSense, refactoring, intelligent rename, "Find all references," and "Go to definition" to increase our productivity. We rely on code analysis tools to improve our code quality, and code generators to aid in application construction. As these tools get smarter, they need access to more and more of the model that only compilers create as they process application code. This is the core mission of the Roslyn APIs: opening up the black boxes and allowing tools and end users to share in the wealth of information compilers have about our code. Instead of being opaque source-code-in and object-code-out translators, through Roslyn, compilers become platforms: APIs that you can use for code-related tasks in your tools and applications.

.NET Compiler Platform SDK concepts

The .NET Compiler Platform SDK dramatically lowers the barrier to entry for creating code focused tools and applications. It creates many opportunities for innovation in areas such as meta-programming, code generation and transformation, interactive use of the C# and VB languages, and embedding of C# and VB in domain specific languages.

The .NET Compiler Platform SDK enables you to build **analyzers** and **code fixes** that find and correct coding mistakes. **Analyzers** understand the syntax and structure of code and detect practices that should be corrected. **Code fixes** provide one or more suggested fixes for addressing coding mistakes found by analyzers. Typically, an analyzer and the associated code fixes are packaged together in a single project.

Analyzers and code fixes use static analysis to understand code. They do not run the code or provide other testing benefits. They can, however, point out practices that often lead to bugs, unmaintainable code, or standard guideline validation.

The .NET Compiler Platform SDK provides a single set of APIs that enable you to examine and understand a C# or Visual Basic codebase. Because you can use this single codebase, you can write analyzers and code fixes more easily by leveraging the syntactic and semantic analysis APIs provided by the .NET Compiler Platform SDK. Freed from the large task of replicating the analysis done by the compiler, you can concentrate on the more focused task of finding and fixing common coding errors for your project or library.

A smaller benefit is that your analyzers and code fixes are smaller and use much less memory when loaded in Visual Studio than they would if you wrote your own codebase to understand the code in a project. By leveraging the same classes used by the compiler and Visual Studio, you can create your own static analysis tools. This means your team can use analyzers and code fixes without a noticeable impact on the IDE's performance.

There are three main scenarios for writing analyzers and code fixes:

1. [*Enforce team coding standards*](#)
2. [*Provide guidance with library packages*](#)
3. [*Provide general guidance*](#)

Enforce team coding standards

Many teams have coding standards that are enforced through code reviews with other team members. Analyzers and code fixes can make this process much more efficient. Code reviews happen when a developer shares their

work with others on the team. The developer will have invested all the time needed to complete a new feature before getting any comments. Weeks may go by while the developer reinforces habits that don't match the team's practices.

Analyzers run as a developer writes code. The developer gets immediate feedback that encourages following the guidance immediately. The developer builds habits to write compliant code as soon as they begin prototyping. When the feature is ready for humans to review, all the standard guidance has been enforced.

Teams can build analyzers and code fixes that look for the most common practices that violate team coding practices. These can be installed on each developer's machine to enforce the standards.

Provide guidance with library packages

There are a wealth of libraries available for .NET developers on NuGet. Some of these come from Microsoft, some from third-party companies, and others from community members and volunteers. These libraries get more adoption and higher reviews when developers can succeed with those libraries.

In addition to providing documentation, you can provide analyzers and code fixes that find and correct common mis-uses of your library. These immediate corrections will help developers succeed more quickly.

You can package analyzers and code fixes with your library on NuGet. In that scenario, every developer who installs your NuGet package will also install the analyzer package. All developers using your library will immediately get guidance from your team in the form of immediate feedback on mistakes and suggested corrections.

Provide general guidance

The .NET developer community has discovered through experience patterns that work well and patterns that are best avoided. Several community members have created analyzers that enforce those recommended patterns. As we learn more, there is always room for new ideas.

These analyzers can be uploaded to the [Visual Studio Marketplace](#) and downloaded by developers using Visual Studio. Newcomers to the language and the platform learn accepted practices quickly and become productive earlier in their .NET journey. As these become more widely used, the community adopts these practices.

Next steps

The .NET Compiler Platform SDK includes the latest language object models for code generation, analysis, and refactoring. This section provides a conceptual overview of the .NET Compiler Platform SDK. Further details can be found in the quickstarts, samples and tutorials sections.

You can learn more about the concepts in the .NET Compiler Platform SDK in these five topics:

- [Explore code with the syntax visualizer](#)
- [Understand the compiler API model](#)
- [Work with syntax](#)
- [Work with semantics](#)
- [Work with a workspace](#)

To get started, you'll need to install the **.NET Compiler Platform SDK**:

Installation instructions

There are two different ways to find the **.NET Compiler Platform SDK** in the **Visual Studio Installer**:

Install using the Workloads view

The .NET Compiler Platform SDK is not automatically selected as part of the Visual Studio extension development workload. You must select it as an optional component.

1. Run **Visual Studio Installer**
2. Select **Modify**
3. Check the **Visual Studio extension development** workload.
4. Open the **Visual Studio extension development** node in the summary tree.
5. Check the box for **.NET Compiler Platform SDK**. You'll find it last under the optional components.

Optionally, you'll also want the **DGML editor** to display graphs in the visualizer:

1. Open the **Individual components** node in the summary tree.
2. Check the box for **DGML editor**

Install using the Individual components tab

1. Run **Visual Studio Installer**
2. Select **Modify**
3. Select the **Individual components** tab
4. Check the box for **.NET Compiler Platform SDK**. You'll find it at the top under the **Compilers, build tools, and runtimes** section.

Optionally, you'll also want the **DGML editor** to display graphs in the visualizer:

1. Check the box for **DGML editor**. You'll find it under the **Code tools** section.

C# programming guide

2/23/2019 • 2 minutes to read • [Edit Online](#)

This section provides detailed information on key C# language features and features accessible to C# through the .NET Framework.

Most of this section assumes that you already know something about C# and general programming concepts. If you are a complete beginner with programming or with C#, you might want to visit the [Introduction to C# Tutorials](#) or [Getting Started with C#](#) interactive tutorial, where no prior programming knowledge is required.

For information about specific keywords, operators and preprocessor directives, see [C# Reference](#). For information about the C# Language Specification, see [C# Language Specification](#).

C# Reference

3/14/2019 • 2 minutes to read • [Edit Online](#)

This section provides reference material about C# keywords, operators, special characters, preprocessor directives, compiler options, and compiler errors and warnings.

In This Section

[C# Keywords](#)

Provides links to information about C# keywords and syntax.

[C# Operators](#)

Provides links to information about C# operators and syntax.

[C# Special Characters](#)

Provides links to information about special contextual characters in C# and their usage.

[C# Preprocessor Directives](#)

Provides links to information about compiler commands for embedding in C# source code.

[C# Compiler Options](#)

Includes information about compiler options and how to use them.

[C# Compiler Errors](#)

Includes code snippets that demonstrate the cause and correction of C# compiler errors and warnings.

[C# Language Specification](#)

The C# 6.0 language specification. This is a draft proposal for the C# 6.0 language. Version 5.0 has been released in December 2017 as the [Standard ECMA-334 5th Edition](#) document.

The features that have been implemented in C# versions after 6.0 are represented in language specification proposals. These documents describe the deltas to the language spec in order to add these new features.

[C# 7.0 Language Proposals](#)

There are a number of new features implemented in C# 7.0. They include pattern matching, local functions, out variable declarations, throw expressions, binary literals, and digit separators. This folder contains the specifications for each of those features.

[C# 7.1 Language Proposals](#)

There are new features added in C# 7.1. First, you can write a `Main` method that returns `Task` or `Task<int>`. This enables you to add the `async` modifier to `Main`. The `default` expression can be used without a type in locations where the type can be inferred. Also, tuple member names can be inferred. Finally, pattern matching can be used with generics.

[C# 7.2 Language Proposals](#)

C# 7.2 added a number of small features. You can pass arguments by readonly reference using the `in` keyword. There are a number of low-level changes to support compile-time safety for `span` and related types. You can use named arguments where later arguments are positional, in some situations. The `private protected` access modifier enables you to specify that callers are limited to derived types implemented in the same assembly. The `?:` operator can resolve to a reference to a variable. You can also format hexadecimal and binary numbers using a leading digit separator.

[C# 7.3 Language Proposals](#)

C# 7.3 is another point release that includes several small updates. You can use new constraints on generic type parameters. Other changes make it easier to work with `fixed` fields, including using `stackalloc` allocations. Local variables declared with the `ref` keyword may be reassigned to refer to new storage. You can place attributes on auto-implemented properties that target the compiler-generated backing field. Expression variables can be used in initializers. Tuples can be compared for equality (or inequality). There have also been some improvements to overload resolution.

C# 8.0 Language Proposals C# 8.0 is available in preview. The following proposals are the current versions of the specifications for those features. Some are more complete; some are still a work in progress. The features that have shipped in previews include nullable reference types, recursive pattern matching, async streams, ranges and indexes, pattern based using and using declarations, and null coalescing assignment.

F# Guide

2/28/2019 • 2 minutes to read • [Edit Online](#)

The F# guide provides many resources to learn the F# language.

Learning F#

[What is F#](#) describes what the F# language is and what programming in it is like, with short code samples. This is recommended if you are new to F#.

[Tour of F#](#) gives an overview of major language features with lots of code samples. This is recommended if you are interested in seeing core F# features in action.

[Get started with F# in Visual Studio](#) if you're on Windows and want the full Visual Studio IDE (Integrated Development Environment) experience.

[Get started with F# in Visual Studio for Mac](#) if you're on macOS and want to use a Visual Studio IDE.

[Get Started with F# in Visual Studio Code](#) if you want a lightweight, cross-platform, and feature-packed IDE experience.

[Get started with F# with the .NET Core CLI](#) if you want to use command-line tools.

[Get started with F# and Xamarin](#) for mobile programming with F#.

[F# for Azure Notebooks](#) is a tutorial for learning F# in a free, hosted Jupyter Notebook.

References

[F# Language Reference](#) is the official, comprehensive reference for all F# language features. Each article explains the syntax and shows code samples. You can use the filter bar in the table of contents to find specific articles.

[F# Core Library Reference](#) is the API reference for the F# Core Library.

Additional guides

[F# for Fun and Profit](#) is a comprehensive and very detailed book on learning F#. Its contents and author are beloved by the F# community. The target audience is primarily developers with an object oriented programming background.

[F# Programming Wikibook](#) is a wikibook about learning F#. It is also a product of the F# community. The target audience is people who are new to F#, with a little bit of object oriented programming background.

Learn F# through videos

[F# tutorial on YouTube](#) is a great introduction to F# using Visual Studio, showing lots of great examples over the course of 1.5 hours. The target audience is Visual Studio developers who are new to F#.

[Introduction to Programming with F#](#) is a great video series that uses Visual Studio Code as the main editor. The video series starts from nothing and ends with building a text-based RPG video game. The target audience is developers who prefer Visual Studio Code (or a lightweight IDE) and are new to F#.

[What's New in Visual Studio 2017 for F# For Developers](#) is a video course that shows some of the newer features for F# in Visual Studio 2017. The target audience is Visual Studio developers who are new to F#.

Other useful resources

The [F# Snippets Website](#) contains a massive set of code snippets showing how to do just about anything in F#, ranging from absolute beginner to highly advanced snippets.

The [F# Software Foundation Slack](#) is a great place for beginners and experts alike, is highly active, and has some of world's best F# programmers available for a chat. We highly recommend joining.

The F# Software Foundation

Although Microsoft is the primary developer of the F# language and its tools in Visual Studio, F# is also backed by an independent foundation, the F# Software Foundation (FSSF).

The mission of the F# Software Foundation is to promote, protect, and advance the F# programming language, and to support and facilitate the growth of a diverse and international community of F# programmers.

To learn more and get involved, check out [fsharp.org](#). It's free to join, and the network of F# developers in the foundation is something you don't want to miss out on!

Get Started with F#

2/28/2019 • 2 minutes to read • [Edit Online](#)

You can get started with F# on your machine or online.

Get started on your machine

There are multiple guides on how to install and use F# for the first time on your machine. You can use the following table to help in making a decision:

OS	PREFER VISUAL STUDIO	PREFER VISUAL STUDIO CODE	PREFER COMMAND LINE
Windows	Get started with Visual Studio	Get started with Visual Studio Code and Ionide	Get started with the .NET Core CLI
macOS	Get started with VS for Mac	Get started with Visual Studio Code and Ionide	Get started with the .NET Core CLI
Linux	N/A	Get started with Visual Studio Code and Ionide	Get started with the .NET Core CLI

In general, there is no specific that is better than the rest. We recommend trying all ways to use F# on your machine to see what you like the best!

Get started online

If you'd rather not install F# and .NET on your machine, you can also get started with F# in the browser:

- [Introduction to F# on Azure Notebooks](#) is a [Jupyter notebook](#) on the free Azure Notebooks service. Just sign in with a Microsoft account and you can hack away directly in the browser!
- [The Fable REPL](#) is an interactive, in-browser REPL that uses [Fable](#) to translate F# code into JavaScript. Check out the numerous samples that range from F# basics to a fully fledged video game all executing in your browser!

Install F#

2/28/2019 • 2 minutes to read • [Edit Online](#)

You can install F# in multiple ways, depending on your environment.

Install F# with Visual Studio

If you're downloading [Visual Studio](#) for the first time, it will first install the Visual Studio installer. Install the appropriate SKU of Visual Studio from the installer. If you already have it installed, click **Modify**.

You'll next see a list of Workloads. Select **ASP.NET and web development** which will install F# support and .NET Core support for ASP.NET Core projects.

Next, click **Modify** in the lower right-hand side. This will install everything you have selected. You can then open Visual Studio 2017 with F# language support by clicking **Launch**.

Install F# with Visual Studio for Mac

F# is installed by default in [Visual Studio for Mac](#), no matter which configuration you choose.

After the install completes, choose "Start Visual Studio". You can also launch it through Finder on macOS.

Install F# with Visual Studio Code

You must have [git installed](#) and available on your PATH to make use of project templates. You can verify that it is installed correctly by typing `git --version` at a command prompt and pressing **Enter**.

- [macOS](#)
- [Linux](#)
- [Windows](#)

[Mono](#) is used for [F# Interactive](#) support. The easiest way to install Mono on macOS is via Homebrew. Simply type the following into your terminal:

```
brew install mono
```

Also install the [.NET Core SDK](#).

You will then need [Visual Studio Code](#) installed.

Next, click the Extensions icon and search for "Ionide":

The only plugin required for F# support in Visual Studio Code is [Ionide-fsharp](#). However, you can also install [Ionide-FAKE](#) to get [FAKE](#) support and [Ionide-Paket](#) to get [Paket](#) support. FAKE and Paket are additional F# community tools for building projects and managing dependencies, respectively.

Get started with F# in Visual Studio

7/11/2018 • 3 minutes to read • [Edit Online](#)

F# and the Visual F# tooling are supported in the Visual Studio IDE.

To begin, ensure that you have [Visual Studio installed with F#](#).

Creating a console application

One of the most basic projects in Visual Studio is the Console Application. Here's how to do it. Once Visual Studio is open:

1. On the **File** menu, point to **New**, and then choose **Project**.
2. In the New Project dialog, under **Templates**, you should see **Visual F#**. Choose this to show the F# templates.
3. Select either **.NET Core Console app** or **Console app**.
4. Choose the **Okay** button to create the F# project! You should now see an F# project in the Solution Explorer.

Writing your code

Let's get started by writing some code first. Make sure that the `Program.fs` file is open, and then replace its contents with the following:

```
module HelloSquare

let square x = x * x

[<EntryPoint>]
let main argv =
    printfn "%d squared is: %d!" 12 (square 12)
    0 // Return an integer exit code
```

In the previous code sample, a function `square` has been defined which takes an input named `x` and multiplies it by itself. Because F# uses [Type Inference](#), the type of `x` doesn't need to be specified. The F# compiler understands the types where multiplication is valid, and will assign a type to `x` based on how `square` is called. If you hover over `square`, you should see the following:

```
val square: x:int -> int
```

This is what is known as the function's type signature. It can be read like this: "Square is a function which takes an integer named `x` and produces an integer". Note that the compiler gave `square` the `int` type for now - this is because multiplication is not generic across *all* types, but rather is generic across a closed set of types. The F# compiler picked `int` at this point, but it will adjust the type signature if you call `square` with a different input type, such as a `float`.

Another function, `main`, is defined, which is decorated with the `EntryPoint` attribute to tell the F# compiler that program execution should start there. It follows the same convention as other [C-style programming languages](#), where command-line arguments can be passed to this function, and an integer code is returned (typically `0`).

It is in this function that we call the `square` function with an argument of `12`. The F# compiler then assigns the type of `square` to be `int -> int` (that is, a function which takes an `int` and produces an `int`). The call to `printfn` is a formatted printing function which uses a format string, similar to C-style programming languages, parameters which correspond to those specified in the format string, and then prints the result and a new line.

Running your code

You can run the code and see results by pressing **Ctrl+F5**. This runs the program without debugging and allows you to see the results. Alternatively, you can choose the **Debug** top-level menu item in Visual Studio and choose **Start Without Debugging**.

You should now see the following printed to the console window that Visual Studio popped up:

```
12 squared is 144!
```

Congratulations! You've created your first F# project in Visual Studio, written an F# function printed the results of calling that function, and run the project to see some results.

Next steps

If you haven't already, check out the [Tour of F#](#), which covers some of the core features of the F# language. It will give you an overview of some of the capabilities of F#, and provide ample code samples that you can copy into Visual Studio and run. There are also some great external resources you can use, showcased in the [F# Guide](#).

See also

- [Tour of F#](#)
- [F# language reference](#)
- [Type inference](#)
- [Symbol and operator reference](#)

Get started with F# in Visual Studio for Mac

1/23/2019 • 5 minutes to read • [Edit Online](#)

F# and the Visual F# tooling are supported in the Visual Studio for Mac IDE. Ensure that you have [Visual Studio for Mac installed](#).

Creating a console application

One of the most basic projects in Visual Studio for Mac is the Console Application. Here's how to do it. Once Visual Studio for Mac is open:

1. On the **File** menu, point to **New Solution**.
2. In the New Project dialog, there are 2 different templates for Console Application. There is one under Other -> .NET which targets the .NET Framework. The other template is under .NET Core -> App which targets .NET Core. Either template should work for the purpose of this article.
3. Under console app, change C# to F# if needed. Choose the **Next** button to move forward!
4. Give your project a name, and choose the options you want for the app. Notice, the preview pane to the side of the screen that will show the directory structure that will be created based on the options selected.
5. Click **Create**. You should now see an F# project in the Solution Explorer.

Writing your code

Let's get started by writing some code first. Make sure that the `Program.fs` file is open, and then replace its contents with the following:

```
module HelloSquare

let square x = x * x

[<EntryPoint>]
let main argv =
    printfn "%d squared is: %d!" 12 (square 12)
    0 // Return an integer exit code
```

In the previous code sample, a function `square` has been defined which takes an input named `x` and multiplies it by itself. Because F# uses [Type Inference](#), the type of `x` doesn't need to be specified. The F# compiler understands the types where multiplication is valid, and will assign a type to `x` based on how `square` is called. If you hover over `square`, you should see the following:

```
val square: x:int -> int
```

This is what is known as the function's type signature. It can be read like this: "Square is a function which takes an integer named `x` and produces an integer". Note that the compiler gave `square` the `int` type for now - this is because multiplication is not generic across *all* types, but rather is generic across a closed set of types. The F# compiler picked `int` at this point, but it will adjust the type signature if you call `square` with a different input type, such as a `float`.

Another function, `main`, is defined, which is decorated with the `EntryPoint` attribute to tell the F# compiler that

program execution should start there. It follows the same convention as other C-style programming languages, where command-line arguments can be passed to this function, and an integer code is returned (typically `0`).

It is in this function that we call the `square` function with an argument of `12`. The F# compiler then assigns the type of `square` to be `int -> int` (that is, a function which takes an `int` and produces an `int`). The call to `printfn` is a formatted printing function which uses a format string, similar to C-style programming languages, parameters which correspond to those specified in the format string, and then prints the result and a new line.

Running your code

You can run the code and see results by clicking on **Run** from the top level menu and then **Start Without Debugging**. This will run the program without debugging and allows you to see the results.

You should now see the following printed to the console window that Visual Studio for Mac popped up:

```
12 squared is 144!
```

Congratulations! You've created your first F# project in Visual Studio for Mac, written an F# function printed the results of calling that function, and run the project to see some results.

Using F# Interactive

One of the best features of the Visual F# tooling in Visual Studio for Mac is the F# Interactive Window. It allows you to send code over to a process where you can call that code and see the result interactively.

To begin using it, highlight the `square` function defined in your code. Next, click on **Edit** from the top level menu. Next select **Send selection to F# Interactive**. This executes the code in the F# Interactive Window. Alternatively, you can right click on the selection and choose **Send selection to F# Interactive**. You should see the F# Interactive Window appear with the following in it:

```
>  
  
val square : x:int -> int  
  
>
```

This shows the same function signature for the `square` function, which you saw earlier when you hovered over the function. Because `square` is now defined in the F# Interactive process, you can call it with different values:

```
> square 12;;  
val it : int = 144  
>square 13;;  
val it : int = 169
```

This executes the function, binds the result to a new name `it`, and displays the type and value of `it`. Note that you must terminate each line with `;;`. This is how F# Interactive knows when your function call is finished. You can also define new functions in F# Interactive:

```
> let isOdd x = x % 2 <> 0;;  
  
val isOdd : x:int -> bool  
  
> isOdd 12;;  
val it : bool = false
```

The above defines a new function, `isOdd`, which takes an `int` and checks to see if it's odd! You can call this function to see what it returns with different inputs. You can call functions within function calls:

```
> isOdd (square 15);;
val it : bool = true
```

You can also use the [pipe-forward operator](#) to pipeline the value into the two functions:

```
> 15 |> square |> isOdd;;
val it : bool = true
```

The pipe-forward operator, and more, are covered in later tutorials.

This is only a glimpse into what you can do with F# Interactive. To learn more, check out [Interactive Programming with F#](#).

Next steps

If you haven't already, check out the [Tour of F#](#), which covers some of the core features of the F# language. It will give you an overview of some of the capabilities of F#, and provide ample code samples that you can copy into Visual Studio for Mac and run. There are also some great external resources you can use, showcased in the [F# Guide](#).

- [Symbol and operator reference](#)

Get Started with F# in Visual Studio Code

3/14/2019 • 8 minutes to read • [Edit Online](#)

You can write F# in [Visual Studio Code](#) with the [Ionide plugin](#) to get a great cross-platform, lightweight Integrated Development Environment (IDE) experience with IntelliSense and basic code refactorings. Visit [Ionide.io](#) to learn more about the plugin.

To begin, ensure that you have [F# and the Ionide plugin correctly installed](#).

NOTE

Ionide will generate .NET Framework F# projects, not dotnet core, which can have cross-platform compatibility issues. If you are running on [Linux](#) or [OSX](#), a simpler way to get started is to use the [command line tools](#).

Creating your first project with Ionide

To create a new F# project, open Visual Studio Code in a new folder (you can name it whatever you like).

Next, open the command palette (**View > Command Palette**) and type the following:

```
> F# new project
```

This is powered by the [FORGE](#) project.

NOTE

If you don't see template options, try refreshing templates by running the following command in the Command Palette:

```
>F#: Refresh Project Templates
```

Select "F#: New Project" by hitting **Enter**. This takes you to the next step, which is for selecting a project template.

Pick the `classlib` template and hit **Enter**.

Next, pick a directory to create the project in. If you leave it blank, it uses the current directory.

Finally, name your project in the final step. F# uses [Pascal case](#) for project names. This article uses `ClassLibraryDemo` as the name. Once you've entered the name you want for your project, hit **Enter**.

If you followed the previous step, you should get the Visual Studio Code Workspace on the left-hand side to appear with the following:

1. The F# project itself, underneath the `ClassLibraryDemo` folder.
2. The correct directory structure for adding packages via `Paket`.
3. A cross-platform build script with `FAKE`.
4. The `paket.exe` executable that can fetch packages and resolve dependencies for you.
5. A `.gitignore` file if you wish to add this project to Git-based source control.

Writing some code

Open the `ClassLibraryDemo` folder. You should see the following files:

1. `ClassLibraryDemo.fs`, an F# implementation file with a class defined.
2. `ClassLibraryDemo.fsproj`, an F# project file used to build this project.
3. `Script.fsx`, an F# script file that loads the source file.
4. `paket.references`, a Paket file that specifies the project dependencies.

Open `Script.fsx`, and add the following code at the end of it:

```
let toPigLatin (word: string) =
    let isVowel (c: char) =
        match c with
        | 'a' | 'e' | 'i' | 'o' | 'u'
        | 'A' | 'E' | 'I' | 'O' | 'U' -> true
        |_ -> false

    if isVowel word.[0] then
        word + "yay"
    else
        word.[1..] + string(word.[0]) + "ay"
```

This function converts a word to a form of [Pig Latin](#). The next step is to evaluate it using F# Interactive (FSI).

Highlight the entire function (it should be 11 lines long). Once it is highlighted, hold the **Alt** key and hit **Enter**. You'll notice a window pop up below, and it should show something like this:

The screenshot shows a terminal window titled "TERMINAL" and an F# Interactive window titled "1: F# Interactive". The F# Interactive window contains the following text:

```
- 
-
-
- let toPigLatin (word: string) =
-     let isVowel (c: char) =
-         match c with
-         | 'a' | 'e' | 'i' | 'o' | 'u'
-         | 'A' | 'E' | 'I' | 'O' | 'U' -> true
-         |_ -> false
-
-     if isVowel word.[0] then
-         word + "yay"
-     else
-         word.[1..] + string(word.[0]) + "ay";;
val toPigLatin : word:string -> string
```

This did three things:

1. It started the FSI process.
2. It sent the code you highlighted over the FSI process.
3. The FSI process evaluated the code you sent over.

Because what you sent over was a [function](#), you can now call that function with FSI! In the interactive window, type the following:

```
toPigLatin "banana";;
```

You should see the following result:

```
val it : string = "ananabay"
```

Now, let's try with a vowel as the first letter. Enter the following:

```
toPigLatin "apple";;
```

You should see the following result:

```
val it : string = "appleyay"
```

The function appears to be working as expected. Congratulations, you just wrote your first F# function in Visual Studio Code and evaluated it with FSI!

NOTE

As you may have noticed, the lines in FSI are terminated with `;;`. This is because FSI allows you to enter multiple lines. The `;;` at the end lets FSI know when the code is finished.

Explaining the code

If you're not sure about what the code is actually doing, here's a step-by-step.

As you can see, `toPigLatin` is a function that takes a word as its input and converts it to a Pig-Latin representation of that word. The rules for this are as follows:

If the first character in a word starts with a vowel, add "yay" to the end of the word. If it doesn't start with a vowel, move that first character to the end of the word and add "ay" to it.

You may have noticed the following in FSI:

```
val toPigLatin : word:string -> string
```

This states that `toPigLatin` is a function that takes in a `string` as input (called `word`), and returns another `string`. This is known as the [type signature of the function](#), a fundamental piece of F# that's key to understanding F# code. You'll also notice this if you hover over the function in Visual Studio Code.

In the body of the function, you'll notice two distinct parts:

1. An inner function, called `isVowel`, that determines if a given character (`c`) is a vowel by checking if it matches one of the provided patterns via [Pattern Matching](#):

```
let isVowel (c: char) =
  match c with
  | 'a' | 'e' | 'i' | 'o' | 'u'
  | 'A' | 'E' | 'I' | 'O' | 'U' -> true
  |_ -> false
```

2. An `if..then..else` expression that checks if the first character is a vowel, and constructs a return value out of the input characters based on if the first character was a vowel or not:

```
if isVowel word.[0] then
  word + "yay"
else
  word.[1..] + string(word.[0]) + "ay"
```

The flow of `toPigLatin` is thus:

Check if the first character of the input word is a vowel. If it is, attach "yay" to the end of the word. Otherwise, move that first character to the end of the word and add "ay" to it.

There's one final thing to notice about this: there's no explicit instruction to return from the function, unlike many other languages out there. This is because F# is Expression-based, and the last expression in the body of a function is the return value. Because `if..then..else` is itself an expression, the body of the `then` block or the body of the `else` block will be returned depending on the input value.

Moving your script code into the implementation file

The previous sections in this article demonstrated a common first step in writing F# code: writing an initial function and executing it interactively with FSI. This is known as REPL-driven development, where **REPL** stands for "Read-Evaluate-Print Loop". It's a great way to experiment with functionality until you have something working.

The next step in REPL-driven development is to move working code into an F# implementation file. It can then be compiled by the F# compiler into an assembly that can be executed.

To begin, open `ClassLibraryDemo.fs`. You'll notice that some code is already in there. Go ahead and delete the class definition, but make sure to leave the `namespace` declaration at the top.

Next, create a new `module` called `PigLatin` and copy the `toPigLatin` function into it as such:

```
namespace ClassLibraryDemo

module PigLatin =
    let toPigLatin (word: string) =
        let isVowel (c: char) =
            match c with
            | 'a' | 'e' | 'i' | 'o' | 'u'
            | 'A' | 'E' | 'I' | 'O' | 'U' -> true
            |_ -> false

        if isVowel word.[0] then
            word + "yay"
        else
            word.[1..] + string(word.[0]) + "ay"
```

Next, open the `Script.fsx` file again, and delete the entire `toPigLatin` function, but make sure to keep the following two lines in the file:

```
#load "ClassLibraryDemo.fs"
open ClassLibraryDemo
```

Select both lines of text and press Alt+Enter to execute these lines in FSI. These will load the contents of the Pig Latin library into the FSI process and `open` the `ClassLibraryDemo` namespace so that you have access to the functionality.

Next, in the FSI window, call the function with the `PigLatin` module that you defined earlier:

```
> PigLatin.toPigLatin "banana";;
val it : string = "ananabay"
> PigLatin.toPigLatin "apple";;
val it : string = "appleay"
```

Success! You get the same results as before, but now loaded from an F# implementation file. The major difference here is that F# source files are compiled into assemblies that can be executed anywhere, not just in FSI.

Summary

In this article, you've learned:

1. How to set up Visual Studio Code with Ionide.
2. How to create your first F# project with Ionide.
3. How to use F# Scripting to write your first F# function in Ionide and then execute it in FSI.
4. How to migrate your script code to F# source and then call that code from FSI.

You're now equipped to write much more F# code using Visual Studio Code and Ionide.

Troubleshooting

Here are a few ways you can troubleshoot certain problems that you might run into:

1. To get the code editing features of Ionide, your F# files need to be saved to disk and inside of a folder that is open in the Visual Studio Code workspace.
2. If you've made changes to your system or installed Ionide prerequisites with Visual Studio Code open, restart Visual Studio Code.
3. Check that you can use the F# compiler and F# interactive from the command line without a fully-qualified path. You can do so by typing `fsc` in a command line for the F# compiler, and `fsi` or `fsharp` for the Visual F# tools on Windows and Mono on Mac/Linux, respectively.
4. If you have invalid characters in your project directories, Ionide might not work. Rename your project directories if this is the case.
5. If none of the Ionide commands are working, check your [Visual Studio Code keybindings](#) to see if you're overriding them by accident.
6. If Ionide is broken on your machine and none of the above has fixed your problem, try removing the `ionide-fsharp` directory on your machine and reinstall the plugin suite.

Ionide is an open source project built and maintained by members of the F# community. Please report issues and feel free to contribute at the [Ionide-VSCode: FSharp GitHub repository](#).

If you have an issue to report, please follow [the instructions for getting logs to use when reporting an issue](#).

You can also ask for further help from the Ionide developers and F# community in the [Ionide Gitter channel](#).

Next steps

To learn more about F# and the features of the language, check out [Tour of F#](#).

Get started with F# with the .NET Core CLI

1/9/2019 • 2 minutes to read • [Edit Online](#)

This article covers how you can get started with F# on any operating system (Windows, macOS, or Linux) with the .NET Core CLI. It goes through building a multi-project solution with a class library that is called by a console application.

Prerequisites

To begin, you must install the latest [.NET Core SDK](#).

This article assumes that you know how to use a command line and have a preferred text editor. If you don't already use it, [Visual Studio Code](#) is a great option as a text editor for F#.

Build a simple multi-project solution

Open a command prompt/terminal and use the `dotnet new` command to create new solution file called

`FSNetCore` :

```
dotnet new sln -o FSNetCore
```

The following directory structure is produced after running the previous command:

```
FSNetCore
├── FSNetCore.sln
```

Write a class library

Change directories to `FSNetCore`.

Use the `dotnet new` command, create a class library project in the `src` folder named `Library`.

```
dotnet new classlib -lang F# -o src/Library
```

The following directory structure is produced after running the previous command:

```
└── FSNetCore
    ├── FSNetCore.sln
    └── src
        └── Library
            ├── Library.fs
            └── Library.fsproj
```

Replace the contents of `Library.fs` with the following code:

```
module Library

open Newtonsoft.Json

let getJsonNetJson value =
    sprintf "I used to be %s but now I'm %s thanks to JSON.NET!" value ( JsonConvert.SerializeObject(value))
```

Add the `Newtonsoft.Json` NuGet package to the `Library` project.

```
dotnet add src/Library/Library.fsproj package Newtonsoft.Json
```

Add the `Library` project to the `FSNetCore` solution using the [dotnet sln add](#) command:

```
dotnet sln add src/Library/Library.fsproj
```

Run `dotnet build` to build the project. Unresolved dependencies will be restored when building.

Write a console application that consumes the class library

Use the `dotnet new` command, create a console application in the `src` folder named `App`.

```
dotnet new console -lang F# -o src/App
```

The following directory structure is produced after running the previous command:

```
└── FSNetCore
    ├── FSNetCore.sln
    └── src
        ├── App
        │   ├── App.fsproj
        │   └── Program.fs
        └── Library
            ├── Library.fs
            └── Library.fsproj
```

Replace the contents of the `Program.fs` file with the following code:

```
open System
open Library

[<EntryPoint>]
let main argv =
    printfn "Nice command-line arguments! Here's what JSON.NET has to say about them:"
```

argv
|> Array.map getJsonNetJson
|> Array.iter (printfn "%s")

```
0 // return an integer exit code
```

Add a reference to the `Library` project using [dotnet add reference](#).

```
dotnet add src/App/App.fsproj reference src/Library/Library.fsproj
```

Add the `App` project to the `FSNetCore` solution using the `dotnet sln add` command:

```
dotnet sln add src/App/App.fsproj
```

Restore the NuGet dependencies, `dotnet restore` and run `dotnet build` to build the project.

Change directory to the `src/App` console project and run the project passing `Hello World` as arguments:

```
cd src/App  
dotnet run Hello World
```

You should see the following results:

```
Nice command-line arguments! Here's what JSON.NET has to say about them:
```

```
I used to be Hello but now I'm ""Hello"" thanks to JSON.NET!  
I used to be World but now I'm ""World"" thanks to JSON.NET!
```

Next steps

Next, check out the [Tour of F#](#) to learn more about different F# features.

What is F#

2/28/2019 • 2 minutes to read • [Edit Online](#)

F# is a functional programming language that makes it easy to write correct and maintainable code.

F# programming primarily involves defining types and functions that are type-inferred and generalized automatically. This allows your focus to remain on the problem domain and manipulating its data, rather than the details of programming.

```
open System // Gets access to functionality in System namespace.

// Defines a function that takes a name and produces a greeting.
let getGreeting name =
    sprintf "Hello, %s! Isn't F# great?" name

[<EntryPoint>]
let main args =
    // Defines a list of names
    let names = [ "Don"; "Julia"; "Xi" ]

    // Prints a greeting for each name!
    names
    |> List.map getGreeting
    |> List.iter (fun greeting -> printfn "%s" greeting)

0
```

F# has numerous features, including:

- Lightweight syntax
- Immutable by default
- Type inference and automatic generalization
- First-class functions
- Powerful data types
- Pattern matching
- Async programming

A full set of features are documented in the [F# language reference](#).

Rich data types

Data types such as [Records](#) and [Discriminated Unions](#) let you represent complex data and domains.

```

// Group data with Records
type SuccessfulWithdrawal = {
    Amount: decimal
    Balance: decimal
}

type FailedWithdrawal = {
    Amount: decimal
    Balance: decimal
    IsOverdraft: bool
}

// Use discriminated unions to represent data of 1 or more forms
type WithdrawalResult =
    | Success of SuccessfulWithdrawal
    | InsufficientFunds of FailedWithdrawal
    | CardExpired of System.DateTime
    | UndisclosedFailure

```

F# records and discriminated unions are non-null, immutable, and comparable by default, making them very easy to use.

Enforced correctness with functions and pattern matching

F# functions are easy to declare and powerful in practice. When combined with [pattern matching](#), they allow you to define behavior whose correctness is enforced by the compiler.

```

// Returns a WithdrawalResult
let withdrawMoney amount = // Implementation elided

let handleWithdrawal amount =
    let w = withdrawMoney amount

    // The F# compiler enforces accounting for each case!
    match w with
    | Success s -> printfn "Successfully withdrew %f" s.Amount
    | InsufficientFunds f -> printfn "Failed: balance is %f" f.Balance
    | CardExpired d -> printfn "Failed: card expired on %O" d
    | UndisclosedFailure -> printfn "Failed: unknown :("

```

F# functions are also first-class, meaning they can be passed as parameters and returned from other functions.

Functions to define operations on objects

F# has full support for objects, which are useful data types when you need to blend data and functionality. F# functions are used to manipulate objects.

```
type Set<[<EqualityConditionOn>] 'T when 'T: comparison>(elements: seq<'T>) =
    member s.IsEmpty = // Implementation elided
    member s.Contains (value) =// Implementation elided
    member s.Add (value) = // Implementation elided
    // ...
    // Further Implementation elided
    // ...
    interface IEnumerable<'T>
    interface IReadOnlyCollection<'T>

[<RequireQualifiedAccess>]
module Set =
    let isEmpty (set: Set<'T>) = set.IsEmpty

    let contains element (set: Set<'T>) = set.Contains(element)

    let add value (set: Set<'T>) = set.Add(value)
```

Rather than writing code that is object-oriented, in F#, you will often write code that treats objects as another data type for functions to manipulate. Features such as [generic interfaces](#), [object expressions](#), and judicious use of [members](#) are common in larger F# programs.

Next steps

To learn more about a larger set of F# features, check out the [F# Tour](#).

Tour of F#

3/16/2019 • 31 minutes to read • [Edit Online](#)

The best way to learn about F# is to read and write F# code. This article will act as a tour through some of the key features of the F# language and give you some code snippets that you can execute on your machine. To learn about setting up a development environment, check out [Getting Started](#).

There are two primary concepts in F#: functions and types. This tour will emphasize features of the language which fall into these two concepts.

Executing the code online

If you don't have F# installed on your machine, you can execute all of the samples online with the [Fable REPL](#). Fable is a dialect of F# that executes directly in your browser. To view the samples that follow in the REPL, check out [Samples > Learn > Tour of F#](#) in the left-hand menu bar of the Fable REPL.

Functions and Modules

The most fundamental pieces of any F# program are **functions** organized into **modules**. Functions perform work on inputs to produce outputs, and they are organized under **Modules**, which are the primary way you group things in F#. They are defined using the `let` binding, which give the function a name and define its arguments.

```

module BasicFunctions =

    /// You use 'let' to define a function. This one accepts an integer argument and returns an integer.
    /// Parentheses are optional for function arguments, except for when you use an explicit type
    annotation.
    let sampleFunction1 x = x*x + 3

    /// Apply the function, naming the function return result using 'let'.
    /// The variable type is inferred from the function return type.
    let result1 = sampleFunction1 4573

    // This line uses '%d' to print the result as an integer. This is type-safe.
    // If 'result1' were not of type 'int', then the line would fail to compile.
    printfn "The result of squaring the integer 4573 and adding 3 is %d" result1

    /// When needed, annotate the type of a parameter name using '(argument:type)'. Parentheses are
    required.
    let sampleFunction2 (x:int) = 2*x*x - x/5 + 3

    let result2 = sampleFunction2 (7 + 4)
    printfn "The result of applying the 2nd sample function to (7 + 4) is %d" result2

    /// Conditionals use if/then/elif/else.
    ///
    /// Note that F# uses white space indentation-aware syntax, similar to languages like Python.
    let sampleFunction3 x =
        if x < 100.0 then
            2.0*x*x - x/5.0 + 3.0
        else
            2.0*x*x + x/5.0 - 37.0

    let result3 = sampleFunction3 (6.5 + 4.5)

    // This line uses '%f' to print the result as a float. As with '%d' above, this is type-safe.
    printfn "The result of applying the 2nd sample function to (6.5 + 4.5) is %f" result3

```

`let` bindings are also how you bind a value to a name, similar to a variable in other languages. `let` bindings are **immutable** by default, which means that once a value or function is bound to a name, it cannot be changed in-place. This is in contrast to variables in other languages, which are **mutable**, meaning their values can be changed at any point in time. If you require a mutable binding, you can use `let mutable ...` syntax.

```

module Immutability =

    /// Binding a value to a name via 'let' makes it immutable.
    ///
    /// The second line of code fails to compile because 'number' is immutable and bound.
    /// Re-defining 'number' to be a different value is not allowed in F#.
    let number = 2
    // let number = 3

    /// A mutable binding. This is required to be able to mutate the value of 'otherNumber'.
    let mutable otherNumber = 2

    printfn "'otherNumber' is %d" otherNumber

    // When mutating a value, use '<->' to assign a new value.
    //
    // Note that '=' is not the same as this. '=' is used to test equality.
    otherNumber <- otherNumber + 1

    printfn "'otherNumber' changed to be %d" otherNumber

```

Numbers, Booleans, and Strings

As a .NET language, F# supports the same underlying [primitive types](#) that exist in .NET.

Here is how various numeric types are represented in F#:

```
module IntegersAndNumbers =  
  
    /// This is a sample integer.  
    let sampleInteger = 176  
  
    /// This is a sample floating point number.  
    let sampleDouble = 4.1  
  
    /// This computed a new number by some arithmetic. Numeric types are converted using  
    /// functions 'int', 'double' and so on.  
    let sampleInteger2 = (sampleInteger/4 + 5 - 7) * 4 + int sampleDouble  
  
    /// This is a list of the numbers from 0 to 99.  
    let sampleNumbers = [ 0 .. 99 ]  
  
    /// This is a list of all tuples containing all the numbers from 0 to 99 and their squares.  
    let sampleTableOfSquares = [ for i in 0 .. 99 -> (i, i*i) ]  
  
    // The next line prints a list that includes tuples, using '%A' for generic printing.  
    printfn "The table of squares from 0 to 99 is:\n%A" sampleTableOfSquares
```

Here's what Boolean values and performing basic conditional logic looks like:

```
module Booleans =  
  
    /// Booleans values are 'true' and 'false'.  
    let boolean1 = true  
    let boolean2 = false  
  
    /// Operators on booleans are 'not', '&&' and '||'.  
    let boolean3 = not boolean1 && (boolean2 || false)  
  
    // This line uses '%b' to print a boolean value. This is type-safe.  
    printfn "The expression 'not boolean1 && (boolean2 || false)' is %b" boolean3
```

And here's what basic [string](#) manipulation looks like:

```

module StringManipulation =

    /// Strings use double quotes.
    let string1 = "Hello"
    let string2 = "world"

    /// Strings can also use @ to create a verbatim string literal.
    /// This will ignore escape characters such as '\', '\n', '\t', etc.
    let string3 = @"C:\Program Files\"

    /// String literals can also use triple-quotes.
    let string4 = """The computer said "hello world" when I told it to!"""

    /// String concatenation is normally done with the '+' operator.
    let helloWorld = string1 + " " + string2

    // This line uses '%s' to print a string value. This is type-safe.
    printfn "%s" helloWorld

    /// Substrings use the indexer notation. This line extracts the first 7 characters as a substring.
    /// Note that like many languages, Strings are zero-indexed in F#.
    let substring = helloWorld.[0..6]
    printfn "%s" substring

```

Tuples

[Tuples](#) are a big deal in F#. They are a grouping of unnamed, but ordered values, that can be treated as values themselves. Think of them as values which are aggregated from other values. They have many uses, such as conveniently returning multiple values from a function, or grouping values for some ad-hoc convenience.

```

module Tuples =

    /// A simple tuple of integers.
    let tuple1 = (1, 2, 3)

    /// A function that swaps the order of two values in a tuple.
    ///
    /// F# Type Inference will automatically generalize the function to have a generic type,
    /// meaning that it will work with any type.
    let swapElems (a, b) = (b, a)

    printfn "The result of swapping (1, 2) is %A" (swapElems (1,2))

    /// A tuple consisting of an integer, a string,
    /// and a double-precision floating point number.
    let tuple2 = (1, "fred", 3.1415)

    printfn "tuple1: %A\ttuple2: %A" tuple1 tuple2

```

As of F# 4.1, you can also create `struct` tuples. These also interoperate fully with C#7/Visual Basic 15 tuples, which are also `struct` tuples:

```
/// Tuples are normally objects, but they can also be represented as structs.  
///  
/// These interoperate completely with structs in C# and Visual Basic.NET; however,  
/// struct tuples are not implicitly convertible with object tuples (often called reference tuples).  
///  
/// The second line below will fail to compile because of this. Uncomment it to see what happens.  
let sampleStructTuple = struct (1, 2)  
//let thisWillNotCompile: (int*int) = struct (1, 2)  
  
// Although you can  
let convertFromStructTuple (struct(a, b)) = (a, b)  
let convertToStructTuple (a, b) = struct(a, b)  
  
printfn "Struct Tuple: %A\nReference tuple made from the Struct Tuple: %A" sampleStructTuple  
(sampleStructTuple |> convertFromStructTuple)
```

It's important to note that because `struct` tuples are value types, they cannot be implicitly converted to reference tuples, or vice versa. You must explicitly convert between a reference and struct tuple.

Pipelines and Composition

Pipe operators such as `|>` are used extensively when processing data in F#. These operators are functions that allow you to establish "pipelines" of functions in a flexible manner. The following example walks through how you can take advantage of these operators to build a simple functional pipeline:

```

module PipelinesAndComposition =

    /// Squares a value.
    let square x = x * x

    /// Adds 1 to a value.
    let addOne x = x + 1

    /// Tests if an integer value is odd via modulo.
    let isOdd x = x % 2 <> 0

    /// A list of 5 numbers. More on lists later.
    let numbers = [ 1; 2; 3; 4; 5 ]

    /// Given a list of integers, it filters out the even numbers,
    /// squares the resulting odds, and adds 1 to the squared odds.
    let squareOddValuesAndAddOne values =
        let odds = List.filter isOdd values
        let squares = List.map square odds
        let result = List.map addOne squares
        result

    printfn "processing %A through 'squareOddValuesAndAddOne' produces: %A"
    (squareOddValuesAndAddOne numbers)

    /// A shorter way to write 'squareOddValuesAndAddOne' is to nest each
    /// sub-result into the function calls themselves.
    ///
    /// This makes the function much shorter, but it's difficult to see the
    /// order in which the data is processed.
    let squareOddValuesAndAddOneNested values =
        List.map addOne (List.map square (List.filter isOdd values))

    printfn "processing %A through 'squareOddValuesAndAddOneNested' produces: %A"
    (squareOddValuesAndAddOneNested numbers)

    /// A preferred way to write 'squareOddValuesAndAddOne' is to use F# pipe operators.
    /// This allows you to avoid creating intermediate results, but is much more readable
    /// than nesting function calls like 'squareOddValuesAndAddOneNested'
    let squareOddValuesAndAddOnePipeline values =
        values
        |> List.filter isOdd
        |> List.map square
        |> List.map addOne

    printfn "processing %A through 'squareOddValuesAndAddOnePipeline' produces: %A"
    (squareOddValuesAndAddOnePipeline numbers)

    /// You can shorten 'squareOddValuesAndAddOnePipeline' by moving the second `List.map` call
    /// into the first, using a Lambda Function.
    ///
    /// Note that pipelines are also being used inside the lambda function. F# pipe operators
    /// can be used for single values as well. This makes them very powerful for processing data.
    let squareOddValuesAndAddOneShorterPipeline values =
        values
        |> List.filter isOdd
        |> List.map(fun x -> x |> square |> addOne)

    printfn "processing %A through 'squareOddValuesAndAddOneShorterPipeline' produces: %A"
    (squareOddValuesAndAddOneShorterPipeline numbers)

```

The previous sample made use of many features of F#, including list processing functions, first-class functions, and [partial application](#). Although a deep understanding of each of those concepts can become somewhat advanced, it should be clear how easily functions can be used to process data when building pipelines.

Lists, Arrays, and Sequences

Lists, Arrays, and Sequences are three primary collection types in the F# core library.

[Lists](#) are ordered, immutable collections of elements of the same type. They are singly-linked lists, which means they are meant for enumeration, but a poor choice for random access and concatenation if they're large. This is in contrast to Lists in other popular languages, which typically do not use a singly-linked list to represent Lists.

```
module Lists =  
  
    /// Lists are defined using [ ... ].  This is an empty list.  
    let list1 = []  
  
    /// This is a list with 3 elements.  ';' is used to separate elements on the same line.  
    let list2 = [ 1; 2; 3 ]  
  
    /// You can also separate elements by placing them on their own lines.  
    let list3 = [  
        1  
        2  
        3  
    ]  
  
    /// This is a list of integers from 1 to 1000  
    let numberList = [ 1 .. 1000 ]  
  
    /// Lists can also be generated by computations. This is a list containing  
    /// all the days of the year.  
    let daysList =  
        [ for month in 1 .. 12 do  
            for day in 1 .. System.DateTime.DaysInMonth(2017, month) do  
                yield System.DateTime(2017, month, day) ]  
  
    // Print the first 5 elements of 'daysList' using 'List.take'.  
    printfn "The first 5 days of 2017 are: %A" (daysList |> List.take 5)  
  
    /// Computations can include conditionals. This is a list containing the tuples  
    /// which are the coordinates of the black squares on a chess board.  
    let blackSquares =  
        [ for i in 0 .. 7 do  
            for j in 0 .. 7 do  
                if (i+j) % 2 = 1 then  
                    yield (i, j) ]  
  
    /// Lists can be transformed using 'List.map' and other functional programming combinators.  
    /// This definition produces a new list by squaring the numbers in numberList, using the pipeline  
    /// operator to pass an argument to List.map.  
    let squares =  
        numberList  
        |> List.map (fun x -> x*x)  
  
    /// There are many other list combinations. The following computes the sum of the squares of the  
    /// numbers divisible by 3.  
    let sumOfSquares =  
        numberList  
        |> List.filter (fun x -> x % 3 = 0)  
        |> List.sumBy (fun x -> x * x)  
  
    printfn "The sum of the squares of numbers up to 1000 that are divisible by 3 is: %d" sumOfSquares
```

[Arrays](#) are fixed-size, *mutable* collections of elements of the same type. They support fast random access of elements, and are faster than F# lists because they are just contiguous blocks of memory.

```

module Arrays = 

    /// This is The empty array. Note that the syntax is similar to that of Lists, but uses `[]| ... |` instead.
    let array1 = [| |]

    /// Arrays are specified using the same range of constructs as lists.
    let array2 = [| "hello"; "world"; "and"; "hello"; "world"; "again" |]

    /// This is an array of numbers from 1 to 1000.
    let array3 = [| 1 .. 1000 |]

    /// This is an array containing only the words "hello" and "world".
    let array4 =
        [| for word in array2 do
            if word.Contains("l") then
                yield word |]

    /// This is an array initialized by index and containing the even numbers from 0 to 2000.
    let evenNumbers = Array.init 1001 (fun n -> n * 2)

    /// Sub-arrays are extracted using slicing notation.
    let evenNumbersSlice = evenNumbers.[0..500]

    /// You can loop over arrays and lists using 'for' loops.
    for word in array4 do
        printfn "word: %s" word

    // You can modify the contents of an array element by using the left arrow assignment operator.
    //
    // To learn more about this operator, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/values/index#mutable-variables
    array2.[1] <- "WORLD!"

    /// You can transform arrays using 'Array.map' and other functional programming operations.
    /// The following calculates the sum of the lengths of the words that start with 'h'.
    let sumOfLengthsOfWords =
        array2
        |> Array.filter (fun x -> x.StartsWith "h")
        |> Array.sumBy (fun x -> x.Length)

    printfn "The sum of the lengths of the words in Array 2 is: %d" sumOfLengthsOfWords

```

[Sequences](#) are a logical series of elements, all of the same type. These are a more general type than Lists and Arrays, capable of being your "view" into any logical series of elements. They also stand out because they can be **lazy**, which means that elements can be computed only when they are needed.

```

module Sequences =

    /// This is the empty sequence.
    let seq1 = Seq.empty

    /// This a sequence of values.
    let seq2 = seq { yield "hello"; yield "world"; yield "and"; yield "hello"; yield "world"; yield "again"
}

    /// This is an on-demand sequence from 1 to 1000.
    let numbersSeq = seq { 1 .. 1000 }

    /// This is a sequence producing the words "hello" and "world"
    let seq3 =
        seq { for word in seq2 do
                if word.Contains("l") then
                    yield word }

    /// This sequence producing the even numbers up to 2000.
    let evenNumbers = Seq.init 1001 (fun n -> n * 2)

    let rnd = System.Random()

    /// This is an infinite sequence which is a random walk.
    /// This example uses yield! to return each element of a subsequence.
    let rec randomWalk x =
        seq { yield x
              yield! randomWalk (x + rnd.NextDouble() - 0.5) }

    /// This example shows the first 100 elements of the random walk.
    let first100ValuesOfRandomWalk =
        randomWalk 5.0
        |> Seq.truncate 100
        |> Seq.toList

    printfn "First 100 elements of a random walk: %A" first100ValuesOfRandomWalk

```

Recursive Functions

Processing collections or sequences of elements is typically done with [recursion](#) in F#. Although F# has support for loops and imperative programming, recursion is preferred because it is easier to guarantee correctness.

NOTE

The following example makes use of the pattern matching via the `match` expression. This fundamental construct is covered later in this article.

```

module RecursiveFunctions =

    /// This example shows a recursive function that computes the factorial of an
    /// integer. It uses 'let rec' to define a recursive function.
    let rec factorial n =
        if n = 0 then 1 else n * factorial (n-1)

    printfn "Factorial of 6 is: %d" (factorial 6)

    /// Computes the greatest common factor of two integers.
    ///
    /// Since all of the recursive calls are tail calls,
    /// the compiler will turn the function into a loop,
    /// which improves performance and reduces memory consumption.
    let rec greatestCommonFactor a b =
        if a = 0 then b
        elif a < b then greatestCommonFactor a (b - a)
        else greatestCommonFactor (a - b) b

    printfn "The Greatest Common Factor of 300 and 620 is %d" (greatestCommonFactor 300 620)

    /// This example computes the sum of a list of integers using recursion.
    let rec sumList xs =
        match xs with
        | []    -> 0
        | y::ys -> y + sumList ys

    /// This makes 'sumList' tail recursive, using a helper function with a result accumulator.
    let rec private sumListTailRecHelper accumulator xs =
        match xs with
        | []    -> accumulator
        | y::ys -> sumListTailRecHelper (accumulator+y) ys

    /// This invokes the tail recursive helper function, providing '0' as a seed accumulator.
    /// An approach like this is common in F#.
    let sumListTailRecursive xs = sumListTailRecHelper 0 xs

    let oneThroughTen = [1; 2; 3; 4; 5; 6; 7; 8; 9; 10]

    printfn "The sum 1-10 is %d" (sumListTailRecursive oneThroughTen)

```

F# also has full support for Tail Call Optimization, which is a way to optimize recursive calls so that they are just as fast as a loop construct.

Record and Discriminated Union Types

Record and Union types are two fundamental data types used in F# code, and are generally the best way to represent data in an F# program. Although this makes them similar to classes in other languages, one of their primary differences is that they have structural equality semantics. This means that they are "natively" comparable and equality is straightforward - just check if one is equal to the other.

[Records](#) are an aggregate of named values, with optional members (such as methods). If you're familiar with C# or Java, then these should feel similar to POCOs or POJOs - just with structural equality and less ceremony.

```

module RecordTypes =
    /// This example shows how to define a new record type.
    type ContactCard =
        { Name      : string
          Phone     : string
          Verified : bool }

    /// This example shows how to instantiate a record type.
    let contact1 =
        { Name = "Alf"
          Phone = "(206) 555-0157"
          Verified = false }

    /// You can also do this on the same line with ';' separators.
    let contactOnSameLine = { Name = "Alf"; Phone = "(206) 555-0157"; Verified = false }

    /// This example shows how to use "copy-and-update" on record values. It creates
    /// a new record value that is a copy of contact1, but has different values for
    /// the 'Phone' and 'Verified' fields.
    ///
    /// To learn more, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/copy-and-update-record-expressions
    let contact2 =
        { contact1 with
          Phone = "(206) 555-0112"
          Verified = true }

    /// This example shows how to write a function that processes a record value.
    /// It converts a 'ContactCard' object to a string.
    let showContactCard (c: ContactCard) =
        c.Name + " Phone: " + c.Phone + (if not c.Verified then " (unverified)" else "")

    printfn "Alf's Contact Card: %s" (showContactCard contact1)

    /// This is an example of a Record with a member.
    type ContactCardAlternate =
        { Name      : string
          Phone     : string
          Address   : string
          Verified : bool }

        /// Members can implement object-oriented members.
        member this.PrintedContactCard =
            this.Name + " Phone: " + this.Phone + (if not this.Verified then " (unverified)" else "") +
            this.Address

        let contactAlternate =
            { Name = "Alf"
              Phone = "(206) 555-0157"
              Verified = false
              Address = "111 Alf Street" }

    // Members are accessed via the '.' operator on an instantiated type.
    printfn "Alf's alternate contact card is %s" contactAlternate.PrintedContactCard

```

As of F# 4.1, you can also represent Records as `struct`s. This is done with the `[<Struct>]` attribute:

```
/// Records can also be represented as structs via the 'Struct' attribute.  
/// This is helpful in situations where the performance of structs outweighs  
/// the flexibility of reference types.  
[<Struct>]  
type ContactCardStruct =  
    { Name      : string  
      Phone     : string  
      Verified  : bool }
```

[Discriminated Unions \(DUs\)](#) are values which could be a number of named forms or cases. Data stored in the type can be one of several distinct values.

```

module DiscriminatedUnions =

    /// The following represents the suit of a playing card.
    type Suit =
        | Hearts
        | Clubs
        | Diamonds
        | Spades

    /// A Discriminated Union can also be used to represent the rank of a playing card.
    type Rank =
        /// Represents the rank of cards 2 .. 10
        | Value of int
        | Ace
        | King
        | Queen
        | Jack

    /// Discriminated Unions can also implement object-oriented members.
    static member GetAllRanks() =
        [ yield Ace
          for i in 2 .. 10 do yield Value i
          yield Jack
          yield Queen
          yield King ]

    /// This is a record type that combines a Suit and a Rank.
    /// It's common to use both Records and Discriminated Unions when representing data.
    type Card = { Suit: Suit; Rank: Rank }

    /// This computes a list representing all the cards in the deck.
    let fullDeck =
        [ for suit in [ Hearts; Diamonds; Clubs; Spades] do
            for rank in Rank.GetAllRanks() do
                yield { Suit=suit; Rank=rank } ]

    /// This example converts a 'Card' object to a string.
    let showPlayingCard (c: Card) =
        let rankString =
            match c.Rank with
            | Ace -> "Ace"
            | King -> "King"
            | Queen -> "Queen"
            | Jack -> "Jack"
            | Value n -> string n
        let suitString =
            match c.Suit with
            | Clubs -> "clubs"
            | Diamonds -> "diamonds"
            | Spades -> "spades"
            | Hearts -> "hearts"
        rankString + " of " + suitString

    /// This example prints all the cards in a playing deck.
    let printAllCards() =
        for card in fullDeck do
            printfn "%s" (showPlayingCard card)

```

You can also use DUs as *Single-Case Discriminated Unions*, to help with domain modeling over primitive types. Often times, strings and other primitive types are used to represent something, and are thus given a particular meaning. However, using only the primitive representation of the data can result in mistakenly assigning an incorrect value! Representing each type of information as a distinct single-case union can enforce correctness in this scenario.

```

// Single-case DUs are often used for domain modeling. This can buy you extra type safety
// over primitive types such as strings and ints.
//
// Single-case DUs cannot be implicitly converted to or from the type they wrap.
// For example, a function which takes in an Address cannot accept a string as that input,
// or vice versa.
type Address = Address of string
type Name = Name of string
type SSN = SSN of int

// You can easily instantiate a single-case DU as follows.
let address = Address "111 Alf Way"
let name = Name "Alf"
let ssn = SSN 1234567890

/// When you need the value, you can unwrap the underlying value with a simple function.
let unwrapAddress (Address a) = a
let unwrapName (Name n) = n
let unwrapSSN (SSN s) = s

// Printing single-case DUs is simple with unwrapping functions.
printfn "Address: %s, Name: %s, and SSN: %d" (address |> unwrapAddress) (name |> unwrapName) (ssn |>
unwrapSSN)

```

As the above sample demonstrates, to get the underlying value in a single-case Discriminated Union, you must explicitly unwrap it.

Additionally, DUs also support recursive definitions, allowing you to easily represent trees and inherently recursive data. For example, here's how you can represent a Binary Search Tree with `exists` and `insert` functions.

```

/// Discriminated Unions also support recursive definitions.
///
/// This represents a Binary Search Tree, with one case being the Empty tree,
/// and the other being a Node with a value and two subtrees.
type BST<'T> =
    | Empty
    | Node of value:'T * left: BST<'T> * right: BST<'T>

/// Check if an item exists in the binary search tree.
/// Searches recursively using Pattern Matching. Returns true if it exists; otherwise, false.
let rec exists item bst =
    match bst with
    | Empty -> false
    | Node (x, left, right) ->
        if item = x then true
        elif item < x then (exists item left) // Check the left subtree.
        else (exists item right) // Check the right subtree.

/// Inserts an item in the Binary Search Tree.
/// Finds the place to insert recursively using Pattern Matching, then inserts a new node.
/// If the item is already present, it does not insert anything.
let rec insert item bst =
    match bst with
    | Empty -> Node(item, Empty, Empty)
    | Node(x, left, right) as node ->
        if item = x then node // No need to insert, it already exists; return the node.
        elif item < x then Node(x, insert item left, right) // Call into left subtree.
        else Node(x, left, insert item right) // Call into right subtree.

```

Because DUs allow you to represent the recursive structure of the tree in the data type, operating on this recursive structure is straightforward and guarantees correctness. It is also supported in pattern matching, as shown below.

Additionally, you can represent DUs as `struct`s with the `[<Struct>]` attribute:

```
/// Discriminated Unions can also be represented as structs via the 'Struct' attribute.  
/// This is helpful in situations where the performance of structs outweighs  
/// the flexibility of reference types.  
///  
/// However, there are two important things to know when doing this:  
/// 1. A struct DU cannot be recursively-defined.  
/// 2. A struct DU must have unique names for each of its cases.  
[<Struct>]  
type Shape =  
    | Circle of radius: float  
    | Square of side: float  
    | Triangle of height: float * width: float
```

However, there are two key things to keep in mind when doing so:

1. A struct DU cannot be recursively-defined.
2. A struct DU must have unique names for each of its cases.

Failure to follow the above will result in a compilation error.

Pattern Matching

[Pattern Matching](#) is the F# language feature which enables correctness for operating on F# types. In the above samples, you probably noticed quite a bit of `match x with ...` syntax. This construct allows the compiler, which can understand the "shape" of data types, to force you to account for all possible cases when using a data type through what is known as Exhaustive Pattern Matching. This is incredibly powerful for correctness, and can be cleverly used to "lift" what would normally be a runtime concern into compile-time.

```

module PatternMatching = 

    /// A record for a person's first and last name
    type Person = {
        First : string
        Last  : string
    }

    /// A Discriminated Union of 3 different kinds of employees
    type Employee =
        | Engineer of engineer: Person
        | Manager of manager: Person * reports: List<Employee>
        | Executive of executive: Person * reports: List<Employee> * assistant: Employee

    /// Count everyone underneath the employee in the management hierarchy,
    /// including the employee. The matches bind names to the properties
    /// of the cases so that those names can be used inside the match branches.
    /// Note that the names used for binding do not need to be the same as the
    /// names given in the DU definition above.
    let rec countReports(emp : Employee) =
        1 + match emp with
        | Engineer(person) ->
            0
        | Manager(person, reports) ->
            reports |> List.sumBy countReports
        | Executive(person, reports, assistant) ->
            (reports |> List.sumBy countReports) + countReports assistant

    /// Find all managers/executives named "Dave" who do not have any reports.
    /// This uses the 'function' shorthand to as a lambda expression.
    let rec findDaveWithOpenPosition(emps : List<Employee>) =
        emps
        |> List.filter(function
            | Manager({First = "Dave"}, []) -> true // [] matches an empty list.
            | Executive({First = "Dave"}, [], _) -> true
            | _ -> false) // '_' is a wildcard pattern that matches anything.
                           // This handles the "or else" case.

```

Something you may have noticed is the use of the `_` pattern. This is known as the [Wildcard Pattern](#), which is a way of saying "I don't care what something is". Although convenient, you can accidentally bypass Exhaustive Pattern Matching and no longer benefit from compile-time enforcements if you aren't careful in using `_`. It is best used when you don't care about certain pieces of a decomposed type when pattern matching, or the final clause when you have enumerated all meaningful cases in a pattern matching expression.

[Active Patterns](#) are another powerful construct to use with pattern matching. They allow you to partition input data into custom forms, decomposing them at the pattern match call site. They can also be parameterized, thus allowing to define the partition as a function. Expanding the previous example to support Active Patterns looks something like this:

```

// Active Patterns are another powerful construct to use with pattern matching.
// They allow you to partition input data into custom forms, decomposing them at the pattern match call
site.
//
// To learn more, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/active-patterns
let (|Int|_|) = parseInt
let (|Double|_|) = parseDouble
let (|Date|_|) = parseDateTimeOffset
let (|TimeSpan|_|) = parseTimeSpan

/// Pattern Matching via 'function' keyword and Active Patterns often looks like this.
let printParseResult = function
    | Int x -> printfn "%d" x
    | Double x -> printfn "%f" x
    | Date d -> printfn "%s" (d.ToString())
    | TimeSpan t -> printfn "%s" (t.ToString())
    | _ -> printfn "Nothing was parse-able!"

// Call the printer with some different values to parse.
printParseResult "12"
printParseResult "12.045"
printParseResult "12/28/2016"
printParseResult "9:01PM"
printParseResult "banana!"

```

Optional Types

One special case of Discriminated Union types is the Option Type, which is so useful that it's a part of the F# core library.

The [Option Type](#) is a type which represents one of two cases: a value, or nothing at all. It is used in any scenario where a value may or may not result from a particular operation. This then forces you to account for both cases, making it a compile-time concern rather than a runtime concern. These are often used in APIs where `null` is used to represent "nothing" instead, thus eliminating the need to worry about `NullReferenceException` in many circumstances.

```

/// Option values are any kind of value tagged with either 'Some' or 'None'.
/// They are used extensively in F# code to represent the cases where many other
/// languages would use null references.
///
/// To learn more, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/options
module OptionValues =
    /// First, define a zip code defined via Single-case Discriminated Union.
    type ZipCode = ZipCode of string

    /// Next, define a type where the ZipCode is optional.
    type Customer = { ZipCode: ZipCode option }

    /// Next, define an interface type the represents an object to compute the shipping zone for the
    /// customer's zip code,
    /// given implementations for the 'getState' and 'getShippingZone' abstract methods.
    type IShippingCalculator =
        abstract GetState : ZipCode -> string option
        abstract GetShippingZone : string -> int

    /// Next, calculate a shipping zone for a customer using a calculator instance.
    /// This uses combinators in the Option module to allow a functional pipeline for
    /// transforming data with Optionals.
    let CustomerShippingZone (calculator: IShippingCalculator, customer: Customer) =
        customer.ZipCode
        |> Option.bind calculator.GetState
        |> Option.map calculator.GetShippingZone

```

Units of Measure

One unique feature of F#'s type system is the ability to provide context for numeric literals through Units of Measure.

[Units of Measure](#) allow you to associate a numeric type to a unit, such as Meters, and have functions perform work on units rather than numeric literals. This enables the compiler to verify that the types of numeric literals passed in make sense under a certain context, thus eliminating runtime errors associated with that kind of work.

```

/// Units of measure are a way to annotate primitive numeric types in a type-safe way.
/// You can then perform type-safe arithmetic on these values.
///
/// To learn more, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/units-of-measure
module UnitsOfMeasure =

    /// First, open a collection of common unit names
    open Microsoft.FSharp.Data.UnitSystems.SI.UnitNames

    /// Define a unitized constant
    let sampleValue1 = 1600.0<meter>

    /// Next, define a new unit type
    []
    type mile =
        /// Conversion factor mile to meter.
        static member asMeter = 1609.34<meter/mile>

    /// Define a unitized constant
    let sampleValue2 = 500.0<mile>

    /// Compute metric-system constant
    let sampleValue3 = sampleValue2 * mile.asMeter

    // Values using Units of Measure can be used just like the primitive numeric type for things like
    // printing.
    printfn "After a %f race I would walk %f miles which would be %f meters" sampleValue1 sampleValue2
    sampleValue3

```

The F# Core library defines many SI unit types and unit conversions. To learn more, check out the [Microsoft.FSharp.Data.UnitSystems.SI Namespace](#).

Classes and Interfaces

F# also has full support for .NET classes, [Interfaces](#), [Abstract Classes](#), [Inheritance](#), and so on.

[Classes](#) are types that represent .NET objects, which can have properties, methods, and events as its [Members](#).

```

/// Classes are a way of defining new object types in F#, and support standard Object-oriented constructs.
/// They can have a variety of members (methods, properties, events, etc.)
///
/// To learn more about Classes, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/classes
///
/// To learn more about Members, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/members
module DefiningClasses =

    /// A simple two-dimensional Vector class.
    ///
    /// The class's constructor is on the first line,
    /// and takes two arguments: dx and dy, both of type 'double'.
    type Vector2D(dx : double, dy : double) =

        /// This internal field stores the length of the vector, computed when the
        /// object is constructed
        let length = sqrt (dx*dx + dy*dy)

        // 'this' specifies a name for the object's self-identifier.
        // In instance methods, it must appear before the member name.
        member this.DX = dx

        member this.DY = dy

        member this.Length = length

        /// This member is a method. The previous members were properties.
        member this.Scale(k) = Vector2D(k * this.DX, k * this.DY)

    /// This is how you instantiate the Vector2D class.
    let vector1 = Vector2D(3.0, 4.0)

    /// Get a new scaled vector object, without modifying the original object.
    let vector2 = vector1.Scale(10.0)

    printfn "Length of vector1: %f\nLength of vector2: %f" vector1.Length vector2.Length

```

Defining generic classes is also very straightforward.

```

/// Generic classes allow types to be defined with respect to a set of type parameters.
/// In the following, 'T' is the type parameter for the class.
///
/// To learn more, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/generics/
module DefiningGenericClasses =

    type StateTracker<'T>(initialElement: 'T) =
        /// This internal field store the states in a list.
        let mutable states = [ initialElement ]

        /// Add a new element to the list of states.
        member this.UpdateState newState =
            states <- newState :: states // use the '<->' operator to mutate the value.

        /// Get the entire list of historical states.
        member this.History = states

        /// Get the latest state.
        member this.Current = states.Head

    /// An 'int' instance of the state tracker class. Note that the type parameter is inferred.
    let tracker = StateTracker 10

    // Add a state
    tracker.UpdateState 17

```

To implement an Interface, you can use either `interface ... with` syntax or an [Object Expression](#).

```

/// Interfaces are object types with only 'abstract' members.
/// Object types and object expressions can implement interfaces.
///
/// To learn more, see: https://docs.microsoft.com/dotnet/fsharp/language-reference/interfaces
module ImplementingInterfaces =

    /// This is a type that implements IDisposable.
    type ReadFile() =
        let file = new System.IO.StreamReader("readme.txt")

        member this.ReadLine() = file.ReadLine()

        // This is the implementation of IDisposable members.
        interface System.IDisposable with
            member this.Dispose() = file.Close()

    /// This is an object that implements IDisposable via an Object Expression
    /// Unlike other languages such as C# or Java, a new type definition is not needed
    /// to implement an interface.
    let interfaceImplementation =
        { new System.IDisposable with
            member this.Dispose() = printfn "disposed" }

```

Which Types to Use

The presence of Classes, Records, Discriminated Unions, and Tuples leads to an important question: which should you use? Like most everything in life, the answer depends on your circumstances.

Tuples are great for returning multiple values from a function, and using an ad-hoc aggregate of values as a value itself.

Records are a "step up" from Tuples, having named labels and support for optional members. They are great for

a low-ceremony representation of data in-transit through your program. Because they have structural equality, they are easy to use with comparison.

Discriminated Unions have many uses, but the core benefit is to be able to utilize them in conjunction with Pattern Matching to account for all possible "shapes" that a data can have.

Classes are great for a huge number of reasons, such as when you need to represent information and also tie that information to functionality. As a rule of thumb, when you have functionality which is conceptually tied to some data, using Classes and the principles of Object-Oriented Programming is a big benefit. Classes are also the preferred data type when interoperating with C# and Visual Basic, as these languages use classes for nearly everything.

Next Steps

Now that you've seen some of the primary features of the language, you should be ready to write your first F# programs! Check out [Getting Started](#) to learn how to set up your development environment and write some code.

The next steps for learning more can be whatever you like, but we recommend [Introduction to Functional Programming in F#](#) to get comfortable with core Functional Programming concepts. These will be essential in building robust programs in F#.

Also, check out the [F# Language Reference](#) to see a comprehensive collection of conceptual content on F#.

Introduction to Functional Programming in F#

3/19/2019 • 8 minutes to read • [Edit Online](#)

Functional programming is a style of programming that emphasizes the use of functions and immutable data. Typed functional programming is when functional programming is combined with static types, such as with F#. In general, the following concepts are emphasized in functional programming:

- Functions as the primary constructs you use
- Expressions instead of statements
- Immutable values over variables
- Declarative programming over imperative programming

Throughout this series, you'll explore concepts and patterns in functional programming using F#. Along the way, you'll learn some F# too.

Terminology

Functional programming, like other programming paradigms, comes with a vocabulary that you will eventually need to learn. Here are some common terms you'll see all of the time:

- **Function** - A function is a construct that will produce an output when given an input. More formally, it *maps* an item from one set to another set. This formalism is lifted into the concrete in many ways, especially when using functions that operate on collections of data. It is the most basic (and important) concept in functional programming.
- **Expression** - An expression is a construct in code that produces a value. In F#, this value must be bound or explicitly ignored. An expression can be trivially replaced by a function call.
- **Purity** - Purity is a property of a function such that its return value is always the same for the same arguments, and that its evaluation has no side effects. A pure function depends entirely on its arguments.
- **Referential Transparency** - Referential Transparency is a property of expressions such that they can be replaced with their output without affecting a program's behavior.
- **Immutability** - Immutability means that a value cannot be changed in-place. This is in contrast with variables, which can change in place.

Examples

The following examples demonstrate these core concepts.

Functions

The most common and fundamental construct in functional programming is the function. Here's a simple function that adds 1 to an integer:

```
let addOne x = x + 1
```

Its type signature is as follows:

```
val addOne: x:int -> int
```

The signature can be read as, "`addOne` accepts an `int` named `x` and will produce an `int`". More formally,

`addOne` is *mapping* a value from the set of integers to the set of integers. The `->` token signifies this mapping. In F#, you can usually look at the function signature to get a sense for what it does.

So, why is the signature important? In typed functional programming, the implementation of a function is often less important than the actual type signature! The fact that `addOne` adds the value 1 to an integer is interesting at runtime, but when you are constructing a program, the fact that it accepts and returns an `int` is what informs how you will actually use this function. Furthermore, once you use this function correctly (with respect to its type signature), diagnosing any problems can be done only within the body of the `addOne` function. This is the impetus behind typed functional programming.

Expressions

Expressions are constructs that evaluate to a value. In contrast to statements, which perform an action, expressions can be thought of performing an action that gives back a value. Expressions are almost always used in favor of statements in functional programming.

Consider the previous function, `addOne`. The body of `addOne` is an expression:

```
// 'x + 1' is an expression!
let addOne x = x + 1
```

It is the result of this expression that defines the result type of the `addOne` function. For example, the expression that makes up this function could be changed to be a different type, such as a `string`:

```
let addOne x = x.ToString() + "1"
```

The signature of the function is now:

```
val addOne: x:'a -> string
```

Since any type in F# can have `ToString()` called on it, the type of `x` has been made generic (called [Automatic Generalization](#)), and the resultant type is a `string`.

Expressions are not just the bodies of functions. You can have expressions that produce a value you use elsewhere. A common one is `if`:

```
// Checks if 'x' is odd by using the mod operator
let isOdd x = x % 2 <> 0

let addOneIfOdd input =
    let result =
        if isOdd input then
            input + 1
        else
            input

    result
```

The `if` expression produces a value called `result`. Note that you could omit `result` entirely, making the `if` expression the body of the `addOneIfOdd` function. The key thing to remember about expressions is that they produce a value.

There is a special type, `unit`, that is used when there is nothing to return. For example, consider this simple function:

```
let printString (str: string) =
    printfn "String is: %s" str
```

The signature looks like this:

```
val printString: str:string -> unit
```

The `unit` type indicates that there is no actual value being returned. This is useful when you have a routine that must "do work" despite having no value to return as a result of that work.

This is in sharp contrast to imperative programming, where the equivalent `if` construct is a statement, and producing values is often done with mutating variables. For example, in C#, the code might be written like this:

```
bool IsOdd(int x) => x % 2 != 0;

int AddOneIfOdd(int input)
{
    var result = input;

    if (IsOdd(input))
    {
        result = input + 1;
    }

    return result;
}
```

It's worth noting that C# and other C-style languages do support the [ternary expression](#), which allows for expression-based conditional programming.

In functional programming, it is rare to mutate values with statements. Although some functional languages support statements and mutation, it is not common to use these concepts in functional programming.

Pure functions

As previously mentioned, pure functions are functions that:

- Always evaluate to the same value for the same input.
- Have no side effects.

It is helpful to think of mathematical functions in this context. In mathematics, functions depend only on their arguments and do not have any side effects. In the mathematical function $f(x) = x + 1$, the value of $f(x)$ depends only on the value of x . Pure functions in functional programming are the same way.

When writing a pure function, the function must depend only on its arguments and not perform any action that results in a side effect.

Here is an example of a non-pure function because it depends on global, mutable state:

```
let mutable value = 1

let addOneToValue x = x + value
```

The `addOneToValue` function is clearly impure, because `value` could be changed at any time to have a different value than 1. This pattern of depending on a global value is to be avoided in functional programming.

Here is another example of a non-pure function, because it performs a side effect:

```
let addOneToValue x =
    printfn "x is %d" x
    x + 1
```

Although this function does not depend on a global value, it writes the value of `x` to the output of the program. Although there is nothing inherently wrong with doing this, it does mean that the function is not pure. If another part of your program depends on something external to the program, such as the output buffer, then calling this function can affect that other part of your program.

Removing the `printfn` statement makes the function pure:

```
let addOneToValue x = x + 1
```

Although this function is not inherently *better* than the previous version with the `printfn` statement, it does guarantee that all this function does is return a value. Calling this function any number of times produces the same result: it just produces a value. The predictability given by purity is something many functional programmers strive for.

Immutability

Finally, one of the most fundamental concepts of typed functional programming is immutability. In F#, all values are immutable by default. That means they cannot be mutated in-place unless you explicitly mark them as mutable.

In practice, working with immutable values means that you change your approach to programming from, "I need to change something", to "I need to produce a new value".

For example, adding 1 to a value means producing a new value, not mutating the existing one:

```
let value = 1
let secondValue = value + 1
```

In F#, the following code does **not** mutate the `value` function; instead, it performs an equality check:

```
let value = 1
value = value + 1 // Produces a 'bool' value!
```

Some functional programming languages do not support mutation at all. In F#, it is supported, but it is not the default behavior for values.

This concept extends even further to data structures. In functional programming, immutable data structures such as sets (and many more) have a different implementation than you might initially expect. Conceptually, something like adding an item to a set does not change the set, it produces a *new* set with the added value. Under the covers, this is often accomplished by a different data structure that allows for efficiently tracking a value so that the appropriate representation of the data can be given as a result.

This style of working with values and data structures is critical, as it forces you to treat any operation that modifies something as if it creates a new version of that thing. This allows for things like equality and comparability to be consistent in your programs.

Next steps

The next section will thoroughly cover functions, exploring different ways you can use them in functional programming.

[First-class functions](#) explores functions deeply, showing how you can use them in various contexts.

Further reading

The [Thinking Functionally](#) series is another great resource to learn about functional programming with F#. It covers fundamentals of functional programming in a pragmatic and easy-to-read way, using F# features to illustrate the concepts.

First-class functions

11/13/2018 • 22 minutes to read • [Edit Online](#)

A defining characteristic of functional programming languages is the elevation of functions to first-class status. You should be able to do with a function whatever you can do with values of the other built-in types, and be able to do so with a comparable degree of effort.

Typical measures of first-class status include the following:

- Can you bind functions to identifiers? That is, can you give them names?
- Can you store functions in data structures, such as in a list?
- Can you pass a function as an argument in a function call?
- Can you return a function from a function call?

The last two measures define what are known as *higher-order operations* or *higher-order functions*. Higher-order functions accept functions as arguments and return functions as the value of function calls. These operations support such mainstays of functional programming as mapping functions and composition of functions.

Give the Value a Name

If a function is a first-class value, you must be able to name it, just as you can name integers, strings, and other built-in types. This is referred to in functional programming literature as binding an identifier to a value. F# uses `let` **bindings** to bind names to values: `let <identifier> = <value>`. The following code shows two examples.

```
// Integer and string.  
let num = 10  
let str = "F#"
```

You can name a function just as easily. The following example defines a function named `squareIt` by binding the identifier `squareIt` to the **lambda expression** `fun n -> n * n`. Function `squareIt` has one parameter, `n`, and it returns the square of that parameter.

```
let squareIt = fun n -> n * n
```

F# provides the following more concise syntax to achieve the same result with less typing.

```
let squareIt2 n = n * n
```

The examples that follow mostly use the first style, `let <function-name> = <lambda-expression>`, to emphasize the similarities between the declaration of functions and the declaration of other types of values. However, all the named functions can also be written with the concise syntax. Some of the examples are written in both ways.

Store the Value in a Data Structure

A first-class value can be stored in a data structure. The following code shows examples that store values in lists and in tuples.

```

// Lists.

// Storing integers and strings.
let integerList = [ 1; 2; 3; 4; 5; 6; 7 ]
let stringList = [ "one"; "two"; "three" ]

// You cannot mix types in a list. The following declaration causes a
// type-mismatch compiler error.
//let failedList = [ 5; "six" ]

// In F#, functions can be stored in a list, as long as the functions
// have the same signature.

// Function doubleIt has the same signature as squareIt, declared previously.
//let squareIt = fun n -> n * n
let doubleIt = fun n -> 2 * n

// Functions squareIt and doubleIt can be stored together in a list.
let funList = [ squareIt; doubleIt ]

// Function squareIt cannot be stored in a list together with a function
// that has a different signature, such as the following body mass
// index (BMI) calculator.
let BMICalculator = fun ht wt ->
    (float wt / float (squareIt ht)) * 703.0

// The following expression causes a type-mismatch compiler error.
//let failedFunList = [ squareIt; BMICalculator ]

```

```

// Tuples.

// Integers and strings.
let integerTuple = ( 1, -7 )
let stringTuple = ( "one", "two", "three" )

// A tuple does not require its elements to be of the same type.
let mixedTuple = ( 1, "two", 3.3 )

// Similarly, function elements in tuples can have different signatures.
let funTuple = ( squareIt, BMICalculator )

// Functions can be mixed with integers, strings, and other types in
// a tuple. Identifier num was declared previously.
//let num = 10
let moreMixedTuple = ( num, "two", 3.3, squareIt )

```

To verify that a function name stored in a tuple does in fact evaluate to a function, the following example uses the `fst` and `snd` operators to extract the first and second elements from tuple `funAndArgTuple`. The first element in the tuple is `squareIt` and the second element is `num`. Identifier `num` is bound in a previous example to integer 10, a valid argument for the `squareIt` function. The second expression applies the first element in the tuple to the second element in the tuple: `squareIt num`.

```

// You can pull a function out of a tuple and apply it. Both squareIt and num
// were defined previously.
let funAndArgTuple = (squareIt, num)

// The following expression applies squareIt to num, returns 100, and
// then displays 100.
System.Console.WriteLine((fst funAndArgTuple)(snd funAndArgTuple))

```

Similarly, just as identifier `num` and integer 10 can be used interchangeably, so can identifier `squareIt` and lambda expression `fun n -> n * n`.

```
// Make a tuple of values instead of identifiers.
let funAndArgTuple2 = ((fun n -> n * n), 10)

// The following expression applies a squaring function to 10, returns
// 100, and then displays 100.
System.Console.WriteLine((fst funAndArgTuple2)(snd funAndArgTuple2))
```

Pass the Value as an Argument

If a value has first-class status in a language, you can pass it as an argument to a function. For example, it is common to pass integers and strings as arguments. The following code shows integers and strings passed as arguments in F#.

```
// An integer is passed to squareIt. Both squareIt and num are defined in
// previous examples.
//let num = 10
//let squareIt = fun n -> n * n
System.Console.WriteLine(squareIt num)

// String.
// Function repeatString concatenates a string with itself.
let repeatString = fun s -> s + s

// A string is passed to repeatString. HelloHello is returned and displayed.
let greeting = "Hello"
System.Console.WriteLine(repeatString greeting)
```

If functions have first-class status, you must be able to pass them as arguments in the same way. Remember that this is the first characteristic of higher-order functions.

In the following example, function `applyIt` has two parameters, `op` and `arg`. If you send in a function that has one parameter for `op` and an appropriate argument for the function to `arg`, the function returns the result of applying `op` to `arg`. In the following example, both the function argument and the integer argument are sent in the same way, by using their names.

```
// Define the function, again using lambda expression syntax.
let applyIt = fun op arg -> op arg

// Send squareIt for the function, op, and num for the argument you want to
// apply squareIt to, arg. Both squareIt and num are defined in previous
// examples. The result returned and displayed is 100.
System.Console.WriteLine(applyIt squareIt num)

// The following expression shows the concise syntax for the previous function
// definition.
let applyIt2 op arg = op arg
// The following line also displays 100.
System.Console.WriteLine(applyIt2 squareIt num)
```

The ability to send a function as an argument to another function underlies common abstractions in functional programming languages, such as map or filter operations. A map operation, for example, is a higher-order function that captures the computation shared by functions that step through a list, do something to each element, and then return a list of the results. You might want to increment each element in a list of integers, or to square each element, or to change each element in a list of strings to uppercase. The error-prone part of the computation is the recursive process that steps through the list and builds a list of the results to return. That part is captured in the mapping function. All you have to write for a particular application is the function that you want to apply to each list element individually (adding, squaring, changing case). That function is sent as an argument to the mapping

function, just as `squareIt` is sent to `applyIt` in the previous example.

F# provides map methods for most collection types, including [lists](#), [arrays](#), and [sequences](#). The following examples use lists. The syntax is `List.map <the function> <the list>`.

```
// List integerList was defined previously:  
//let integerList = [ 1; 2; 3; 4; 5; 6; 7 ]  
  
// You can send the function argument by name, if an appropriate function  
// is available. The following expression uses squareIt.  
let squareAll = List.map squareIt integerList  
  
// The following line displays [1; 4; 9; 16; 25; 36; 49]  
printfn "%A" squareAll  
  
// Or you can define the action to apply to each list element inline.  
// For example, no function that tests for even integers has been defined,  
// so the following expression defines the appropriate function inline.  
// The function returns true if n is even; otherwise it returns false.  
let evenOrNot = List.map (fun n -> n % 2 = 0) integerList  
  
// The following line displays [false; true; false; true; false; true; false]  
printfn "%A" evenOrNot
```

For more information, see [Lists](#).

Return the Value from a Function Call

Finally, if a function has first-class status in a language, you must be able to return it as the value of a function call, just as you return other types, such as integers and strings.

The following function calls return integers and display them.

```
// Function doubleIt is defined in a previous example.  
//let doubleIt = fun n -> 2 * n  
System.Console.WriteLine(doubleIt 3)  
System.Console.WriteLine(squareIt 4)
```

The following function call returns a string.

```
// str is defined in a previous section.  
//let str = "F#"  
let lowercase = str.ToLower()
```

The following function call, declared inline, returns a Boolean value. The value displayed is `True`.

```
System.Console.WriteLine((fun n -> n % 2 = 1) 15)
```

The ability to return a function as the value of a function call is the second characteristic of higher-order functions. In the following example, `checkFor` is defined to be a function that takes one argument, `item`, and returns a new function as its value. The returned function takes a list as its argument, `lst`, and searches for `item` in `lst`. If `item` is present, the function returns `true`. If `item` is not present, the function returns `false`. As in the previous section, the following code uses a provided list function, [List.exists](#), to search the list.

```

let checkFor item =
    let functionToReturn = fun lst ->
        List.exists (fun a -> a = item) lst
    functionToReturn

```

The following code uses `checkFor` to create a new function that takes one argument, a list, and searches for 7 in the list.

```

// integerList and stringList were defined earlier.
//let integerList = [ 1; 2; 3; 4; 5; 6; 7 ]
//let stringList = [ "one"; "two"; "three" ]

// The returned function is given the name checkFor7.
let checkFor7 = checkFor 7

// The result displayed when checkFor7 is applied to integerList is True.
System.Console.WriteLine(checkFor7 integerList)

// The following code repeats the process for "seven" in stringList.
let checkForSeven = checkFor "seven"

// The result displayed is False.
System.Console.WriteLine(checkForSeven stringList)

```

The following example uses the first-class status of functions in F# to declare a function, `compose`, that returns a composition of two function arguments.

```

// Function compose takes two arguments. Each argument is a function
// that takes one argument of the same type. The following declaration
// uses lambda expression syntax.
let compose =
    fun op1 op2 ->
        fun n ->
            op1 (op2 n)

// To clarify what you are returning, use a nested let expression:
let compose2 =
    fun op1 op2 ->
        // Use a let expression to build the function that will be returned.
        let funToReturn = fun n ->
            op1 (op2 n)
        // Then just return it.
        funToReturn

// Or, integrating the more concise syntax:
let compose3 op1 op2 =
    let funToReturn = fun n ->
        op1 (op2 n)
    funToReturn

```

NOTE

For an even shorter version, see the following section, "Curried Functions."

The following code sends two functions as arguments to `compose`, both of which take a single argument of the same type. The return value is a new function that is a composition of the two function arguments.

```
// Functions squareIt and doubleIt were defined in a previous example.
let doubleAndSquare = compose squareIt doubleIt
// The following expression doubles 3, squares 6, and returns and
// displays 36.
System.Console.WriteLine(doubleAndSquare 3)

let squareAndDouble = compose doubleIt squareIt
// The following expression squares 3, doubles 9, returns 18, and
// then displays 18.
System.Console.WriteLine(squareAndDouble 3)
```

NOTE

F# provides two operators, `<<` and `>>`, that compose functions. For example,

`let squareAndDouble2 = doubleIt << squareIt` is equivalent to `let squareAndDouble = compose doubleIt squareIt` in the previous example.

The following example of returning a function as the value of a function call creates a simple guessing game. To create a game, call `makeGame` with the value that you want someone to guess sent in for `target`. The return value from function `makeGame` is a function that takes one argument (the guess) and reports whether the guess is correct.

```
let makeGame target =
    // Build a lambda expression that is the function that plays the game.
    let game = fun guess ->
        if guess = target then
            System.Console.WriteLine("You win!")
        else
            System.Console.WriteLine("Wrong. Try again.")
    // Now just return it.
    game
```

The following code calls `makeGame`, sending the value `7` for `target`. Identifier `playGame` is bound to the returned lambda expression. Therefore, `playGame` is a function that takes as its one argument a value for `guess`.

```
let playGame = makeGame 7
// Send in some guesses.
playGame 2
playGame 9
playGame 7

// Output:
// Wrong. Try again.
// Wrong. Try again.
// You win!

// The following game specifies a character instead of an integer for target.
let alphaGame = makeGame 'q'
alphaGame 'c'
alphaGame 'r'
alphaGame 'j'
alphaGame 'q'

// Output:
// Wrong. Try again.
// Wrong. Try again.
// Wrong. Try again.
// You win!
```

Curried Functions

Many of the examples in the previous section can be written more concisely by taking advantage of the implicit *currying* in F# function declarations. Currying is a process that transforms a function that has more than one parameter into a series of embedded functions, each of which has a single parameter. In F#, functions that have more than one parameter are inherently curried. For example, `compose` from the previous section can be written as shown in the following concise style, with three parameters.

```
let compose4 op1 op2 n = op1 (op2 n)
```

However, the result is a function of one parameter that returns a function of one parameter that in turn returns another function of one parameter, as shown in `compose4curried`.

```
let compose4curried =
    fun op1 ->
        fun op2 ->
            fun n -> op1 (op2 n)
```

You can access this function in several ways. Each of the following examples returns and displays 18. You can replace `compose4` with `compose4curried` in any of the examples.

```
// Access one layer at a time.
System.Console.WriteLine(((compose4 doubleIt) squareIt) 3)

// Access as in the original compose examples, sending arguments for
// op1 and op2, then applying the resulting function to a value.
System.Console.WriteLine((compose4 doubleIt squareIt) 3)

// Access by sending all three arguments at the same time.
System.Console.WriteLine(compose4 doubleIt squareIt 3)
```

To verify that the function still works as it did before, try the original test cases again.

```
let doubleAndSquare4 = compose4 squareIt doubleIt
// The following expression returns and displays 36.
System.Console.WriteLine(doubleAndSquare4 3)

let squareAndDouble4 = compose4 doubleIt squareIt
// The following expression returns and displays 18.
System.Console.WriteLine(squareAndDouble4 3)
```

NOTE

You can restrict currying by enclosing parameters in tuples. For more information, see "Parameter Patterns" in [Parameters and Arguments](#).

The following example uses implicit currying to write a shorter version of `makeGame`. The details of how `makeGame` constructs and returns the `game` function are less explicit in this format, but you can verify by using the original test cases that the result is the same.

```

let makeGame2 target guess =
    if guess = target then
        System.Console.WriteLine("You win!")
    else
        System.Console.WriteLine("Wrong. Try again.")

let playGame2 = makeGame2 7
playGame2 2
playGame2 9
playGame2 7

let alphaGame2 = makeGame2 'q'
alphaGame2 'c'
alphaGame2 'r'
alphaGame2 'j'
alphaGame2 'q'

```

For more information about currying, see "Partial Application of Arguments" in [Functions](#).

Identifier and Function Definition Are Interchangeable

The variable name `num` in the previous examples evaluates to the integer 10, and it is no surprise that where `num` is valid, 10 is also valid. The same is true of function identifiers and their values: anywhere the name of the function can be used, the lambda expression to which it is bound can be used.

The following example defines a `Boolean` function called `isNegative`, and then uses the name of the function and the definition of the function interchangeably. The next three examples all return and display `False`.

```

let isNegative = fun n -> n < 0

// This example uses the names of the function argument and the integer
// argument. Identifier num is defined in a previous example.
//let num = 10
System.Console.WriteLine(applyIt isNegative num)

// This example substitutes the value that num is bound to for num, and the
// value that isNegative is bound to for isNegative.
System.Console.WriteLine(applyIt (fun n -> n < 0) 10)

```

To take it one step further, substitute the value that `applyIt` is bound to for `applyIt`.

```
System.Console.WriteLine((fun op arg -> op arg) (fun n -> n < 0) 10)
```

Functions Are First-Class Values in F#

The examples in the previous sections demonstrate that functions in F# satisfy the criteria for being first-class values in F#:

- You can bind an identifier to a function definition.

```
let squareIt = fun n -> n * n
```

- You can store a function in a data structure.

```
let funTuple2 = ( BMIcalculator, fun n -> n * n )
```

- You can pass a function as an argument.

```
let increments = List.map (fun n -> n + 1) [ 1; 2; 3; 4; 5; 6; 7 ]
```

- You can return a function as the value of a function call.

```
let checkFor item =
    let functionToReturn = fun lst ->
        List.exists (fun a -> a = item) lst
    functionToReturn
```

For more information about F#, see the [F# Language Reference](#).

Example

Description

The following code contains all the examples in this topic.

Code

```
// ** GIVE THE VALUE A NAME **

// Integer and string.
let num = 10
let str = "F#"

let squareIt = fun n -> n * n

let squareIt2 n = n * n

// ** STORE THE VALUE IN A DATA STRUCTURE **

// Lists.

// Storing integers and strings.
let integerList = [ 1; 2; 3; 4; 5; 6; 7 ]
let stringList = [ "one"; "two"; "three" ]

// You cannot mix types in a list. The following declaration causes a
// type-mismatch compiler error.
//let failedList = [ 5; "six" ]

// In F#, functions can be stored in a list, as long as the functions
// have the same signature.

// Function doubleIt has the same signature as squareIt, declared previously.
//let squareIt = fun n -> n * n
let doubleIt = fun n -> 2 * n

// Functions squareIt and doubleIt can be stored together in a list.
let funList = [ squareIt; doubleIt ]

// Function squareIt cannot be stored in a list together with a function
// that has a different signature, such as the following body mass
// index (RMT) calculator
```

```

// INDEX (BMI) CALCULATOR.
let BMICalculator = fun ht wt ->
    (float wt / float (squareIt ht)) * 703.0

// The following expression causes a type-mismatch compiler error.
//let failedFunList = [ squareIt; BMICalculator ]

// Tuples.

// Integers and strings.
let integerTuple = ( 1, -7 )
let stringTuple = ( "one", "two", "three" )

// A tuple does not require its elements to be of the same type.
let mixedTuple = ( 1, "two", 3.3 )

// Similarly, function elements in tuples can have different signatures.
let funTuple = ( squareIt, BMICalculator )

// Functions can be mixed with integers, strings, and other types in
// a tuple. Identifier num was declared previously.
//let num = 10
let moreMixedTuple = ( num, "two", 3.3, squareIt )

// You can pull a function out of a tuple and apply it. Both squareIt and num
// were defined previously.
let funAndArgTuple = (squareIt, num)

// The following expression applies squareIt to num, returns 100, and
// then displays 100.
System.Console.WriteLine((fst funAndArgTuple)(snd funAndArgTuple))

// Make a list of values instead of identifiers.
let funAndArgTuple2 = ((fun n -> n * n), 10)

// The following expression applies a squaring function to 10, returns
// 100, and then displays 100.
System.Console.WriteLine((fst funAndArgTuple2)(snd funAndArgTuple2))

// ** PASS THE VALUE AS AN ARGUMENT **

// An integer is passed to squareIt. Both squareIt and num are defined in
// previous examples.
//let num = 10
//let squareIt = fun n -> n * n
System.Console.WriteLine(squareIt num)

// String.
// Function repeatString concatenates a string with itself.
let repeatString = fun s -> s + s

// A string is passed to repeatString. HelloHello is returned and displayed.
let greeting = "Hello"
System.Console.WriteLine(repeatString greeting)

// Define the function, again using lambda expression syntax.
let applyIt = fun op arg -> op arg

// Send squareIt for the function, op, and num for the argument you want to
// applyIt to. Both squareIt and num are defined in previous examples.

```

```

// apply squareIt to, arg. Both squareIt and num are defined in previous
// examples. The result returned and displayed is 100.
System.Console.WriteLine(applyIt squareIt num)

// The following expression shows the concise syntax for the previous function
// definition.
let applyIt2 op arg = op arg
// The following line also displays 100.
System.Console.WriteLine(applyIt2 squareIt num)

// List integerList was defined previously:
//let integerList = [ 1; 2; 3; 4; 5; 6; 7 ]

// You can send the function argument by name, if an appropriate function
// is available. The following expression uses squareIt.
let squareAll = List.map squareIt integerList

// The following line displays [1; 4; 9; 16; 25; 36; 49]
printfn "%A" squareAll

// Or you can define the action to apply to each list element inline.
// For example, no function that tests for even integers has been defined,
// so the following expression defines the appropriate function inline.
// The function returns true if n is even; otherwise it returns false.
let evenOrNot = List.map (fun n -> n % 2 = 0) integerList

// The following line displays [false; true; false; true; false; true; false]
printfn "%A" evenOrNot

// ** RETURN THE VALUE FROM A FUNCTION CALL **

// Function doubleIt is defined in a previous example.
//let doubleIt = fun n -> 2 * n
System.Console.WriteLine(doubleIt 3)
System.Console.WriteLine(squareIt 4)

// The following function call returns a string:

// str is defined in a previous section.
//let str = "F#"
let lowercase = str.ToLower()

System.Console.WriteLine((fun n -> n % 2 = 1) 15)

let checkFor item =
    let functionToReturn = fun lst ->
        List.exists (fun a -> a = item) lst
    functionToReturn

// integerList and stringList were defined earlier.
//let integerList = [ 1; 2; 3; 4; 5; 6; 7 ]
//let stringList = [ "one"; "two"; "three" ]

// The returned function is given the name checkFor7.
let checkFor7 = checkFor 7

// The result displayed when checkFor7 is applied to integerList is True.

```

```

System.Console.WriteLine(checkFor7 integerList)

// The following code repeats the process for "seven" in stringList.
let checkForSeven = checkFor "seven"

// The result displayed is False.
System.Console.WriteLine(checkForSeven stringList)

// Function compose takes two arguments. Each argument is a function
// that takes one argument of the same type. The following declaration
// uses lambda expression syntax.
let compose =
    fun op1 op2 ->
        fun n ->
            op1 (op2 n)

// To clarify what you are returning, use a nested let expression:
let compose2 =
    fun op1 op2 ->
        // Use a let expression to build the function that will be returned.
        let funToReturn = fun n ->
            op1 (op2 n)
        // Then just return it.
        funToReturn

// Or, integrating the more concise syntax:
let compose3 op1 op2 =
    let funToReturn = fun n ->
        op1 (op2 n)
    funToReturn

// Functions squareIt and doubleIt were defined in a previous example.
let doubleAndSquare = compose squareIt doubleIt
// The following expression doubles 3, squares 6, and returns and
// displays 36.
System.Console.WriteLine(doubleAndSquare 3)

let squareAndDouble = compose doubleIt squareIt
// The following expression squares 3, doubles 9, returns 18, and
// then displays 18.
System.Console.WriteLine(squareAndDouble 3)

let makeGame target =
    // Build a lambda expression that is the function that plays the game.
    let game = fun guess ->
        if guess = target then
            System.Console.WriteLine("You win!")
        else
            System.Console.WriteLine("Wrong. Try again.")
    // Now just return it.
    game

let playGame = makeGame 7
// Send in some guesses.
playGame 2
playGame 9
playGame 7

// Output:
// Wrong. Try again.
// Wrong. Try again.

```

```
// You win!

// The following game specifies a character instead of an integer for target.
let alphaGame = makeGame 'q'
alphaGame 'c'
alphaGame 'r'
alphaGame 'j'
alphaGame 'q'

// Output:
// Wrong. Try again.
// Wrong. Try again.
// Wrong. Try again.
// You win!
```

```
// ** CURRIED FUNCTIONS **
```

```
let compose4 op1 op2 n = op1 (op2 n)
```

```
let compose4curried =
  fun op1 ->
    fun op2 ->
      fun n -> op1 (op2 n)
```

```
// Access one layer at a time.
System.Console.WriteLine((compose4 doubleIt) squareIt) 3)

// Access as in the original compose examples, sending arguments for
// op1 and op2, then applying the resulting function to a value.
System.Console.WriteLine((compose4 doubleIt squareIt) 3)

// Access by sending all three arguments at the same time.
System.Console.WriteLine(compose4 doubleIt squareIt 3)
```

```
let doubleAndSquare4 = compose4 squareIt doubleIt
// The following expression returns and displays 36.
System.Console.WriteLine(doubleAndSquare4 3)
```

```
let squareAndDouble4 = compose4 doubleIt squareIt
// The following expression returns and displays 18.
System.Console.WriteLine(squareAndDouble4 3)
```

```
let makeGame2 target guess =
  if guess = target then
    System.Console.WriteLine("You win!")
  else
    System.Console.WriteLine("Wrong. Try again.")
```

```
let playGame2 = makeGame2 7
playGame2 2
playGame2 9
playGame2 7
```

```
let alphaGame2 = makeGame2 'q'
alphaGame2 'c'
alphaGame2 'r'
alphaGame2 'j'
alphaGame2 'q'
```

```
// ** IDENTIFIER AND FUNCTION DEFINITION ARE INTERCHANGEABLE **

let isNegative = fun n -> n < 0

// This example uses the names of the function argument and the integer
// argument. Identifier num is defined in a previous example.
//let num = 10
System.Console.WriteLine(applyIt isNegative num)

// This example substitutes the value that num is bound to for num, and the
// value that isNegative is bound to for isNegative.
System.Console.WriteLine(applyIt (fun n -> n < 0) 10)

System.Console.WriteLine((fun op arg -> op arg) (fun n -> n < 0) 10)

// ** FUNCTIONS ARE FIRST-CLASS VALUES IN F# **

//let squareIt = fun n -> n * n

let funTuple2 = ( BMIcalculator, fun n -> n * n )

let increments = List.map (fun n -> n + 1) [ 1; 2; 3; 4; 5; 6; 7 ]

//let checkFor item =
//    let functionToReturn = fun lst ->
//        List.exists (fun a -> a = item) lst
//    functionToReturn
```

Async Programming in F#

2/28/2019 • 6 minutes to read • [Edit Online](#)

NOTE

Some inaccuracies have been discovered in this article. It is being rewritten. See [Issue #666](#) to learn about the changes.

Async programming in F# can be accomplished through a language-level programming model designed to be easy to use and natural to the language.

The core of async programming in F# is `Async<'T>`, a representation of work that can be triggered to run in the background, where `'T` is either the type returned via the special `return` keyword or `unit` if the async workflow has no result to return.

The key concept to understand is that an async expression's type is `Async<'T>`, which is merely a *specification* of work to be done in an asynchronous context. It is not executed until you explicitly start it with one of the starting functions (such as `Async.RunSynchronously`). Although this is a different way of thinking about doing work, it ends up being quite simple in practice.

For example, say you wanted to download the HTML from `dotnetfoundation.org` without blocking the main thread. You can accomplish it like this:

```
open System
open System.Net

let fetchHtmlAsync url =
    async {
        let uri = Uri(url)
        use webClient = new WebClient()

        // Execution of fetchHtmlAsync won't continue until the result
        // of AsyncDownloadString is bound.
        let! html = webClient.AsyncDownloadString(uri)
        return html
    }

let html = "https://dotnetfoundation.org" |> fetchHtmlAsync |> Async.RunSynchronously
printfn "%s" html
```

And that's it! Aside from the use of `async`, `let!`, and `return`, this is just normal F# code.

There are a few syntactical constructs which are worth noting:

- `let!` binds the result of an async expression (which runs on another context).
- `use!` works just like `let!`, but disposes its bound resources when it goes out of scope.
- `do!` will await an async workflow which doesn't return anything.
- `return` simply returns a result from an async expression.
- `return!` executes another async workflow and returns its return value as a result.

Additionally, normal `let`, `use`, and `do` keywords can be used alongside the async versions just as they would in a normal function.

How to start Async Code in F#

As mentioned earlier, async code is a specification of work to be done in another context which needs to be explicitly started. Here are two primary ways to accomplish this:

1. `Async.RunSynchronously` will start an async workflow on another thread and await its result.

```
open System
open System.Net

let fetchHtmlAsync url =
    async {
        let uri = Uri(url)
        use webClient = new WebClient()
        let! html = webClient.AsyncDownloadString(uri)
        return html
    }

// Execution will pause until fetchHtmlAsync finishes
let html = "https://dotnetfoundation.org" |> fetchHtmlAsync |> Async.RunSynchronously

// you actually have the result from fetchHtmlAsync now!
printfn "%s" html
```

2. `Async.Start` will start an async workflow on another thread, and will **not** await its result.

```
open System
open System.Net

let uploadDataAsync url data =
    async {
        let uri = Uri(url)
        use webClient = new WebClient()
        webClient.UploadStringAsync(uri, data)
    }

let workflow = uploadDataAsync "https://url-to-upload-to.com" "hello, world!"

// Execution will continue after calling this!
Async.Start(workflow)

printfn "%s" "uploadDataAsync is running in the background..."
```

There are other ways to start an async workflow available for more specific scenarios. They are detailed [in the Async reference](#).

A Note on Threads

The phrase "on another thread" is mentioned above, but it is important to know that **this does not mean that async workflows are a facade for multithreading**. The workflow actually "jumps" between threads, borrowing them for a small amount of time to do useful work. When an async workflow is effectively "waiting" (for example, waiting for a network call to return something), any thread it was borrowing at the time is freed up to go do useful work on something else. This allows async workflows to utilize the system they run on as effectively as possible, and makes them especially strong for high-volume I/O scenarios.

How to Add Parallelism to Async Code

Sometimes you may need to perform multiple asynchronous jobs in parallel, collect their results, and interpret them in some way. `Async.Parallel` allows you to do this without needing to use the Task Parallel Library, which would involve needing to coerce `Task<'T>` and `Async<'T>` types.

The following example will use `Async.Parallel` to download the HTML from four popular sites in parallel, wait for those tasks to complete, and then print the HTML which was downloaded.

```
open System
open System.Net

let urlList =
    [ "https://www.microsoft.com"
      "https://www.google.com"
      "https://www.amazon.com"
      "https://www.facebook.com" ]

let fetchHtmlAsync url =
    async {
        let uri = Uri(url)
        use webClient = new WebClient()
        let! html = webClient.AsyncDownloadString(uri)
        return html
    }

let getHtmlList urls =
    urls
    |> Seq.map fetchHtmlAsync // Build an Async<'T> for each site
    |> Async.Parallel        // Returns an Async<'T []>
    |> Async.RunSynchronously // Wait for the result of the parallel work

let htmlList = getHtmlList urlList

// We now have the downloaded HTML for each site!
for html in htmlList do
    printfn "%s" html
```

Important Info and Advice

- Append "Async" to the end of any functions you'll consume

Although this is just a naming convention, it does make things like API discoverability easier. Particularly if there are synchronous and asynchronous versions of the same routine, it's a good idea to explicitly state which is asynchronous via the name.

- Listen to the compiler!

F#'s compiler is very strict, making it nearly impossible to do something troubling like run "async" code synchronously. If you come across a warning, that's a sign that the code won't execute how you think it will. If you can make the compiler happy, your code will most likely execute as expected.

For the C#/VB Programmer Looking Into F#

This section assumes you're familiar with the async model in C#/VB. If you are not, [Async Programming in C#](#) is a starting point.

There is a fundamental difference between the C#/VB async model and the F# async model.

When you call a function which returns a `Task` or `Task<'T>`, that job has already begun execution. The handle returned represents an already-running asynchronous job. In contrast, when you call an `async` function in F#, the `Async<'a>` returned represents a job which will be **generated** at some point. Understanding this model is powerful, because it allows for asynchronous jobs in F# to be chained together easier, performed conditionally, and be started with a finer grain of control.

There are a few other similarities and differences worth noting.

Similarities

- `let!`, `use!`, and `do!` are analogous to `await` when calling an async job from within an `async{ }` block.

The three keywords can only be used within an `async { }` block, similar to how `await` can only be invoked inside an `async` method. In short, `let!` is for when you want to capture and use a result, `use!` is the same but for something whose resources should get cleaned after it's used, and `do!` is for when you want to wait for an async workflow with no return value to finish before moving on.

- F# supports data-parallelism in a similar way.

Although it operates very differently, `Async.Parallel` corresponds to `Task.WhenAll` for the scenario of wanting the results of a set of async jobs when they all complete.

Differences

- Nested `let!` is not allowed, unlike nested `await`

Unlike `await`, which can be nested indefinitely, `let!` cannot and must have its result bound before using it inside of another `let!`, `do!`, or `use!`.

- Cancellation support is simpler in F# than in C#/VB.

Supporting cancellation of a task midway through its execution in C#/VB requires checking the `IsCancellationRequested` property or calling `ThrowIfCancellationRequested()` on a `CancellationToken` object that's passed into the `async` method.

In contrast, F# async workflows are more naturally cancellable. Cancellation is a simple three-step process.

1. Create a new `CancellationTokenSource`.
2. Pass it into a starting function.
3. Call `Cancel` on the token.

Example:

```
open System.Threading

// Create a workflow which will loop forever.
let workflow =
    async {
        while true do
            printfn "Working..."
            do! Async.Sleep 1000
    }

let tokenSource = new CancellationTokenSource()

// Start the workflow in the background
Async.Start (workflow, tokenSource.Token)

// Executing the next line will stop the workflow
tokenSource.Cancel()
```

And that's it!

Type Providers

12/19/2018 • 2 minutes to read • [Edit Online](#)

An F# type provider is a component that provides types, properties, and methods for use in your program. Type Providers generate what are known as **Provided Types**, which are generated by the F# compiler and are based on an external data source.

For example, an F# Type Provider for SQL can generate types representing tables and columns in a relational database. In fact, this is what the [SQLProvider](#) Type Provider does.

Provided Types depend on input parameters to a Type Provider. Such input can be a sample data source (such as a JSON schema file), a URL pointing directly to an external service, or a connection string to a data source. A Type Provider can also ensure that groups of types are only expanded on demand; that is, they are expanded if the types are actually referenced by your program. This allows for the direct, on-demand integration of large-scale information spaces such as online data markets in a strongly typed way.

Generative and Erased Type Providers

Type Providers come in two forms: Generative and Erased.

Generative Type Providers produce types that can be written as .NET types into the assembly in which they are produced. This allows them to be consumed from code in other assemblies. This means that the typed representation of the data source must generally be one that is feasible to represent with .NET types.

Erasing Type Providers produce types that can only be consumed in the assembly or project they are generated from. The types are ephemeral; that is, they are not written into an assembly and cannot be consumed by code in other assemblies. They can contain *delayed* members, allowing you to use provided types from a potentially infinite information space. They are useful for using a small subset of a large and interconnected data source.

Commonly used Type Providers

The following widely-used libraries contain Type Providers for different uses:

- [FSharp.Data](#) includes Type Providers for JSON, XML, CSV, and HTML document formats and resources.
- [SQLProvider](#) provides strongly-typed access to relation databases through object mapping and F# LINQ queries against these data sources.
- [FSharp.Data.SqlClient](#) has a set of type providers for compile-time checked embedding of T-SQL in F#.
- [Azure Storage Type provider](#) provides types for Azure Blobs, Tables, and Queues, allowing you to access these resources without needing to specify resource names as strings throughout your program.
- [FSharp.Data.GraphQL](#) contains the **GraphQLProvider**, which provides types based on a GraphQL server specified by URL.

Where necessary, you can [create your own custom type providers](#), or reference type providers that have been created by others. For example, assume your organization has a data service providing a large and growing number of named data sets, each with its own stable data schema. You may choose to create a type provider that reads the schemas and presents the latest available data sets to the programmer in a strongly typed way.

Tutorial: Create a Type Provider

3/8/2019 • 36 minutes to read • [Edit Online](#)

The type provider mechanism in F# is a significant part of its support for information rich programming. This tutorial explains how to create your own type providers by walking you through the development of several simple type providers to illustrate the basic concepts. For more information about the type provider mechanism in F#, see [Type Providers](#).

The F# ecosystem contains a range of type providers for commonly used Internet and enterprise data services. For example:

- [FSharp.Data](#) includes type providers for JSON, XML, CSV and HTML document formats.
- [SQLProvider](#) provides strongly-typed access to SQL databases through object mapping and F# LINQ queries against these data sources.
- [FSharp.Data.SqlClient](#) has a set of type providers for compile-time checked embedding of T-SQL in F#.
- [FSharp.Data.TypeProviders](#) is an older set of type providers for use only with .NET Framework programming for accessing SQL, Entity Framework, OData and WSDL data services.

Where necessary, you can create custom type providers, or you can reference type providers that others have created. For example, your organization could have a data service that provides a large and growing number of named data sets, each with its own stable data schema. You can create a type provider that reads the schemas and presents the current data sets to the programmer in a strongly typed way.

Before You Start

The type provider mechanism is primarily designed for injecting stable data and service information spaces into the F# programming experience.

This mechanism isn't designed for injecting information spaces whose schema changes during program execution in ways that are relevant to program logic. Also, the mechanism isn't designed for intra-language meta-programming, even though that domain contains some valid uses. You should use this mechanism only where necessary and where the development of a type provider yields very high value.

You should avoid writing a type provider where a schema isn't available. Likewise, you should avoid writing a type provider where an ordinary (or even an existing) .NET library would suffice.

Before you start, you might ask the following questions:

- Do you have a schema for your information source? If so, what's the mapping into the F# and .NET type system?
- Can you use an existing (dynamically typed) API as a starting point for your implementation?
- Will you and your organization have enough uses of the type provider to make writing it worthwhile? Would a normal .NET library meet your needs?
- How much will your schema change?
- Will it change during coding?
- Will it change between coding sessions?
- Will it change during program execution?

Type providers are best suited to situations where the schema is stable at runtime and during the lifetime of compiled code.

A Simple Type Provider

This sample is `Samples.HelloWorldTypeProvider`, similar to the samples in the `examples` directory of the [F# Type Provider SDK](#). The provider makes available a "type space" that contains 100 erased types, as the following code shows by using F# signature syntax and omitting the details for all except `Type1`. For more information about erased types, see [Details About Erased Provided Types](#) later in this topic.

```
namespace Samples.HelloWorldTypeProvider

type Type1 =
    /// This is a static property.
    static member StaticProperty : string

    /// This constructor takes no arguments.
    new : unit -> Type1

    /// This constructor takes one argument.
    new : data:string -> Type1

    /// This is an instance property.
    member InstanceProperty : int

    /// This is an instance method.
    member InstanceMethod : x:int -> char

    nested type NestedType =
        /// This is StaticProperty1 on NestedType.
        static member StaticProperty1 : string
        ...
        /// This is StaticProperty100 on NestedType.
        static member StaticProperty100 : string

type Type2 =
    ...

type Type100 =
    ...
```

Note that the set of types and members provided is statically known. This example doesn't leverage the ability of providers to provide types that depend on a schema. The implementation of the type provider is outlined in the following code, and the details are covered in later sections of this topic.

WARNING

There may be differences between this code and the online samples.

```

namespace Samples.FSharp.HelloWorldTypeProvider

open System
open System.Reflection
open ProviderImplementation.ProducedTypes
open FSharp.Core.CompilerServices
open FSharp.Quotations

// This type defines the type provider. When compiled to a DLL, it can be added
// as a reference to an F# command-line compilation, script, or project.
[<TypeProvider>]
type SampleTypeProvider(config: TypeProviderConfig) as this =

    // Inheriting from this type provides implementations of ITypeProvider
    // in terms of the provided types below.
    inherit TypeProviderForNamespaces(config)

    let namespaceName = "Samples.HelloWorldTypeProvider"
    let thisAssembly = Assembly.GetExecutingAssembly()

    // Make one provided type, called TypeN.
    let makeOneProvidedType (n:int) =
        ...

        // Now generate 100 types
        let types = [ for i in 1 .. 100 -> makeOneProvidedType i ]

        // And add them to the namespace
        do this.AddNamespace(namespaceName, types)

    [<assembly:TypeProviderAssembly>]
    do()

```

To use this provider, open a separate instance of Visual Studio, create an F# script, and then add a reference to the provider from your script by using #r as the following code shows:

```

#r @"..\bin\Debug\Samples.HelloWorldTypeProvider.dll"

let obj1 = Samples.HelloWorldTypeProvider.Type1("some data")

let obj2 = Samples.HelloWorldTypeProvider.Type1("some other data")

obj1.InstanceProperty
obj2.InstanceProperty

[ for index in 0 .. obj1.InstanceProperty-1 -> obj1.InstanceMethod(index) ]
[ for index in 0 .. obj2.InstanceProperty-1 -> obj2.InstanceMethod(index) ]

let data1 = Samples.HelloWorldTypeProvider.Type1.NestedType.StaticProperty35

```

Then look for the types under the `Samples.HelloWorldTypeProvider` namespace that the type provider generated.

Before you recompile the provider, make sure that you have closed all instances of Visual Studio and F# Interactive that are using the provider DLL. Otherwise, a build error will occur because the output DLL will be locked.

To debug this provider by using print statements, make a script that exposes a problem with the provider, and then use the following code:

```
fsc.exe -r:bin\Debug\HelloWorldTypeProvider.dll script.fsx
```

To debug this provider by using Visual Studio, open the Developer Command Prompt for Visual Studio with administrative credentials, and run the following command:

```
devenv.exe /debugexe fsc.exe -r:bin\Debug\HelloWorldTypeProvider.dll script.fsx
```

As an alternative, open Visual Studio, open the Debug menu, choose `Debug/Attach to process...`, and attach to another `devenv` process where you're editing your script. By using this method, you can more easily target particular logic in the type provider by interactively typing expressions into the second instance (with full IntelliSense and other features).

You can disable Just My Code debugging to better identify errors in generated code. For information about how to enable or disable this feature, see [Navigating through Code with the Debugger](#). Also, you can also set first-chance exception catching by opening the `Debug` menu and then choosing `Exceptions` or by choosing the `Ctrl+Alt+E` keys to open the `Exceptions` dialog box. In that dialog box, under `Common Language Runtime Exceptions`, select the `Thrown` check box.

Implementation of the Type Provider

This section walks you through the principal sections of the type provider implementation. First, you define the type for the custom type provider itself:

```
[<TypeProvider>]  
type SampleTypeProvider(config: TypeProviderConfig) as this =
```

This type must be public, and you must mark it with the `TypeProvider` attribute so that the compiler will recognize the type provider when a separate F# project references the assembly that contains the type. The `config` parameter is optional, and, if present, contains contextual configuration information for the type provider instance that the F# compiler creates.

Next, you implement the `ITypeProvider` interface. In this case, you use the `TypeProviderForNamespaces` type from the `ProvidedTypes` API as a base type. This helper type can provide a finite collection of eagerly provided namespaces, each of which directly contains a finite number of fixed, eagerly provided types. In this context, the provider *eagerly* generates types even if they aren't needed or used.

```
inherit TypeProviderForNamespaces(config)
```

Next, define local private values that specify the namespace for the provided types, and find the type provider assembly itself. This assembly is used later as the logical parent type of the erased types that are provided.

```
let namespaceName = "Samples.HelloWorldTypeProvider"  
let thisAssembly = Assembly.GetExecutingAssembly()
```

Next, create a function to provide each of the types Type1...Type100. This function is explained in more detail later in this topic.

```
let makeOneProvidedType (n:int) = ...
```

Next, generate the 100 provided types:

```
let types = [ for i in 1 .. 100 -> makeOneProvidedType i ]
```

Next, add the types as a provided namespace:

```
do this.AddNamespace(namespaceName, types)
```

Finally, add an assembly attribute that indicates that you are creating a type provider DLL:

```
[<assembly:TypeProviderAssembly>]  
do()
```

Providing One Type And Its Members

The `makeOneProvidedType` function does the real work of providing one of the types.

```
let makeOneProvidedType (n:int) =  
...
```

This step explains the implementation of this function. First, create the provided type (for example, `Type1`, when `n` = 1, or `Type57`, when `n` = 57).

```
// This is the provided type. It is an erased provided type and, in compiled code,  
// will appear as type 'obj'.  
let t = ProvidedTypeDefinition(thisAssembly, namespaceName,  
                               "Type" + string n,  
                               baseType = Some typeof<obj>)
```

You should note the following points:

- This provided type is erased. Because you indicate that the base type is `obj`, instances will appear as values of type `obj` in compiled code.
- When you specify a non-nested type, you must specify the assembly and namespace. For erased types, the assembly should be the type provider assembly itself.

Next, add XML documentation to the type. This documentation is delayed, that is, computed on-demand if the host compiler needs it.

```
t.AddXmlDocDelayed (fun () -> sprintf "This provided type %s" ("Type" + string n))
```

Next you add a provided static property to the type:

```
let staticProp = ProvidedProperty(propertyName = "StaticProperty",  
                                 propertyType = typeof<string>,  
                                 isStatic = true,  
                                 getterCode = (fun args -> <@@ "Hello!" @@>))
```

Getting this property will always evaluate to the string "Hello!". The `GetterCode` for the property uses an F# quotation, which represents the code that the host compiler generates for getting the property. For more information about quotations, see [Code Quotations \(F#\)](#).

Add XML documentation to the property.

```
staticProp.AddXmlDocDelayed(fun () -> "This is a static property")
```

Now attach the provided property to the provided type. You must attach a provided member to one and only one type. Otherwise, the member will never be accessible.

```
t.AddMember staticProp
```

Now create a provided constructor that takes no parameters.

```
let ctor = ProvidedConstructor(parameters = [ ],
                               invokeCode = (fun args -> <@@ "The object data" :> obj @@>))
```

The `InvokeCode` for the constructor returns an F# quotation, which represents the code that the host compiler generates when the constructor is called. For example, you can use the following constructor:

```
new Type10()
```

An instance of the provided type will be created with underlying data "The object data". The quoted code includes a conversion to `obj` because that type is the erasure of this provided type (as you specified when you declared the provided type).

Add XML documentation to the constructor, and add the provided constructor to the provided type:

```
ctor.AddXmlDocDelayed(fun () -> "This is a constructor")
t.AddMember ctor
```

Create a second provided constructor that takes one parameter:

```
let ctor2 =
ProvidedConstructor(parameters = [ ProvidedParameter("data",typeof<string>) ],
                     invokeCode = (fun args -> <@@ (%(args.[0]) : string) :> obj @@>))
```

The `InvokeCode` for the constructor again returns an F# quotation, which represents the code that the host compiler generated for a call to the method. For example, you can use the following constructor:

```
new Type10("ten")
```

An instance of the provided type is created with underlying data "ten". You may have already noticed that the `InvokeCode` function returns a quotation. The input to this function is a list of expressions, one per constructor parameter. In this case, an expression that represents the single parameter value is available in `args.[0]`. The code for a call to the constructor coerces the return value to the erased type `obj`. After you add the second provided constructor to the type, you create a provided instance property:

```
let instanceProp =
    ProvidedProperty(propertyName = "InstanceProperty",
                      propertyType = typeof<int>,
                      getterCode= (fun args ->
                           <@@ (%(args.[0]) : obj) :?> string).Length @@>)
instanceProp.AddXmlDocDelayed(fun () -> "This is an instance property")
t.AddMember instanceProp
```

Getting this property will return the length of the string, which is the representation object. The `GetterCode` property returns an F# quotation that specifies the code that the host compiler generates to get the property. Like `InvokeCode`, the `GetterCode` function returns a quotation. The host compiler calls this function with a list of arguments. In this case, the arguments include just the single expression that represents the instance upon which

the getter is being called, which you can access by using `args.[0]`. The implementation of `GetterCode` then splices into the result quotation at the erased type `obj`, and a cast is used to satisfy the compiler's mechanism for checking types that the object is a string. The next part of `makeOneProvidedType` provides an instance method with one parameter.

```
let instanceMeth =
    ProvidedMethod(methodName = "InstanceMethod",
                  parameters = [ProvidedParameter("x",typeof<int>)],
                  returnType = typeof<char>,
                  invokeCode = (fun args -
                                <@@ ((%%(args.[0])) : obj) :?> string).Chars(%(args.[1]) : int) @@))

instanceMeth.AddXmlDocDelayed(fun () -> "This is an instance method")
// Add the instance method to the type.
t.AddMember instanceMeth
```

Finally, create a nested type that contains 100 nested properties. The creation of this nested type and its properties is delayed, that is, computed on-demand.

```
t.AddMembersDelayed(fun () ->
    let nestedType = ProvidedTypeDefinition("NestedType", Some typeof<obj>)

    nestedType.AddMembersDelayed (fun () ->
        let staticPropsInNestedType =
            [ for i in 1 .. 100 do
                let valueOfTheProperty = "I am string " + string i

                let p =
                    ProvidedProperty(propertyName = "StaticProperty" + string i,
                                    propertyType = typeof<string>,
                                    isStatic = true,
                                    getterCode= (fun args -> <@@ valueOfTheProperty @@)))

                p.AddXmlDocDelayed(fun () ->
                    sprintf "This is StaticProperty%d on NestedType" i)

                yield p ]
            staticPropsInNestedType)
        [nestedType])
```

Details about Erased Provided Types

The example in this section provides only *erased provided types*, which are particularly useful in the following situations:

- When you are writing a provider for an information space that contains only data and methods.
- When you are writing a provider where accurate runtime-type semantics aren't critical for practical use of the information space.
- When you are writing a provider for an information space that is so large and interconnected that it isn't technically feasible to generate real .NET types for the information space.

In this example, each provided type is erased to type `obj`, and all uses of the type will appear as type `obj` in compiled code. In fact, the underlying objects in these examples are strings, but the type will appear as `System.Object` in .NET compiled code. As with all uses of type erasure, you can use explicit boxing, unboxing, and casting to subvert erased types. In this case, a cast exception that isn't valid may result when the object is used. A provider runtime can define its own private representation type to help protect against false representations. You can't define erased types in F# itself. Only provided types may be erased. You must understand the ramifications,

both practical and semantic, of using either erased types for your type provider or a provider that provides erased types. An erased type has no real .NET type. Therefore, you cannot do accurate reflection over the type, and you might subvert erased types if you use runtime casts and other techniques that rely on exact runtime type semantics. Subversion of erased types frequently results in type cast exceptions at runtime.

Choosing Representations for Erased Provided Types

For some uses of erased provided types, no representation is required. For example, the erased provided type might contain only static properties and members and no constructors, and no methods or properties would return an instance of the type. If you can reach instances of an erased provided type, you must consider the following questions:

What is the erasure of a provided type?

- The erasure of a provided type is how the type appears in compiled .NET code.
- The erasure of a provided erased class type is always the first non-erased base type in the inheritance chain of the type.
- The erasure of a provided erased interface type is always `System.Object`.

What are the representations of a provided type?

- The set of possible objects for an erased provided type are called its representations. In the example in this document, the representations of all the erased provided types `Type1..Type100` are always string objects.

All representations of a provided type must be compatible with the erasure of the provided type. (Otherwise, either the F# compiler will give an error for a use of the type provider, or unverifiable .NET code that isn't valid will be generated. A type provider isn't valid if it returns code that gives a representation that isn't valid.)

You can choose a representation for provided objects by using either of the following approaches, both of which are very common:

- If you're simply providing a strongly typed wrapper over an existing .NET type, it often makes sense for your type to erase to that type, use instances of that type as representations, or both. This approach is appropriate when most of the existing methods on that type still make sense when using the strongly typed version.
- If you want to create an API that differs significantly from any existing .NET API, it makes sense to create runtime types that will be the type erasure and representations for the provided types.

The example in this document uses strings as representations of provided objects. Frequently, it may be appropriate to use other objects for representations. For example, you may use a dictionary as a property bag:

```
ProvidedConstructor(parameters = [],
    invokeCode= (fun args -> <@ (new Dictionary<string,obj>()) :> obj @>))
```

As an alternative, you may define a type in your type provider that will be used at runtime to form the representation, along with one or more runtime operations:

```
type DataObject() =
    let data = Dictionary<string,obj>()
    member x.RuntimeOperation() = data.Count
```

Provided members can then construct instances of this object type:

```
ProvidedConstructor(parameters = [],
    invokeCode= (fun args -> <@@ (new DataObject()) :> obj @@>))
```

In this case, you may (optionally) use this type as the type erasure by specifying this type as the `baseType` when constructing the `ProvidedTypeDefinition`:

```
ProvidedTypeDefinition(..., baseType = Some typeof<DataObject> )
...
ProvidedConstructor(..., InvokeCode = (fun args -> <@@ new DataObject() @@>), ...)
```

Key Lessons

The previous section explained how to create a simple erasing type provider that provides a range of types, properties, and methods. This section also explained the concept of type erasure, including some of the advantages and disadvantages of providing erased types from a type provider, and discussed representations of erased types.

A Type Provider That Uses Static Parameters

The ability to parameterize type providers by static data enables many interesting scenarios, even in cases when the provider doesn't need to access any local or remote data. In this section, you'll learn some basic techniques for putting together such a provider.

Type Checked Regex Provider

Imagine that you want to implement a type provider for regular expressions that wraps the .NET [Regex](#) libraries in an interface that provides the following compile-time guarantees:

- Verifying whether a regular expression is valid.
- Providing named properties on matches that are based on any group names in the regular expression.

This section shows you how to use type providers to create a `RegexTyped` type that the regular expression pattern parameterizes to provide these benefits. The compiler will report an error if the supplied pattern isn't valid, and the type provider can extract the groups from the pattern so that you can access them by using named properties on matches. When you design a type provider, you should consider how its exposed API should look to end users and how this design will translate to .NET code. The following example shows how to use such an API to get the components of the area code:

```
type T = RegexTyped< @"(?<AreaCode>^\d{3})-(?<PhoneNumber>\d{3}-\d{4}$)">
let reg = T()
let result = T.IsMatch("425-555-2345")
let r = reg.Match("425-555-2345").Group_AreaCode.Value //r equals "425"
```

The following example shows how the type provider translates these calls:

```
let reg = new Regex(@"(?<AreaCode>^\d{3})-(?<PhoneNumber>\d{3}-\d{4}$)")
let result = reg.IsMatch("425-123-2345")
let r = reg.Match("425-123-2345").Groups.[ "AreaCode" ].Value //r equals "425"
```

Note the following points:

- The standard `Regex` type represents the parameterized `RegexTyped` type.
- The `RegexTyped` constructor results in a call to the `Regex` constructor, passing in the static type argument for the pattern.

- The results of the `Match` method are represented by the standard `Match` type.
- Each named group results in a provided property, and accessing the property results in a use of an indexer on a match's `Groups` collection.

The following code is the core of the logic to implement such a provider, and this example omits the addition of all members to the provided type. For information about each added member, see the appropriate section later in this topic. For the full code, download the sample from the [F# 3.0 Sample Pack](#) on the CodePlex website.

```
namespace Samples.FSharp.RegexTypeProvider

open System.Reflection
open Microsoft.FSharp.Core.CompilerServices
open Samples.FSharp.ProducedTypes
open System.Text.RegularExpressions

[<TypeProvider>]
type public CheckedRegexProvider() as this =
    inherit TypeProviderForNamespaces()

    // Get the assembly and namespace used to house the provided types
    let thisAssembly = Assembly.GetExecutingAssembly()
    let rootNamespace = "Samples.FSharp.RegexTypeProvider"
    let baseTy = typeof<obj>
    let staticParams = [ProvidedStaticParameter("pattern", typeof<string>)]

    let regexTy = ProvidedTypeDefinition(thisAssembly, rootNamespace, "RegexTyped", Some baseTy)

    do regexTy.DefineStaticParameters(
        parameters=staticParams,
        instantiationFunction=(fun typeName parameterValues ->

            match parameterValues with
            | [| :? string as pattern|] ->

                // Create an instance of the regular expression.
                //
                // This will fail with System.ArgumentException if the regular expression is not valid.
                // The exception will escape the type provider and be reported in client code.
                let r = System.Text.RegularExpressions.Regex(pattern)

                // Declare the typed regex provided type.
                // The type erasure of this type is 'obj', even though the representation will always be a Regex
                // This, combined with hiding the object methods, makes the IntelliSense experience simpler.
                let ty =
                    ProvidedTypeDefinition(
                        thisAssembly,
                        rootNamespace,
                        typeName,
                        baseType = Some baseTy)

                ...

                ty
            | _ -> failwith "unexpected parameter values"))

    do this.AddNamespace(rootNamespace, [regexTy])

[<TypeProviderAssembly>]
do ()
```

Note the following points:

- The type provider takes two static parameters: the `pattern`, which is mandatory, and the `options`, which are optional (because a default value is provided).

- After the static arguments are supplied, you create an instance of the regular expression. This instance will throw an exception if the Regex is malformed, and this error will be reported to users.
- Within the `DefineStaticParameters` callback, you define the type that will be returned after the arguments are supplied.
- This code sets `HideObjectMethods` to true so that the IntelliSense experience will remain streamlined. This attribute causes the `Equals`, `GetHashCode`, `Finalize`, and `GetType` members to be suppressed from IntelliSense lists for a provided object.
- You use `obj` as the base type of the method, but you'll use a `Regex` object as the runtime representation of this type, as the next example shows.
- The call to the `Regex` constructor throws a [ArgumentException](#) when a regular expression isn't valid. The compiler catches this exception and reports an error message to the user at compile time or in the Visual Studio editor. This exception enables regular expressions to be validated without running an application.

The type defined above isn't useful yet because it doesn't contain any meaningful methods or properties. First, add a static `.IsMatch` method:

```
let isMatch =
    ProvidedMethod(
        methodName = "IsMatch",
        parameters = [ProvidedParameter("input", typeof<string>)],
        returnType = typeof<bool>,
        isStatic = true,
        invokeCode = fun args -> <@@ Regex.IsMatch(%args.[0], pattern) @@>

isMatch.AddXmlDoc "Indicates whether the regular expression finds a match in the specified input string."
ty.AddMember isMatch
```

The previous code defines a method `.IsMatch`, which takes a string as input and returns a `bool`. The only tricky part is the use of the `args` argument within the `InvokeCode` definition. In this example, `args` is a list of quotations that represents the arguments to this method. If the method is an instance method, the first argument represents the `this` argument. However, for a static method, the arguments are all just the explicit arguments to the method. Note that the type of the quoted value should match the specified return type (in this case, `bool`). Also note that this code uses the `AddXmlDoc` method to make sure that the provided method also has useful documentation, which you can supply through IntelliSense.

Next, add an instance Match method. However, this method should return a value of a provided `Match` type so that the groups can be accessed in a strongly typed fashion. Thus, you first declare the `Match` type. Because this type depends on the pattern that was supplied as a static argument, this type must be nested within the parameterized type definition:

```
let matchTy =
    ProvidedTypeDefinition(
        "MatchType",
        baseType = Some baseTy,
        hideObjectMethods = true)

ty.AddMember matchTy
```

You then add one property to the Match type for each group. At runtime, a match is represented as a `Match` value, so the quotation that defines the property must use the `Groups` indexed property to get the relevant group.

```

for group in r.GetGroupNames() do
    // Ignore the group named 0, which represents all input.
    if group <> "0" then
        let prop =
            ProvidedProperty(
                propertyName = group,
                propertyType = typeof<Group>,
                getterCode = fun args -> <@@ ((%args.[0]:obj) :?> Match).Groups.[group] @@>
                prop.AddXmlDoc(sprintf @"Gets the """%s"" group from this match" group)
            )
        matchTy.AddMember prop

```

Again, note that you're adding XML documentation to the provided property. Also note that a property can be read if a `GetterCode` function is provided, and the property can be written if a `SetterCode` function is provided, so the resulting property is read only.

Now you can create an instance method that returns a value of this `Match` type:

```

let matchMethod =
    ProvidedMethod(
        methodName = "Match",
        parameters = [ProvidedParameter("input", typeof<string>)],
        returnType = matchTy,
        invokeCode = fun args -> <@@ ((%args.[0]:obj) :?> Regex.Match(%args.[1])) :> obj @@>

matchMeth.AddXmlDoc "Searches the specified input string for the first occurrence of this regular expression"

ty.AddMember matchMeth

```

Because you are creating an instance method, `args.[0]` represents the `RegexTyped` instance on which the method is being called, and `args.[1]` is the input argument.

Finally, provide a constructor so that instances of the provided type can be created.

```

let ctor =
    ProvidedConstructor(
        parameters = [],
        invokeCode = fun args -> <@@ Regex(pattern, options) :> obj @@>

ctor.AddXmlDoc("Initializes a regular expression instance.")

ty.AddMember ctor

```

The constructor merely erases to the creation of a standard .NET `Regex` instance, which is again boxed to an object because `obj` is the erasure of the provided type. With that change, the sample API usage that specified earlier in the topic works as expected. The following code is complete and final:

```

namespace Samples.FSharp.RegexTypeProvider

open System.Reflection
open Microsoft.FSharp.Core.CompilerServices
open Samples.FSharp.ProvidedTypes
open System.Text.RegularExpressions

[<TypeProvider>]
type public CheckedRegexProvider() as this =
    inherit TypeProviderForNamespaces()

    // Get the assembly and namespace used to house the provided types.
    let thisAssembly = Assembly.GetExecutingAssembly()
    let rootNamespace = "Samples.FSharp.RegexTypeProvider"
    let baseTy = typeOf<object>

```

```

let baseTy = typeof<obj>
let staticParams = [ProvidedStaticParameter("pattern", typeof<string>)]

let regexTy = ProvidedTypeDefinition(thisAssembly, rootNamespace, "RegexTyped", Some baseTy)

do regexTy.DefineStaticParameters(
    parameters=staticParams,
    instantiationFunction=(fun typeName parameterValues ->

        match parameterValues with
        | [] :? string as pattern|[] ->

            // Create an instance of the regular expression.

            let r = System.Text.RegularExpressions.Regex(pattern)

            // Declare the typed regex provided type.

            let ty =
                ProvidedTypeDefinition(
                    thisAssembly,
                    rootNamespace,
                    typeName,
                    baseType = Some baseTy)

            ty.AddXmlDoc "A strongly typed interface to the regular expression '%s'"

            // Provide strongly typed version of Regex.IsMatch static method.
            let isMatch =
                ProvidedMethod(
                    methodName = "IsMatch",
                    parameters = [ProvidedParameter("input", typeof<string>)],
                    returnType = typeof<bool>,
                    isStatic = true,
                    invokeCode = fun args -> <@@ Regex.IsMatch(%args.[0], pattern) @@>)

            isMatch.AddXmlDoc "Indicates whether the regular expression finds a match in the specified
input string"

            ty.AddMember isMatch

            // Provided type for matches
            // Again, erase to obj even though the representation will always be a Match
            let matchTy =
                ProvidedTypeDefinition(
                    "MatchType",
                    baseType = Some baseTy,
                    hideObjectMethods = true)

            // Nest the match type within parameterized Regex type.
            ty.AddMember matchTy

            // Add group properties to match type
            for group in r.GetGroupNames() do
                // Ignore the group named 0, which represents all input.
                if group <> "0" then
                    let prop =
                        ProvidedProperty(
                            propertyName = group,
                            propertyType = typeof<Group>,
                            getterCode = fun args -> <@@ ((%args.[0]:obj) :?> Match).Groups.[group] @@>
                            prop.AddXmlDoc(sprintf @"Gets the """%s"" group from this match" group)
                    matchTy.AddMember(prop)

            // Provide strongly typed version of Regex.Match instance method.
            let matchMeth =
                ProvidedMethod(
                    methodName = "Match",
                    parameters = [ProvidedParameter("input", typeof<string>)],

```

```

        returnType = matchTy,
        invokeCode = fun args -> <@@ ((%args.[0]:obj) :?> Regex).Match(%args.[1]) :> obj @@@)
    matchMeth.AddXmlDoc "Searches the specified input string for the first occurrence of this
regular expression"

    ty.AddMember matchMeth

    // Declare a constructor.
    let ctor =
        ProvidedConstructor(
            parameters = [],
            invokeCode = fun args -> <@@ Regex(pattern) :> obj @@@>)

    // Add documentation to the constructor.
    ctor.AddXmlDoc "Initializes a regular expression instance"

    ty.AddMember ctor

    ty
| _ -> failwith "unexpected parameter values"))

do this.AddNamespace(rootNamespace, [regexTy])

[<TypeProviderAssembly>]
do ()

```

Key Lessons

This section explained how to create a type provider that operates on its static parameters. The provider checks the static parameter and provides operations based on its value.

A Type Provider That Is Backed By Local Data

Frequently you might want type providers to present APIs based on not only static parameters but also information from local or remote systems. This section discusses type providers that are based on local data, such as local data files.

Simple CSV File Provider

As a simple example, consider a type provider for accessing scientific data in Comma Separated Value (CSV) format. This section assumes that the CSV files contain a header row followed by floating point data, as the following table illustrates:

DISTANCE (METER)	TIME (SECOND)
50.0	3.7
100.0	5.2
150.0	6.4

This section shows how to provide a type that you can use to get rows with a `Distance` property of type `float<meter>` and a `Time` property of type `float<second>`. For simplicity, the following assumptions are made:

- Header names are either unit-less or have the form "Name (unit)" and don't contain commas.
- Units are all System International (SI) units as the [Microsoft.FSharp.Data.UnitSystems.SI.UnitNames Module \(F#\)](#) module defines.
- Units are all simple (for example, meter) rather than compound (for example, meter/second).
- All columns contain floating point data.

A more complete provider would loosen these restrictions.

Again the first step is to consider how the API should look. Given an `info.csv` file with the contents from the previous table (in comma-separated format), users of the provider should be able to write code that resembles the following example:

```
let info = new MiniCsv<"info.csv">()
for row in info.Data do
    let time = row.Time
    printfn "%f" (float time)
```

In this case, the compiler should convert these calls into something like the following example:

```
let info = new CsvFile("info.csv")
for row in info.Data do
    let (time:float) = row.[1]
    printfn "%f" (float time)
```

The optimal translation will require the type provider to define a real `CsvFile` type in the type provider's assembly. Type providers often rely on a few helper types and methods to wrap important logic. Because measures are erased at runtime, you can use a `float[]` as the erased type for a row. The compiler will treat different columns as having different measure types. For example, the first column in our example has type `float<meter>`, and the second has `float<second>`. However, the erased representation can remain quite simple.

The following code shows the core of the implementation.

```
// Simple type wrapping CSV data
type CsvFile(filename) =
    // Cache the sequence of all data lines (all lines but the first)
    let data =
        seq { for line in File.ReadAllLines(filename) |> Seq.skip 1 do
                yield line.Split(',') |> Array.map float }
        |> Seq.cache
    member __.Data = data

[<TypeProvider>]
type public MiniCsvProvider(cfg:TypeProviderConfig) as this =
    inherit TypeProviderForNamespaces(cfg)

    // Get the assembly and namespace used to house the provided types.
    let asm = System.Reflection.Assembly.GetExecutingAssembly()
    let ns = "Samples.FSharp.MiniCsvProvider"

    // Create the main provided type.
    let csvTy = ProvidedTypeDefinition(asm, ns, "MiniCsv", Some(typeof<obj>))

    // Parameterize the type by the file to use as a template.
    let filename = ProvidedStaticParameter("filename", typeof<string>)
    do csvTy.DefineStaticParameters([filename], fun tyName [| :? string as filename |] ->

        // Resolve the filename relative to the resolution folder.
        let resolvedFilename = Path.Combine(cfg.ResolutionFolder, filename)

        // Get the first line from the file.
        let headerLine = File.ReadLines(resolvedFilename) |> Seq.head

        // Define a provided type for each row, erasing to a float[].
        let rowTy = ProvidedTypeDefinition("Row", Some(typeof<float[]>))

        // Extract header names from the file, splitting on commas.
        // use Regex matching to get the position in the row at which the field occurs
        let headers = Regex.Matches(headerLine, "[^,]+")
```

```

// Add one property per CSV field.
for i in 0 .. headers.Count - 1 do
    let headerText = headers.[i].Value

    // Try to decompose this header into a name and unit.
    let fieldName, fieldTy =
        let m = Regex.Match(headerText, @"^(?<field>.+)\((?<unit>.+)\)$")
        if m.Success then

            let unitName = m.Groups["unit"].Value
            let units = ProvidedMeasureBuilder.Default.SI unitName
            m.Groups["field"].Value, ProvidedMeasureBuilder.Default.AnnotateType(typeof<float>,
[units])

        else
            // no units, just treat it as a normal float
            headerText, typeof<float>

    let prop =
        ProvidedProperty(fieldName, fieldTy,
            getterCode = fun [row] -> <@@ (%row:float[]).[i] @@@>)

    // Add metadata that defines the property's location in the referenced file.
    prop.AddDefinitionLocation(1, headers.[i].Index + 1, filename)
    rowTy.AddMember(prop)

    // Define the provided type, erasing to CsvFile.
    let ty = ProvidedTypeDefinition(asm, ns, tyName, Some(typeof<CsvFile>))

    // Add a parameterless constructor that loads the file that was used to define the schema.
    let ctor0 =
        ProvidedConstructor([], 
            invokeCode = fun [] -> <@@ CsvFile(resolvedFilename) @@@>)
    ty.AddMember ctor0

    // Add a constructor that takes the file name to load.
    let ctor1 = ProvidedConstructor([ProvidedParameter("filename", typeof<string>)],
        invokeCode = fun [filename] -> <@@ CsvFile(%filename) @@@>)
    ty.AddMember ctor1

    // Add a more strongly typed Data property, which uses the existing property at runtime.
    let prop =
        ProvidedProperty("Data", typeof<seq<_>>.MakeGenericType(rowTy),
            getterCode = fun [csvFile] -> <@@ (%csvFile:CsvFile).Data @@@>)
    ty.AddMember prop

    // Add the row type as a nested type.
    ty.AddMember rowTy
    ty)

// Add the type to the namespace.
do this.AddNamespace(ns, [csvTy])

```

Note the following points about the implementation:

- Overloaded constructors allow either the original file or one that has an identical schema to be read. This pattern is common when you write a type provider for local or remote data sources, and this pattern allows a local file to be used as the template for remote data.
- You can use the [TypeProviderConfig](#) value that's passed in to the type provider constructor to resolve relative file names.
- You can use the [AddDefinitionLocation](#) method to define the location of the provided properties. Therefore, if you use [Go To Definition](#) on a provided property, the CSV file will open in Visual Studio.

- You can use the `ProvidedMeasureBuilder` type to look up the SI units and to generate the relevant `float<_>` types.

Key Lessons

This section explained how to create a type provider for a local data source with a simple schema that's contained in the data source itself.

Going Further

The following sections include suggestions for further study.

A Look at the Compiled Code for Erased Types

To give you some idea of how the use of the type provider corresponds to the code that's emitted, look at the following function by using the `HelloWorldTypeProvider` that's used earlier in this topic.

```
let function1 () =
    let obj1 = Samples.HelloWorldTypeProvider.Type1("some data")
    obj1.InstanceProperty
```

Here's an image of the resulting code decompiled by using ildasm.exe:

```
.class public abstract auto ansi sealed Module1
extends [mscorlib]System.Object
{
.custom instance void [FSharp.Core]Microsoft.FSharp.Core.CompilationMappingAttribute::ctor(valuetype [FSharp.Core]Microsoft.FSharp.Core.SourceConstructFlags)
= ( 01 00 07 00 00 00 00 00 )
.method public static int32 function1() cil managed
{
// Code size     24 (0x18)
.maxstack 3
.locals init ([0] object obj1)
IL_0000: nop
IL_0001: ldstr      "some data"
IL_0006: unbox.any  [mscorlib]System.Object
IL_000b: stloc.0
IL_000c: ldloc.0
IL_000d: call       !!0 [FSharp.Core_2]Microsoft.FSharp.Core.LanguagePrimitives/IntrinsicFunctions::UnboxGeneric<string>(object)
IL_0012: callvirt   instance int32 [mscorlib_3]System.String::get_Length()
IL_0017: ret
} // end of method Module1::function1

} // end of class Module1
```

As the example shows, all mentions of the type `Type1` and the `InstanceProperty` property have been erased, leaving only operations on the runtime types involved.

Design and Naming Conventions for Type Providers

Observe the following conventions when authoring type providers.

Providers for Connectivity Protocols In general, names of most provider DLLs for data and service connectivity protocols, such as OData or SQL connections, should end in `TypeProvider` or `TypeProviders`. For example, use a DLL name that resembles the following string:

```
Fabrikam.Management.BasicTypeProviders.dll
```

Ensure that your provided types are members of the corresponding namespace, and indicate the connectivity

protocol that you implemented:

```
Fabrikam.Management.BasicTypeProviders.WmiConnection<...>
Fabrikam.Management.BasicTypeProviders.DataProtocolConnection<...>
```

Utility Providers for General Coding. For a utility type provider such as that for regular expressions, the type provider may be part of a base library, as the following example shows:

```
#r "Fabrikam.Core.Text.Utilities.dll"
```

In this case, the provided type would appear at an appropriate point according to normal .NET design conventions:

```
open Fabrikam.Core.Text.RegexTyped

let regex = new RegexTyped<"a+b+a+b+">()
```

Singleton Data Sources. Some type providers connect to a single dedicated data source and provide only data. In this case, you should drop the `TypeProvider` suffix and use normal conventions for .NET naming:

```
#r "Fabrikam.Data.Freebase.dll"

let data = Fabrikam.Data.Freebase.Astronomy.Asteroids
```

For more information, see the `GetConnection` design convention that's described later in this topic.

Design Patterns for Type Providers

The following sections describe design patterns you can use when authoring type providers.

The `GetConnection` Design Pattern

Most type providers should be written to use the `GetConnection` pattern that's used by the type providers in `FSharp.Data.TypeProviders.dll`, as the following example shows:

```
#r "Fabrikam.Data.WebDataStore.dll"

type Service = Fabrikam.Data.WebDataStore<...static connection parameters...>

let connection = Service.GetConnection(...dynamic connection parameters...)

let data = connection.Astronomy.Asteroids
```

Type Providers Backed By Remote Data and Services

Before you create a type provider that's backed by remote data and services, you must consider a range of issues that are inherent in connected programming. These issues include the following considerations:

- schema mapping
- liveness and invalidation in the presence of schema change
- schema caching
- asynchronous implementations of data access operations
- supporting queries, including LINQ queries
- credentials and authentication

This topic doesn't explore these issues further.

Additional Authoring Techniques

When you write your own type providers, you might want to use the following additional techniques.

Creating Types and Members On-Demand

The ProvidedType API has delayed versions of AddMember.

```
type ProvidedType =
    member AddMemberDelayed : (unit -> MemberInfo)      -> unit
    member AddMembersDelayed : (unit -> MemberInfo list) -> unit
```

These versions are used to create on-demand spaces of types.

Providing Array types and Generic Type Instantiations

You make provided members (whose signatures include array types, byref types, and instantiations of generic types) by using the normal `MakeArrayType`, `MakePointerType`, and `MakeGenericType` on any instance of `Type`, including `ProvidedTypeDefinitions`.

NOTE

In some cases you may have to use the helper in `ProvidedTypeBuilder.MakeGenericType`. See the [Type Provider SDK documentation](#) for more details.

Providing Unit of Measure Annotations

The ProvidedTypes API provides helpers for providing measure annotations. For example, to provide the type `float<kg>`, use the following code:

```
let measures = ProvidedMeasureBuilder.Default
let kg = measures.SI "kilogram"
let m = measures.SI "meter"
let float_kg = measures.AnnotateType(typeof<float>,[kg])
```

To provide the type `Nullable<decimal<kg/m^2>>`, use the following code:

```
let kgpm2 = measures.Ratio(kg, measures.Square m)
let dkgpm2 = measures.AnnotateType(typeof<decimal>,[kgpm2])
let nullableDecimal_kgpm2 = typedefof<System.Nullable<_>>.MakeGenericType [|dkgpm2|]
```

Accessing Project-Local or Script-Local Resources

Each instance of a type provider can be given a `TypeProviderConfig` value during construction. This value contains the "resolution folder" for the provider (that is, the project folder for the compilation or the directory that contains a script), the list of referenced assemblies, and other information.

Invalidation

Providers can raise invalidation signals to notify the F# language service that the schema assumptions may have changed. When invalidation occurs, a typecheck is redone if the provider is being hosted in Visual Studio. This signal will be ignored when the provider is hosted in F# Interactive or by the F# Compiler (fsc.exe).

Caching Schema Information

Providers must often cache access to schema information. The cached data should be stored by using a file name that's given as a static parameter or as user data. An example of schema caching is the `LocalSchemaFile` parameter in the type providers in the `FSharp.Data.TypeProviders` assembly. In the implementation of these providers, this

static parameter directs the type provider to use the schema information in the specified local file instead of accessing the data source over the network. To use cached schema information, you must also set the static parameter `ForceUpdate` to `false`. You could use a similar technique to enable online and offline data access.

Backing Assembly

When you compile a `.dll` or `.exe` file, the backing `.dll` file for generated types is statically linked into the resulting assembly. This link is created by copying the Intermediate Language (IL) type definitions and any managed resources from the backing assembly into the final assembly. When you use F# Interactive, the backing `.dll` file isn't copied and is instead loaded directly into the F# Interactive process.

Exceptions and Diagnostics from Type Providers

All uses of all members from provided types may throw exceptions. In all cases, if a type provider throws an exception, the host compiler attributes the error to a specific type provider.

- Type provider exceptions should never result in internal compiler errors.
- Type providers can't report warnings.
- When a type provider is hosted in the F# compiler, an F# development environment, or F# Interactive, all exceptions from that provider are caught. The `Message` property is always the error text, and no stack trace appears. If you're going to throw an exception, you can throw the following examples:

```
System.NotSupportedException , System.IO.IOException , System.Exception .
```

Providing Generated Types

So far, this document has explained how to provide erased types. You can also use the type provider mechanism in F# to provide generated types, which are added as real .NET type definitions into the users' program. You must refer to generated provided types by using a type definition.

```
open Microsoft.FSharp.TypeProviders

type Service = ODataService<"http://services.odata.org/Northwind/Northwind.svc/">
```

The `ProvidedTypes`-0.2 helper code that is part of the F# 3.0 release has only limited support for providing generated types. The following statements must be true for a generated type definition:

- `isErased` must be set to `false`.
- The generated type must be added to a newly constructed `ProvidedAssembly()`, which represents a container for generated code fragments.
- The provider must have an assembly that has an actual backing .NET `.dll` file with a matching `.dll` file on disk.

Rules and Limitations

When you write type providers, keep the following rules and limitations in mind.

Provided types must be reachable

All provided types should be reachable from the non-nested types. The non-nested types are given in the call to the `TypeProviderForNamespaces` constructor or a call to `AddNamespace`. For example, if the provider provides a type `StaticClass.P : T`, you must ensure that `T` is either a non-nested type or nested under one.

For example, some providers have a static class such as `DataTypes` that contain these `T1, T2, T3, ...` types.

Otherwise, the error says that a reference to type `T` in assembly A was found, but the type couldn't be found in that assembly. If this error appears, verify that all your subtypes can be reached from the provider types. Note: These `T1, T2, T3...` types are referred to as the *on-the-fly* types. Remember to put them in an accessible namespace or

a parent type.

Limitations of the Type Provider Mechanism

The type provider mechanism in F# has the following limitations:

- The underlying infrastructure for type providers in F# doesn't support provided generic types or provided generic methods.
- The mechanism doesn't support nested types with static parameters.

Development Tips

You might find the following tips helpful during the development process:

Run two instances of Visual Studio

You can develop the type provider in one instance and test the provider in the other because the test IDE will take a lock on the .dll file that prevents the type provider from being rebuilt. Thus, you must close the second instance of Visual Studio while the provider is built in the first instance, and then you must reopen the second instance after the provider is built.

Debug type providers by using invocations of fsc.exe

You can invoke type providers by using the following tools:

- fsc.exe (The F# command line compiler)
- fsi.exe (The F# Interactive compiler)
- devenv.exe (Visual Studio)

You can often debug type providers most easily by using fsc.exe on a test script file (for example, script.fsx). You can launch a debugger from a command prompt.

```
devenv /debugexe fsc.exe script.fsx
```

You can use print-to-stdout logging.

Type Provider Security

12/19/2018 • 2 minutes to read • [Edit Online](#)

Type providers are assemblies (DLLs) referenced by your F# project or script that contain code to connect to external data sources and surface this type information to the F# type environment. Typically, code in referenced assemblies is only run when you compile and then execute the code (or in the case of a script, send the code to F# Interactive). However, a type provider assembly will run inside Visual Studio when the code is merely browsed in the editor. This happens because type providers need to run to add extra information to the editor, such as Quick Info tooltips, IntelliSense completions, and so on. As a result, there are extra security considerations for type provider assemblies, since they run automatically inside the Visual Studio process.

Security Warning Dialog

When using a particular type provider assembly for the first time, Visual Studio displays a security dialog that warns you that the type provider is about to run. Before Visual Studio loads the type provider, it gives you the opportunity to decide if you trust this particular provider. If you trust the source of the type provider, then select "I trust this type provider." If you do not trust the source of the type provider, then select "I do not trust this type provider." Trusting the provider enables it to run inside Visual Studio and provide IntelliSense and build features. But if the type provider itself is malicious, running its code could compromise your machine.

If your project contains code that references type providers that you chose in the dialog not to trust, then at compile time, the compiler will report an error that indicates that the type provider is untrusted. Any types that are dependent on the untrusted type provider are indicated by red squiggles. It is safe to browse the code in the editor.

If you decide to change the trust setting directly in Visual Studio, perform the following steps.

To change the trust settings for type providers

1. On the `Tools` menu, select `Options`, and expand the `F# Tools` node.
2. Select `Type Providers`, and in the list of type providers, select the check box for type providers you trust, and clear the check box for those you don't trust.

Troubleshooting Type Providers

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic describes and provides potential solutions for the problems that you are most likely to encounter when you use type providers.

Possible Problems with Type Providers

If you encounter a problem when you work with type providers, you can review the following table for the most common solutions.

PROBLEM	SUGGESTED ACTIONS
Schema Changes. Type providers work best when the data source schema is stable. If you add a data table or column or make another change to that schema, the type provider doesn't automatically recognize these changes.	Clean or rebuild the project. To clean the project, choose Build , Clean ProjectName on the menu bar. To rebuild the project, choose Build , Rebuild ProjectName on the menu bar. These actions reset all type provider state and force the provider to reconnect to the data source and obtain updated schema information.
Connection Failure. The URL or connection string is incorrect, the network is down, or the data source or service is unavailable.	For a web service or OData service, you can try the URL in Internet Explorer to verify whether the URL is correct and the service is available. For a database connection string, you can use the data connection tools in Server Explorer to verify whether the connection string is valid and the database is available. After you restore your connection, you should then clean or rebuild the project so that the type provider will reconnect to the network.
Not Valid Credentials. You must have valid permissions for the data source or web service.	For a SQL connection, the username and the password that are specified in the connection string or configuration file must be valid for the database. If you are using Windows Authentication, you must have access to the database. The database administrator can identify what permissions you need for access to each database and each element within a database. For a web service or a data service, you must have appropriate credentials. Most type providers provide a <code>DataContext</code> object, which contains a <code>Credentials</code> property that you can set with the appropriate username and access key.
Not Valid Path. A path to a file was not valid.	Verify whether the path is correct and the file exists. In addition, you must either quote any backslashes in the path appropriately or use a verbatim string or triple-quoted string.

Interactive Programming with F#

2/28/2019 • 4 minutes to read • [Edit Online](#)

NOTE

This article currently describes the experience for Windows only. It will be rewritten.

NOTE

The API reference link will take you to MSDN. The docs.microsoft.com API reference is not complete.

F# Interactive (fsi.exe) is used to run F# code interactively at the console, or to execute F# scripts. In other words, F# interactive executes a REPL (Read, Evaluate, Print Loop) for the F# language.

To run F# Interactive from the console, run fsi.exe. You will find fsi.exe in:

```
C:\Program Files (x86)\Microsoft Visual Studio\2017\<sku>\Common7\IDE\CommonExtensions\Microsoft\FSharp
```

where `<sku>` is either `Community`, `Professional`, or `Enterprise`.

For information about command line options available, see [F# Interactive Options](#).

To run F# Interactive through Visual Studio, you can click the appropriate toolbar button labeled **F# Interactive**, or use the keys **Ctrl+Alt+F**. Doing this will open the interactive window, a tool window running an F# Interactive session. You can also select some code that you want to run in the interactive window and hit the key combination **ALT+ENTER**. F# Interactive starts in a tool window labeled **F# Interactive**. When you use this key combination, make sure that the editor window has the focus.

Whether you are using the console or Visual Studio, a command prompt appears and the interpreter awaits your input. You can enter code just as you would in a code file. To compile and execute the code, enter two semicolons (`;;`) to terminate a line or several lines of input.

F# Interactive attempts to compile the code and, if successful, it executes the code and prints the signature of the types and values that it compiled. If errors occur, the interpreter prints the error messages.

Code entered in the same session has access to any constructs entered previously, so you can build up programs. An extensive buffer in the tool window allows you to copy the code into a file if needed.

When run in Visual Studio, F# Interactive runs independently of your project, so, for example, you cannot use constructs defined in your project in F# Interactive unless you copy the code for the function into the interactive window.

If you have a project open that references some libraries, you can reference these in F# Interactive through **Solution Explorer**. To reference a library in F# Interactive, expand the **References** node, open the shortcut menu for the library, and choose **Send to F# Interactive**.

You can control the F# Interactive command line arguments (options) by adjusting the settings. On the **Tools** menu, select **Options...**, and then expand **F# Tools**. The two settings that you can change are the F# Interactive options and the **64-bit F# Interactive** setting, which is relevant only if you are running F# Interactive on a 64-bit machine. This setting determines whether you want to run the dedicated 64-bit version of fsi.exe or fsianycpu.exe, which uses the machine architecture to determine whether to run as a 32-bit or 64-bit process.

Scripting with F#

Scripts use the file extension **.fsx** or **.fsscript**. Instead of compiling source code and then later running the compiled assembly, you can just run **fsi.exe** and specify the filename of the script of F# source code, and F# interactive reads the code and executes it in real time.

Differences Between the Interactive, Scripting and Compiled Environments

When you are compiling code in F# Interactive, whether you are running interactively or running a script, the symbol **INTERACTIVE** is defined. When you are compiling code in the compiler, the symbol **COMPILED** is defined. Thus, if code needs to be different in compiled and interactive modes, you can use preprocessor directives for conditional compilation to determine which to use.

Some directives are available when you are executing scripts in F# Interactive that are not available when you are executing the compiler. The following table summarizes directives that are available when you are using F# Interactive.

DIRECTIVE	DESCRIPTION
#help	Displays information about available directives.
#I	Specifies an assembly search path in quotation marks.
#load	Reads a source file, compiles it, and runs it.
#quit	Terminates an F# Interactive session.
#r	References an assembly.
#time ["on" "off"]	By itself, #time toggles whether to display performance information. When it is enabled, F# Interactive measures real time, CPU time, and garbage collection information for each section of code that is interpreted and executed.

When you specify files or paths in F# Interactive, a string literal is expected. Therefore, files and paths must be in quotation marks, and the usual escape characters apply. Also, you can use the @ character to cause F# Interactive to interpret a string that contains a path as a verbatim string. This causes F# Interactive to ignore any escape characters.

One of the differences between compiled and interactive mode is the way you access command line arguments. In compiled mode, use **System.Environment.GetCommandLineArgs**. In scripts, use **fsi.CommandLineArgs**.

The following code illustrates how to create a function that reads the command line arguments in a script and also demonstrates how to reference another assembly from a script. The first code file, **MyAssembly.fs**, is the code for the assembly being referenced. Compile this file with the command line: **fsc -a MyAssembly.fs** and then execute the second file as a script with the command line: **fsi --exec file1.fsx test**

```
// MyAssembly.fs
module MyAssembly
let myFunction x y = x + 2 * y
```

```
// file1.fsx
#r "MyAssembly.dll"

printfn "Command line arguments: "

for arg in fsi.CommandLineArgs do
    printfn "%s" arg

printfn "%A" (MyAssembly.myFunction 10 40)
```

The output is as follows:

```
Command line arguments:
file1.fsx
test
90
```

TITLE	DESCRIPTION
F# Interactive Options	Describes command-line syntax and options for the F# Interactive, fsi.exe.
F# Interactive Library Reference	Describes library functionality available when executing code in F# interactive.

F# Language Reference

3/14/2019 • 8 minutes to read • [Edit Online](#)

This section is a reference to the F# language, a multi-paradigm programming language targeting .NET. The F# language supports functional, object-oriented and imperative programming models.

F# Tokens

The following table shows reference topics that provide tables of keywords, symbols and literals used as tokens in F#.

TITLE	DESCRIPTION
Keyword Reference	Contains links to information about all F# language keywords.
Symbol and Operator Reference	Contains a table of symbols and operators that are used in the F# language.
Literals	Describes the syntax for literal values in F# and how to specify type information for F# literals.

F# Language Concepts

The following table shows reference topics available that describe language concepts.

TITLE	DESCRIPTION
Functions	Functions are the fundamental unit of program execution in any programming language. As in other languages, an F# function has a name, can have parameters and take arguments, and has a body. F# also supports functional programming constructs such as treating functions as values, using unnamed functions in expressions, composition of functions to form new functions, curried functions, and the implicit definition of functions by way of the partial application of function arguments.
F# Types	Describes the types that are used in F# and how F# types are named and described.
Type Inference	Describes how the F# compiler infers the types of values, variables, parameters and return values.
Automatic Generalization	Describes generic constructs in F#.
Inheritance	Describes inheritance, which is used to model the "is-a" relationship, or subtyping, in object-oriented programming.
Members	Describes members of F# object types.

TITLE	DESCRIPTION
Parameters and Arguments	Describes language support for defining parameters and passing arguments to functions, methods, and properties. It includes information about how to pass by reference.
Operator Overloading	Describes how to overload arithmetic operators in a class or record type, and at the global level.
Casting and Conversions	Describes support for type conversions in F#.
Access Control	Describes access control in F#. Access control means declaring what clients are able to use certain program elements, such as types, methods, functions and so on.
Pattern Matching	Describes patterns, which are rules for transforming input data that are used throughout the F# language to extract compare data with a pattern, decompose data into constituent parts, or extract information from data in various ways.
Active Patterns	Describes active patterns. Active patterns enable you to define named partitions that subdivide input data. You can use active patterns to decompose data in a customized manner for each partition.
Assertions	Describes the <code>assert</code> expression, which is a debugging feature that you can use to test an expression. Upon failure in Debug mode, an assertion generates a system error dialog box.
Exception Handling	Contains information about exception handling support in the F# language.
attributes	Describes attributes, which enable metadata to be applied to a programming construct.
Resource Management: The <code>use</code> Keyword	Describes the keywords <code>use</code> and <code>using</code> , which can control the initialization and release of resources
namespaces	Describes namespace support in F#. A namespace lets you organize code into areas of related functionality by enabling you to attach a name to a grouping of program elements.
Modules	Describes modules. An F# module is a grouping of F# code, such as values, types, and function values, in an F# program. Grouping code in modules helps keep related code together and helps avoid name conflicts in your program.
Import Declarations: The <code>open</code> Keyword	Describes how <code>open</code> works. An import declaration specifies a module or namespace whose elements you can reference without using a fully qualified name.

TITLE	DESCRIPTION
Signatures	Describes signatures and signature files. A signature file contains information about the public signatures of a set of F# program elements, such as types, namespaces, and modules. It can be used to specify the accessibility of these program elements.
XML Documentation	Describes support for generating documentation files for XML doc comments, also known as triple slash comments. You can produce documentation from code comments in F# just as in other .NET languages.
Verbose Syntax	Describes the syntax for F# constructs when lightweight syntax is not enabled. Verbose syntax is indicated by the <code>#light "off"</code> directive at the top of the code file.

F# Types

The following table shows reference topics available that describe types supported by the F# language.

TITLE	DESCRIPTION
values	Describes values, which are immutable quantities that have a specific type; values can be integral or floating point numbers, characters or text, lists, sequences, arrays, tuples, discriminated unions, records, class types, or function values.
Basic Types	Describes the fundamental basic types that are used in the F# language. It also provides the corresponding .NET types and the minimum and maximum values for each type.
Unit Type	Describes the <code>unit</code> type, which is a type that indicates the absence of a specific value; the <code>unit</code> type has only a single value, which acts as a placeholder when no other value exists or is needed.
Strings	Describes strings in F#. The <code>string</code> type represents immutable text, as a sequence of Unicode characters. <code>string</code> is an alias for <code>System.String</code> in the .NET Framework.
Tuples	Describes tuples, which are groupings of unnamed but ordered values of possibly different types.
F# Collection Types	An overview of the F# functional collection types, including types for arrays, lists, sequences (seq), maps, and sets.
Lists	Describes lists. A list in F# is an ordered, immutable series of elements all of the same type.

TITLE	DESCRIPTION
Options	Describes the option type. An option in F# is used when a value may or may not exist. An option has an underlying type and may either hold a value of that type or it may not have a value.
Sequences	Describes sequences. A sequence is a logical series of elements all of one type. Individual sequence elements are only computed if required, so the representation may be smaller than a literal element count indicates.
Arrays	Describes arrays. Arrays are fixed-size, zero-based, mutable sequences of consecutive data elements, all of the same type.
Records	Describes records. Records represent simple aggregates of named values, optionally with members.
Discriminated Unions	Describes discriminated unions, which provides support for values which may be one of a variety of named cases, each with possibly different values and types.
Enumerations	Describes enumerations are types that have a defined set of named values. You can use them in place of literals to make code more readable and maintainable.
Reference Cells	Describes reference cells, which are storage locations that enable you to create mutable variables with reference semantics.
Type Abbreviations	Describes type abbreviations, which are alternate names for types.
Classes	Describes classes, which are types that represent objects that can have properties, methods, and events.
Structures	Describes structures, which are compact object types that can be more efficient than a class for types that have a small amount of data and simple behavior.
Interfaces	Describes interfaces, which specify sets of related members that other classes implement.
Abstract Classes	Describes abstract classes, which are classes that leave some or all members unimplemented, so that implementations can be provided by derived classes.
Type Extensions	Describes type extensions, which let you add new members to a previously defined object type.
Flexible Types	Describes flexible types. A flexible type annotation is an indication that a parameter, variable or value has a type that is compatible with type specified, where compatibility is determined by position in an object-oriented hierarchy of classes or interfaces.

TITLE	DESCRIPTION
Delegates	Describes delegates, which represent a function call as an object.
Units of Measure	Describes units of measure. Floating point values in F# can have associated units of measure, which are typically used to indicate length, volume, mass, and so on.
Type Providers	Describes type providers and provides links to walkthroughs on using the built-in type providers to access databases and web services.

F# Expressions

The following table lists topics that describe F# expressions.

TITLE	DESCRIPTION
Conditional Expressions: <code>if...then...else</code>	Describes the <code>if...then...else</code> expression, which runs different branches of code and also evaluates to a different value depending on the Boolean expression given.
Match Expressions	Describes the <code>match</code> expression, which provides branching control that is based on the comparison of an expression with a set of patterns.
Loops: <code>for...to</code> Expression	Describes the <code>for...to</code> expression, which is used to iterate in a loop over a range of values of a loop variable.
Loops: <code>for...in</code> Expression	Describes the <code>for...in</code> expression, a looping construct that is used to iterate over the matches of a pattern in an enumerable collection such as a range expression, sequence, list, array, or other construct that supports enumeration.
Loops: <code>while...do</code> Expression	Describes the <code>while...do</code> expression, which is used to perform iterative execution (looping) while a specified test condition is true.
Object Expressions	Describes object expressions, which are expressions that create new instances of a dynamically created, anonymous object type that is based on an existing base type, interface, or set of interfaces.
Lazy Expressions	Describes lazy expressions, which are computations that are not evaluated immediately, but are instead evaluated when the result is actually needed.

TITLE	DESCRIPTION
Computation Expressions	Describes computation expressions in F#, which provide a convenient syntax for writing computations that can be sequenced and combined using control flow constructs and bindings. They can be used to provide a convenient syntax for <i>monads</i> , a functional programming feature that can be used to manage data, control and side effects in functional programs. One type of computation expression, the asynchronous workflow, provides support for asynchronous and parallel computations. For more information, see Asynchronous Workflows .
Asynchronous Workflows	Describes asynchronous workflows, a language feature that lets you write asynchronous code in a way that is very close to the way you would naturally write synchronous code.
Code Quotations	Describes code quotations, a language feature that enables you to generate and work with F# code expressions programmatically.
Query Expressions	Describes query expressions, a language feature that implements LINQ for F# and enables you to write queries against a data source or enumerable collection.

Compiler-supported Constructs

The following table lists topics that describe special compiler-supported constructs.

TOPIC	DESCRIPTION
Compiler Options	Describes the command-line options for the F# compiler.
Compiler Directives	Describes processor directives and compiler directives.
Source Line, File, and Path Identifiers	Describes the identifiers <code>__LINE__</code> , <code>__SOURCE_DIRECTORY__</code> and <code>__SOURCE_FILE__</code> , which are built-in values that enable you to access the source line number, directory and file name in your code.

Keyword Reference

3/14/2019 • 7 minutes to read • [Edit Online](#)

This topic contains links to information about all F# language keywords.

F# Keyword Table

The following table shows all F# keywords in alphabetical order, together with brief descriptions and links to relevant topics that contain more information.

KEYWORD	LINK	DESCRIPTION
<code>abstract</code>	Members Abstract Classes	Indicates a method that either has no implementation in the type in which it is declared or that is virtual and has a default implementation.
<code>and</code>	let Bindings Records Members Constraints	Used in mutually recursive bindings and records, in property declarations, and with multiple constraints on generic parameters.
<code>as</code>	Classes Pattern Matching	Used to give the current class object an object name. Also used to give a name to a whole pattern within a pattern match.
<code>assert</code>	Assertions	Used to verify code during debugging.
<code>base</code>	Classes Inheritance	Used as the name of the base class object.
<code>begin</code>	Verbose Syntax	In verbose syntax, indicates the start of a code block.
<code>class</code>	Classes	In verbose syntax, indicates the start of a class definition.
<code>default</code>	Members	Indicates an implementation of an abstract method; used together with an abstract method declaration to create a virtual method.
<code>delegate</code>	Delegates	Used to declare a delegate.

KEYWORD	LINK	DESCRIPTION
<code>do</code>	do Bindings Loops: <code>for...to</code> Expression Loops: <code>for...in</code> Expression Loops: <code>while...do</code> Expression	Used in looping constructs or to execute imperative code.
<code>done</code>	Verbose Syntax	In verbose syntax, indicates the end of a block of code in a looping expression.
<code>downto</code>	Casting and Conversions	Used to convert to a type that is lower in the inheritance chain.
<code>elif</code>	Loops: for...to Expression Conditional Expressions: if...then...else	In a <code>for</code> expression, used when counting in reverse.
<code>else</code>	Conditional Expressions: if...then...else	Used in conditional branching.
<code>end</code>	Structures Discriminated Unions Records Type Extensions Verbose Syntax	In type definitions and type extensions, indicates the end of a section of member definitions. In verbose syntax, used to specify the end of a code block that starts with the <code>begin</code> keyword.
<code>exception</code>	Exception Handling Exception Types	Used to declare an exception type.
<code>extern</code>	External Functions	Indicates that a declared program element is defined in another binary or assembly.
<code>false</code>	Primitive Types	Used as a Boolean literal.
<code>finally</code>	Exceptions: The try...finally Expression	Used together with <code>try</code> to introduce a block of code that executes regardless of whether an exception occurs.
<code>fixed</code>	Fixed	Used to "pin" a pointer on the stack to prevent it from being garbage collected.
<code>for</code>	Loops: for...to Expression Loops: for...in Expression	Used in looping constructs.

KEYWORD	LINK	DESCRIPTION
<code>fun</code>	Lambda Expressions: The <code>fun</code> Keyword	Used in lambda expressions, also known as anonymous functions.
<code>function</code>	Match Expressions Lambda Expressions: The <code>fun</code> Keyword	Used as a shorter alternative to the <code>fun</code> keyword and a <code>match</code> expression in a lambda expression that has pattern matching on a single argument.
<code>global</code>	Namespaces	Used to reference the top-level .NET namespace.
<code>if</code>	Conditional Expressions: <code>if...then...else</code>	Used in conditional branching constructs.
<code>in</code>	Loops: <code>for...in</code> Expression Verbose Syntax	Used for sequence expressions and, in verbose syntax, to separate expressions from bindings.
<code>inherit</code>	Inheritance	Used to specify a base class or base interface.
<code>inline</code>	Functions Inline Functions	Used to indicate a function that should be integrated directly into the caller's code.
<code>interface</code>	Interfaces	Used to declare and implement interfaces.
<code>internal</code>	Access Control	Used to specify that a member is visible inside an assembly but not outside it.
<code>lazy</code>	Lazy Expressions	Used to specify an expression that is to be performed only when a result is needed.
<code>let</code>	<code>let</code> Bindings	Used to associate, or bind, a name to a value or function.
<code>let!</code>	Asynchronous Workflows Computation Expressions	Used in asynchronous workflows to bind a name to the result of an asynchronous computation, or, in other computation expressions, used to bind a name to a result, which is of the computation type.
<code>match</code>	Match Expressions	Used to branch by comparing a value to a pattern.
<code>match!</code>	Computation Expressions	Used to inline a call to a computation expression and pattern match on its result.
<code>member</code>	Members	Used to declare a property or method in an object type.

KEYWORD	LINK	DESCRIPTION
<code>module</code>	Modules	Used to associate a name with a group of related types, values, and functions, to logically separate it from other code.
<code>mutable</code>	let Bindings	Used to declare a variable, that is, a value that can be changed.
<code>namespace</code>	Namespaces	Used to associate a name with a group of related types and modules, to logically separate it from other code.
<code>new</code>	Constructors Constraints	Used to declare, define, or invoke a constructor that creates or that can create an object. Also used in generic parameter constraints to indicate that a type must have a certain constructor.
<code>not</code>	Symbol and Operator Reference Constraints	Not actually a keyword. However, <code>not struct</code> in combination is used as a generic parameter constraint.
<code>null</code>	Null Values Constraints	Indicates the absence of an object. Also used in generic parameter constraints.
<code>of</code>	Discriminated Unions Delegates Exception Types	Used in discriminated unions to indicate the type of categories of values, and in delegate and exception declarations.
<code>open</code>	Import Declarations: The <code>open</code> Keyword	Used to make the contents of a namespace or module available without qualification.
<code>or</code>	Symbol and Operator Reference Constraints	Used with Boolean conditions as a Boolean <code>or</code> operator. Equivalent to <code> </code> . Also used in member constraints.
<code>override</code>	Members	Used to implement a version of an abstract or virtual method that differs from the base version.
<code>private</code>	Access Control	Restricts access to a member to code in the same type or module.
<code>public</code>	Access Control	Allows access to a member from outside the type.
<code>rec</code>	Functions	Used to indicate that a function is recursive.

KEYWORD	LINK	DESCRIPTION
<code>return</code>	Asynchronous Workflows Computation Expressions	Used to indicate a value to provide as the result of a computation expression.
<code>return!</code>	Computation Expressions Asynchronous Workflows	Used to indicate a computation expression that, when evaluated, provides the result of the containing computation expression.
<code>select</code>	Query Expressions	Used in query expressions to specify what fields or columns to extract. Note that this is a contextual keyword, which means that it is not actually a reserved word and it only acts like a keyword in appropriate context.
<code>static</code>	Members	Used to indicate a method or property that can be called without an instance of a type, or a value member that is shared among all instances of a type.
<code>struct</code>	Structures Tuples Constraints	Used to declare a structure type. Used to specify a struct tuple. Also used in generic parameter constraints. Used for OCaml compatibility in module definitions.
<code>then</code>	Conditional Expressions: if...then...else Constructors	Used in conditional expressions. Also used to perform side effects after object construction.
<code>to</code>	Loops: for...to Expression	Used in <code>for</code> loops to indicate a range.
<code>true</code>	Primitive Types	Used as a Boolean literal.
<code>try</code>	Exceptions: The try...with Expression Exceptions: The try...finally Expression	Used to introduce a block of code that might generate an exception. Used together with <code>with</code> or <code>finally</code> .

KEYWORD	LINK	DESCRIPTION
<code>type</code>	F# Types Classes Records Structures Enumerations Discriminated Unions Type Abbreviations Units of Measure	Used to declare a class, record, structure, discriminated union, enumeration type, unit of measure, or type abbreviation.
<code>upcast</code>	Casting and Conversions	Used to convert to a type that is higher in the inheritance chain.
<code>use</code>	Resource Management: The <code>use</code> Keyword	Used instead of <code>let</code> for values that require <code>Dispose</code> to be called to free resources.
<code>use!</code>	Computation Expressions Asynchronous Workflows	Used instead of <code>let!</code> in asynchronous workflows and other computation expressions for values that require <code>Dispose</code> to be called to free resources.
<code>val</code>	Explicit Fields: The <code>val</code> Keyword Signatures Members	Used in a signature to indicate a value, or in a type to declare a member, in limited situations.
<code>void</code>	Primitive Types	Indicates the .NET <code>void</code> type. Used when interoperating with other .NET languages.
<code>when</code>	Constraints	Used for Boolean conditions (<i>when guards</i>) on pattern matches and to introduce a constraint clause for a generic type parameter.
<code>while</code>	Loops: <code>while...do</code> Expression	Introduces a looping construct.
<code>with</code>	Match Expressions Object Expressions Copy and Update Record Expressions Type Extensions Exceptions: The <code>try...with</code> Expression	Used together with the <code>match</code> keyword in pattern matching expressions. Also used in object expressions, record copying expressions, and type extensions to introduce member definitions, and to introduce exception handlers.

KEYWORD	LINK	DESCRIPTION
<code>yield</code>	Sequences	Used in a sequence expression to produce a value for a sequence.
<code>yield!</code>	Computation Expressions Asynchronous Workflows	Used in a computation expression to append the result of a given computation expression to a collection of results for the containing computation expression.

The following tokens are reserved in F# because they are keywords in the OCaml language:

- `asr`
- `land`
- `lor`
- `lsl`
- `lsr`
- `lxor`
- `mod`
- `sig`

If you use the `--mlcompatibility` compiler option, the above keywords are available for use as identifiers.

The following tokens are reserved as keywords for future expansion of the F# language:

- `atomic`
- `break`
- `checked`
- `component`
- `const`
- `constraint`
- `constructor`
- `continue`
- `eager`
- `event`
- `external`
- `functor`
- `include`
- `method`
- `mixin`
- `object`
- `parallel`
- `process`
- `protected`
- `pure`
- `sealed`
- `tailcall`
- `trait`

- `virtual`
- `volatile`

Symbol and Operator Reference

2/12/2019 • 8 minutes to read • [Edit Online](#)

NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

This topic includes a table of symbols and operators that are used in the F# language.

Table of Symbols and Operators

The following table describes symbols used in the F# language, provides links to topics that provide more information, and provides a brief description of some of the uses of the symbol. Symbols are ordered according to the ASCII character set ordering.

SYMBOL OR OPERATOR	LINKS	DESCRIPTION
!	Reference Cells Computation Expressions	<ul style="list-style-type: none">Dereferences a reference cell.After a keyword, indicates a modified version of the keyword's behavior as controlled by a workflow.
!=	Not applicable.	<ul style="list-style-type: none">Not used in F#. Use <code><></code> for inequality operations.
"	Literals Strings	<ul style="list-style-type: none">Delimits a text string.
"""	Strings	Delimits a verbatim text string. Differs from <code>@"..."</code> in that you can indicate a quotation mark character by using a single quote in the string.
#	Compiler Directives Flexible Types	<ul style="list-style-type: none">Prefixes a preprocessor or compiler directive, such as <code>#light</code>.When used with a type, indicates a <i>flexible type</i>, which refers to a type or any one of its derived types.
\$	No more information available.	<ul style="list-style-type: none">Used internally for certain compiler-generated variable and function names.

SYMBOL OR OPERATOR	LINKS	DESCRIPTION
%	Arithmetic Operators Code Quotations	<ul style="list-style-type: none"> Computes the integer remainder. Used for splicing expressions into typed code quotations.
%%	Code Quotations	<ul style="list-style-type: none"> Used for splicing expressions into untyped code quotations.
%?	Nullable Operators	<ul style="list-style-type: none"> Computes the integer remainder, when the right side is a nullable type.
&	Match Expressions	<ul style="list-style-type: none"> Computes the address of a mutable value, for use when interoperating with other languages. Used in AND patterns.
&&	Boolean Operators	<ul style="list-style-type: none"> Computes the Boolean AND operation.
&&&	Bitwise Operators	<ul style="list-style-type: none"> Computes the bitwise AND operation.
'	Literals Automatic Generalization	<ul style="list-style-type: none"> Delimits a single-character literal. Indicates a generic type parameter.
``...``	No more information available.	<ul style="list-style-type: none"> Delimits an identifier that would otherwise not be a legal identifier, such as a language keyword.
()	Unit Type	<ul style="list-style-type: none"> Represents the single value of the unit type.
(...)	Tuples Operator Overloading	<ul style="list-style-type: none"> Indicates the order in which expressions are evaluated. Delimits a tuple. Used in operator definitions.
(*...*)		<ul style="list-style-type: none"> Delimits a comment that could span multiple lines.

SYMBOL OR OPERATOR	LINKS	DESCRIPTION
(. . .)	Active Patterns	<ul style="list-style-type: none"> • Delimits an active pattern. Also called <i>banana clips</i>.
*	Arithmetic Operators Tuples Units of Measure	<ul style="list-style-type: none"> • When used as a binary operator, multiplies the left and right sides. • In types, indicates pairing in a tuple. • Used in units of measure types.
*?	Nullable Operators	<ul style="list-style-type: none"> • Multiplies the left and right sides, when the right side is a nullable type.
**	Arithmetic Operators	<ul style="list-style-type: none"> • Computes the exponentiation operation ($x ** y$ means x to the power of y).
+	Arithmetic Operators	<ul style="list-style-type: none"> • When used as a binary operator, adds the left and right sides. • When used as a unary operator, indicates a positive quantity. (Formally, it produces the same value with the sign unchanged.)
+?	Nullable Operators	<ul style="list-style-type: none"> • Adds the left and right sides, when the right side is a nullable type.
,	Tuples	<ul style="list-style-type: none"> • Separates the elements of a tuple, or type parameters.
-	Arithmetic Operators	<ul style="list-style-type: none"> • When used as a binary operator, subtracts the right side from the left side. • When used as a unary operator, performs a negation operation.
-	Nullable Operators	<ul style="list-style-type: none"> • Subtracts the right side from the left side, when the right side is a nullable type.

SYMBOL OR OPERATOR	LINKS	DESCRIPTION
->	Functions Match Expressions	<ul style="list-style-type: none"> In function types, delimits arguments and return values. Yields an expression (in sequence expressions); equivalent to the <code>yield</code> keyword. Used in match expressions
.	Members Primitive Types	<ul style="list-style-type: none"> Accesses a member, and separates individual names in a fully qualified name. Specifies a decimal point in floating point numbers.

## Operator Precedence

The following table shows the order of precedence of operators and other expression keywords in the F# language, in order from lowest precedence to the highest precedence. Also listed is the associativity, if applicable.

OPERATOR	ASSOCIATIVITY
as	Right
when	Right
(pipe)	Left
;	Right
let	Nonassociative
function , fun , match , try	Nonassociative

OPERATOR	ASSOCIATIVITY
<code>if</code>	Nonassociative
<code>-&gt;</code>	Right
<code>:=</code>	Right
<code>,</code>	Nonassociative
<code>or</code> , <code>  </code>	Left
<code>&amp;</code> , <code>&amp;&amp;</code>	Left
<code>:&gt;</code> , <code>:?&gt;</code>	Right
<code>&lt; op</code> , <code>&gt; op</code> , <code>=</code> , <code>  op</code> , <code>&amp; op</code> , <code>&amp;</code> (including <code>&lt;&lt;</code> , <code>&gt;&gt;</code> , <code>   </code> , <code>&amp;&amp;&amp;</code> )	Left
<code>^ op</code> (including <code>^^^</code> )	Right
<code>::</code>	Right
<code>:?</code>	Not associative
<code>- op</code> , <code>+ op</code>	Applies to infix uses of these symbols
<code>* op</code> , <code>/ op</code> , <code>% op</code>	Left
<code>** op</code>	Right
<code>f x</code> (function application)	Left
<code> </code> (pattern match)	Right
prefix operators ( <code>+ op</code> , <code>- op</code> , <code>%</code> , <code>%%</code> , <code>&amp;</code> , <code>&amp;&amp;</code> , <code>! op</code> , <code>~ op</code> )	Left
<code>.</code>	Left
<code>f(x)</code>	Left
<code>f&lt; types &gt;</code>	Left

F# supports custom operator overloading. This means that you can define your own operators. In the previous table, `op` can be any valid (possibly empty) sequence of operator characters, either built-in or user-defined. Thus, you can use this table to determine what sequence of characters to use for a custom operator to achieve the desired level of precedence. Leading `.` characters are ignored when the compiler determines precedence.

# Arithmetic Operators

12/19/2018 • 3 minutes to read • [Edit Online](#)

This topic describes arithmetic operators that are available in the F# language.

## Summary of Binary Arithmetic Operators

The following table summarizes the binary arithmetic operators that are available for unboxed integral and floating-point types.

BINARY OPERATOR	NOTES	
+ (addition, plus)	Unchecked. Possible overflow condition when numbers are added together and the sum exceeds the maximum absolute value supported by the type.	
- (subtraction, minus)	Unchecked. Possible underflow condition when unsigned types are subtracted, or when floating-point values are too small to be represented by the type.	
*	(multiplication, times)	Unchecked. Possible overflow condition when numbers are multiplied and the product exceeds the maximum absolute value supported by the type.
/	(division, divided by)	Division by zero causes a <a href="#">DivideByZeroException</a> for integral types. For floating-point types, division by zero gives you the special floating-point values <code>+Infinity</code> or <code>-Infinity</code> . There is also a possible underflow condition when a floating-point number is too small to be represented by the type.
%	(remainder, rem)	Returns the remainder of a division operation. The sign of the result is the same as the sign of the first operand.
**	(exponentiation, to the power of)	Possible overflow condition when the result exceeds the maximum absolute value for the type.  The exponentiation operator works only with floating-point types.

## Summary of Unary Arithmetic Operators

The following table summarizes the unary arithmetic operators that are available for integral and floating-point types.

UNARY OPERATOR	NOTES	
+	(positive)	Can be applied to any arithmetic expression. Does not change the sign of the value.
-	(negation, negative)	Can be applied to any arithmetic expression. Changes the sign of the value.

The behavior at overflow or underflow for integral types is to wrap around. This causes an incorrect result. Integer overflow is a potentially serious problem that can contribute to security issues when software is not written to account for it. If this is a concern for your application, consider using the checked operators in [Microsoft.FSharp.Core.Operators.Checked](#).

## Summary of Binary Comparison Operators

The following table shows the binary comparison operators that are available for integral and floating-point types. These operators return values of type `bool`.

Floating-point numbers should never be directly compared for equality, because the IEEE floating-point representation does not support an exact equality operation. Two numbers that you can easily verify to be equal by inspecting the code might actually have different bit representations.

OPERATOR	NOTES
<code>=</code> (equality, equals)	This is not an assignment operator. It is used only for comparison. This is a generic operator.
<code>&gt;</code> (greater than)	This is a generic operator.
<code>&lt;</code> (less than)	This is a generic operator.
<code>&gt;=</code> (greater than or equals)	This is a generic operator.
<code>&lt;=</code> (less than or equals)	This is a generic operator.
<code>&lt;&gt;</code> (not equal)	This is a generic operator.

## Overloaded and Generic Operators

All of the operators discussed in this topic are defined in the **Microsoft.FSharp.Core.Operators** namespace. Some of the operators are defined by using statically resolved type parameters. This means that there are individual definitions for each specific type that works with that operator. All of the unary and binary arithmetic and bitwise operators are in this category. The comparison operators are generic and therefore work with any type, not just primitive arithmetic types. Discriminated union and record types have their own custom implementations that are generated by the F# compiler. Class types use the method [Equals](#).

The generic operators are customizable. To customize the comparison functions, override [Equals](#) to provide your own custom equality comparison, and then implement [IComparable](#). The [System.IComparable](#) interface has a single method, the [CompareTo](#) method.

## Operators and Type Inference

The use of an operator in an expression constrains type inference on that operator. Also, the use of operators prevents automatic generalization, because the use of operators implies an arithmetic type. In the absence of any other information, the F# compiler infers `int` as the type of arithmetic expressions. You can override this behavior by specifying another type. Thus the argument types and return type of `function1` in the following code are inferred to be `int`, but the types for `function2` are inferred to be `float`.

```
// x, y and return value inferred to be int
// function1: int -> int -> int
let function1 x y = x + y

// x, y and return value inferred to be float
// function2: float -> float -> float
let function2 (x: float) y = x + y
```

# Boolean Operators

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic describes the support for Boolean operators in the F# language.

## Summary of Boolean Operators

The following table summarizes the Boolean operators that are available in the F# language. The only type supported by these operators is the `bool` type.

OPERATOR	DESCRIPTION
<code>not</code>	Boolean negation
<code>  </code>	Boolean OR
<code>&amp;&amp;</code>	Boolean AND

The Boolean AND and OR operators perform *short-circuit evaluation*, that is, they evaluate the expression on the right of the operator only when it is necessary to determine the overall result of the expression. The second expression of the `&&` operator is evaluated only if the first expression evaluates to `true`; the second expression of the `||` operator is evaluated only if the first expression evaluates to `false`.

# Bitwise Operators

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic describes bitwise operators that are available in the F# language.

## Summary of Bitwise Operators

The following table describes the bitwise operators that are supported for unboxed integral types in the F# language.

OPERATOR	NOTES
<code>&amp;&amp;</code>	Bitwise AND operator. Bits in the result have the value 1 if and only if the corresponding bits in both source operands are 1.
<code>   </code>	Bitwise OR operator. Bits in the result have the value 1 if either of the corresponding bits in the source operands are 1.
<code>^^^</code>	Bitwise exclusive OR operator. Bits in the result have the value 1 if and only if bits in the source operands have unequal values.
<code>~~~</code>	Bitwise negation operator. This is a unary operator and produces a result in which all 0 bits in the source operand are converted to 1 bits and all 1 bits are converted to 0 bits.
<code>&lt;&lt;&lt;</code>	Bitwise left-shift operator. The result is the first operand with bits shifted left by the number of bits in the second operand. Bits shifted off the most significant position are not rotated into the least significant position. The least significant bits are padded with zeros. The type of the second argument is <code>int32</code> .
<code>&gt;&gt;&gt;</code>	Bitwise right-shift operator. The result is the first operand with bits shifted right by the number of bits in the second operand. Bits shifted off the least significant position are not rotated into the most significant position. For unsigned types, the most significant bits are padded with zeros. For signed types with negative values, the most significant bits are padded with ones. The type of the second argument is <code>int32</code> .

The following types can be used with bitwise operators: `byte`, `sbyte`, `int16`, `uint16`, `int32 (int)`, `uint32`, `int64`, `uint64`, `nativeint`, and `unativeint`.

# Nullable Operators

12/19/2018 • 3 minutes to read • [Edit Online](#)

Nullable operators are binary arithmetic or comparison operators that work with nullable arithmetic types on one or both sides. Nullable types arise frequently when you work with data from sources such as databases that allow nulls in place of actual values. Nullable operators are used frequently in query expressions. In addition to nullable operators for arithmetic and comparison, conversion operators can be used to convert between nullable types. There are also nullable versions of certain query operators.

## Table of Nullable Operators

The following table lists nullable operators supported in the F# language.

NULLABLE ON LEFT	NULLABLE ON RIGHT	BOTH SIDES NULLABLE
?>=	>=?	?>=?
?>	?>	?>?
?<=	?=>	?<=?
?<	?<	?<?
?=	=?	?=?
?<>	?<>?	?<>?
?+	+?	?+?
?-	-?	?-?
?*	*?	?*?
?/	?/	?/?
?%	?%	?%?

## Remarks

The nullable operators are included in the `NullableOperators` module in the namespace `Microsoft.FSharp.Linq`. The type for nullable data is `System.Nullable<'T>`.

In query expressions, nullable types arise when selecting data from a data source that allows nulls instead of values. In a SQL Server database, each data column in a table has an attribute that indicates whether nulls are allowed. If nulls are allowed, the data returned from the database can contain nulls that cannot be represented by a primitive data type such as `int`, `float`, and so on. Therefore, the data is returned as a `System.Nullable<int>` instead of `int`, and `System.Nullable<float>` instead of `float`. The actual value can be obtained from a `System.Nullable<'T>` object by using the `Value` property, and you can determine if a `System.Nullable<'T>` object has a value by calling the `HasValue` method. Another useful method is the

`System.Nullable<'T>.GetValueOrDefault` method, which allows you to get the value or a default value of the appropriate type. The default value is some form of "zero" value, such as 0, 0.0, or `false`.

Nullable types may be converted to non-nullable primitive types using the usual conversion operators such as `int` or `float`. It is also possible to convert from one nullable type to another nullable type by using the conversion operators for nullable types. The appropriate conversion operators have the same name as the standard ones, but they are in a separate module, the `Nullable` module in the `Microsoft.FSharp.Linq` namespace. Typically, you open this namespace when working with query expressions. In that case, you can use the nullable conversion operators by adding the prefix `Nullable.` to the appropriate conversion operator, as shown in the following code.

```
open Microsoft.FSharp.Linq

let nullableInt = new System.Nullable<int>(10)

// Use the Nullable.float conversion operator to convert from one nullable type to another nullable type.
let nullableFloat = Nullable.float nullableInt

// Use the regular non-nullable float operator to convert to a non-nullable float.
printfn "%f" (float nullableFloat)
```

The output is `10.000000`.

Query operators on nullable data fields, such as `sumByNullable`, also exist for use in query expressions. The query operators for non-nullable types are not type-compatible with nullable types, so you must use the nullable version of the appropriate query operator when you are working with nullable data values. For more information, see [Query Expressions](#).

The following example shows the use of nullable operators in an F# query expression. The first query shows how you would write a query without a nullable operator; the second query shows an equivalent query that uses a nullable operator. For the full context, including how to set up the database to use this sample code, see [Walkthrough: Accessing a SQL Database by Using Type Providers](#).

```
open System
open System.Data
open System.Data.Linq
open Microsoft.FSharp.Data.TypeProviders
open Microsoft.FSharp.Linq

[<Generate>]
type dbSchema = SqlDataConnection<"Data Source=MY SERVER\INSTANCE;Initial Catalog=MyDatabase;Integrated Security=SSPI;">

let db = dbSchema.GetDataContext()

query {
    for row in db.Table2 do
        where (row.TestData1.HasValue && row.TestData1.Value > 2)
        select row
} |> Seq.iter (fun row -> printfn "%d %s" row.TestData1.Value row.Name)

query {
    for row in db.Table2 do
        // Use a nullable operator ?>
        where (row.TestData1 ?> 2)
        select row
} |> Seq.iter (fun row -> printfn "%d %s" (row.TestData1.GetValueOrDefault()) row.Name)
```

# Functions

12/19/2018 • 9 minutes to read • [Edit Online](#)

Functions are the fundamental unit of program execution in any programming language. As in other languages, an F# function has a name, can have parameters and take arguments, and has a body. F# also supports functional programming constructs such as treating functions as values, using unnamed functions in expressions, composition of functions to form new functions, curried functions, and the implicit definition of functions by way of the partial application of function arguments.

You define functions by using the `let` keyword, or, if the function is recursive, the `let rec` keyword combination.

## Syntax

```
// Non-recursive function definition.  
let [inline] function-name parameter-list [ : return-type ] = function-body  
// Recursive function definition.  
let rec function-name parameter-list = recursive-function-body
```

## Remarks

The *function-name* is an identifier that represents the function. The *parameter-list* consists of successive parameters that are separated by spaces. You can specify an explicit type for each parameter, as described in the Parameters section. If you do not specify a specific argument type, the compiler attempts to infer the type from the function body. The *function-body* consists of an expression. The expression that makes up the function body is typically a compound expression consisting of a number of expressions that culminate in a final expression that is the return value. The *return-type* is a colon followed by a type and is optional. If you do not specify the type of the return value explicitly, the compiler determines the return type from the final expression.

A simple function definition resembles the following:

```
let f x = x + 1
```

In the previous example, the function name is `f`, the argument is `x`, which has type `int`, the function body is `x + 1`, and the return value is of type `int`.

Functions can be marked `inline`. For information about `inline`, see [Inline Functions](#).

## Scope

At any level of scope other than module scope, it is not an error to reuse a value or function name. If you reuse a name, the name declared later shadows the name declared earlier. However, at the top level scope in a module, names must be unique. For example, the following code produces an error when it appears at module scope, but not when it appears inside a function:

```
let list1 = [ 1; 2; 3]
// Error: duplicate definition.
let list1 = []
let function1 =
  let list1 = [1; 2; 3]
  let list1 = []
  list1
```

But the following code is acceptable at any level of scope:

```
let list1 = [ 1; 2; 3]
let sumPlus x =
  // OK: inner list1 hides the outer list1.
  let list1 = [1; 5; 10]
  x + List.sum list1
```

## Parameters

Names of parameters are listed after the function name. You can specify a type for a parameter, as shown in the following example:

```
let f (x : int) = x + 1
```

If you specify a type, it follows the name of the parameter and is separated from the name by a colon. If you omit the type for the parameter, the parameter type is inferred by the compiler. For example, in the following function definition, the argument `x` is inferred to be of type `int` because 1 is of type `int`.

```
let f x = x + 1
```

However, the compiler will attempt to make the function as generic as possible. For example, note the following code:

```
let f x = (x, x)
```

The function creates a tuple from one argument of any type. Because the type is not specified, the function can be used with any argument type. For more information, see [Automatic Generalization](#).

## Function Bodies

A function body can contain definitions of local variables and functions. Such variables and functions are in scope in the body of the current function but not outside it. When you have the lightweight syntax option enabled, you must use indentation to indicate that a definition is in a function body, as shown in the following example:

```
let cylinderVolume radius length =
  // Define a local value pi.
  let pi = 3.14159
  length * pi * radius * radius
```

For more information, see [Code Formatting Guidelines](#) and [Verbose Syntax](#).

## Return Values

The compiler uses the final expression in a function body to determine the return value and type. The compiler might infer the type of the final expression from previous expressions. In the function `cylinderVolume`, shown in the previous section, the type of `pi` is determined from the type of the literal `3.14159` to be `float`. The compiler uses the type of `pi` to determine the type of the expression `h * pi * r * r` to be `float`. Therefore, the overall return type of the function is `float`.

To specify the return value explicitly, write the code as follows:

```
let cylinderVolume radius length : float =
    // Define a local value pi.
    let pi = 3.14159
    length * pi * radius * radius
```

As the code is written above, the compiler applies `float` to the entire function; if you mean to apply it to the parameter types as well, use the following code:

```
let cylinderVolume (radius : float) (length : float) : float
```

## Calling a Function

You call functions by specifying the function name followed by a space and then any arguments separated by spaces. For example, to call the function `cylinderVolume` and assign the result to the value `vol`, you write the following code:

```
let vol = cylinderVolume 2.0 3.0
```

## Partial Application of Arguments

If you supply fewer than the specified number of arguments, you create a new function that expects the remaining arguments. This method of handling arguments is referred to as *currying* and is a characteristic of functional programming languages like F#. For example, suppose you are working with two sizes of pipe: one has a radius of **2.0** and the other has a radius of **3.0**. You could create functions that determine the volume of pipe as follows:

```
let smallPipeRadius = 2.0
let bigPipeRadius = 3.0

// These define functions that take the length as a remaining
// argument:

let smallPipeVolume = cylinderVolume smallPipeRadius
let bigPipeVolume = cylinderVolume bigPipeRadius
```

You would then supply the additional argument as needed for various lengths of pipe of the two different sizes:

```
let length1 = 30.0
let length2 = 40.0
let smallPipeVol1 = smallPipeVolume length1
let smallPipeVol2 = smallPipeVolume length2
let bigPipeVol1 = bigPipeVolume length1
let bigPipeVol2 = bigPipeVolume length2
```

## Recursive Functions

*Recursive functions* are functions that call themselves. They require that you specify the **rec** keyword following the **let** keyword. Invoke the recursive function from within the body of the function just as you would invoke any function call. The following recursive function computes the  $n^{\text{th}}$  Fibonacci number. The Fibonacci number sequence has been known since antiquity and is a sequence in which each successive number is the sum of the previous two numbers in the sequence.

```
let rec fib n = if n < 2 then 1 else fib (n - 1) + fib (n - 2)
```

Some recursive functions might overflow the program stack or perform inefficiently if you do not write them with care and with awareness of special techniques, such as the use of accumulators and continuations.

## Function Values

In F#, all functions are considered values; in fact, they are known as *function values*. Because functions are values, they can be used as arguments to other functions or in other contexts where values are used.

Following is an example of a function that takes a function value as an argument:

```
let apply1 (transform : int -> int) y = transform y
```

You specify the type of a function value by using the `->` token. On the left side of this token is the type of the argument, and on the right side is the return value. In the previous example, `apply1` is a function that takes a function `transform` as an argument, where `transform` is a function that takes an integer and returns another integer. The following code shows how to use `apply1`:

```
let increment x = x + 1  
  
let result1 = apply1 increment 100
```

The value of `result` will be 101 after the previous code runs.

Multiple arguments are separated by successive `->` tokens, as shown in the following example:

```
let apply2 (f: int -> int -> int) x y = f x y  
  
let mul x y = x * y  
  
let result2 = apply2 mul 10 20
```

The result is 200.

## Lambda Expressions

A *lambda expression* is an unnamed function. In the previous examples, instead of defining named functions **increment** and **mul**, you could use lambda expressions as follows:

```
let result3 = apply1 (fun x -> x + 1) 100  
  
let result4 = apply2 (fun x y -> x * y) 10 20
```

You define lambda expressions by using the `fun` keyword. A lambda expression resembles a function

definition, except that instead of the `=` token, the `->` token is used to separate the argument list from the function body. As in a regular function definition, the argument types can be inferred or specified explicitly, and the return type of the lambda expression is inferred from the type of the last expression in the body. For more information, see [Lambda Expressions: The `fun` Keyword](#).

## Function Composition and Pipelining

Functions in F# can be composed from other functions. The composition of two functions **function1** and **function2** is another function that represents the application of **function1** followed the application of **function2**:

```
let function1 x = x + 1
let function2 x = x * 2
let h = function1 >> function2
let result5 = h 100
```

The result is 202.

Pipelining enables function calls to be chained together as successive operations. Pipelining works as follows:

```
let result = 100 |> function1 |> function2
```

The result is again 202.

The composition operators take two functions and return a function; by contrast, the pipeline operators take a function and an argument and return a value. The following code example shows the difference between the pipeline and composition operators by showing the differences in the function signatures and usage.

```
// Function composition and pipeline operators compared.

let addOne x = x + 1
let timesTwo x = 2 * x

// Composition operator
// ( >> ) : ('T1 -> 'T2) -> ('T2 -> 'T3) -> 'T1 -> 'T3
let Compose2 = addOne >> timesTwo

// Backward composition operator
// ( << ) : ('T2 -> 'T3) -> ('T1 -> 'T2) -> 'T1 -> 'T3
let Compose1 = addOne << timesTwo

// Result is 5
let result1 = Compose1 2

// Result is 6
let result2 = Compose2 2

// Pipelining
// Pipeline operator
// ( |> ) : 'T1 -> ('T1 -> 'U) -> 'U
let Pipeline2 x = addOne x |> timesTwo

// Backward pipeline operator
// ( <| ) : ('T -> 'U) -> 'T -> 'U
let Pipeline1 x = addOne <| timesTwo x

// Result is 5
let result3 = Pipeline1 2

// Result is 6
let result4 = Pipeline2 2
```

## Overloading Functions

You can overload methods of a type but not functions. For more information, see [Methods](#).

# let Bindings

12/19/2018 • 5 minutes to read • [Edit Online](#)

A *binding* associates an identifier with a value or function. You use the `let` keyword to bind a name to a value or function.

## Syntax

```
// Binding a value:  
let identifier-or-pattern [: type] =expressionbody-expression  
// Binding a function value:  
let identifier parameter-list [: return-type ] =expressionbody-expression
```

## Remarks

The `let` keyword is used in binding expressions to define values or function values for one or more names. The simplest form of the `let` expression binds a name to a simple value, as follows.

```
let i = 1
```

If you separate the expression from the identifier by using a new line, you must indent each line of the expression, as in the following code.

```
let someVeryLongIdentifier =  
    // Note indentation below.  
    3 * 4 + 5 * 6
```

Instead of just a name, a pattern that contains names can be specified, for example, a tuple, as shown in the following code.

```
let i, j, k = (1, 2, 3)
```

The *body-expression* is the expression in which the names are used. The body expression appears on its own line, indented to line up exactly with the first character in the `let` keyword:

```
let result =  
  
    let i, j, k = (1, 2, 3)  
  
    // Body expression:  
    i + 2*j + 3*k
```

A `let` binding can appear at the module level, in the definition of a class type, or in local scopes, such as in a function definition. A `let` binding at the top level in a module or in a class type does not need to have a body expression, but at other scope levels, the body expression is required. The bound names are usable after the point of definition, but not at any point before the `let` binding appears, as is illustrated in the following code.

```
// Error:  
printfn "%d" x  
let x = 100  
// OK:  
printfn "%d" x
```

## Function Bindings

Function bindings follow the rules for value bindings, except that function bindings include the function name and the parameters, as shown in the following code.

```
let function1 a =  
    a + 1
```

In general, parameters are patterns, such as a tuple pattern:

```
let function2 (a, b) = a + b
```

A `let` binding expression evaluates to the value of the last expression. Therefore, in the following code example, the value of `result` is computed from `100 * function3 (1, 2)`, which evaluates to `300`.

```
let result =  
    let function3 (a, b) = a + b  
    100 * function3 (1, 2)
```

For more information, see [Functions](#).

## Type Annotations

You can specify types for parameters by including a colon (:) followed by a type name, all enclosed in parentheses. You can also specify the type of the return value by appending the colon and type after the last parameter. The full type annotations for `function1`, with integers as the parameter types, would be as follows.

```
let function1 (a: int) : int = a + 1
```

When there are no explicit type parameters, type inference is used to determine the types of parameters of functions. This can include automatically generalizing the type of a parameter to be generic.

For more information, see [Automatic Generalization](#) and [Type Inference](#).

## let Bindings in Classes

A `let` binding can appear in a class type but not in a structure or record type. To use a `let` binding in a class type, the class must have a primary constructor. Constructor parameters must appear after the type name in the class definition. A `let` binding in a class type defines private fields and members for that class type and, together with `do` bindings in the type, forms the code for the primary constructor for the type. The following code examples show a class `MyClass` with private fields `field1` and `field2`.

```
type MyClass(a) =
    let field1 = a
    let field2 = "text"
    do printfn "%d %s" field1 field2
    member this.F input =
        printfn "Field1 %d Field2 %s Input %A" field1 field2 input
```

The scopes of `field1` and `field2` are limited to the type in which they are declared. For more information, see [let Bindings in Classes and Classes](#).

## Type Parameters in let Bindings

A `let` binding at the module level, in a type, or in a computation expression can have explicit type parameters. A `let` binding in an expression, such as within a function definition, cannot have type parameters. For more information, see [Generics](#).

## Attributes on let Bindings

Attributes can be applied to top-level `let` bindings in a module, as shown in the following code.

```
[<Obsolete>]
let function1 x y = x + y
```

## Scope and Accessibility of Let Bindings

The scope of an entity declared with a `let` binding is limited to the portion of the containing scope (such as a function, module, file or class) after the binding appears. Therefore, it can be said that a `let` binding introduces a name into a scope. In a module, a `let`-bound value or function is accessible to clients of a module as long as the module is accessible, since the `let` bindings in a module are compiled into public functions of the module. By contrast, `let` bindings in a class are private to the class.

Normally, functions in modules must be qualified by the name of the module when used by client code. For example, if a module `Module1` has a function `function1`, users would specify `Module1.function1` to refer to the function.

Users of a module may use an import declaration to make the functions within that module available for use without being qualified by the module name. In the example just mentioned, users of the module can in that case open the module by using the import declaration `open Module1` and thereafter refer to `function1` directly.

```
module Module1 =
    let function1 x = x + 1.0

module Module2 =
    let function2 x =
        Module1.function1 x

open Module1

let function3 x =
    function1 x
```

Some modules have the attribute [RequireQualifiedAccess](#), which means that the functions that they expose must be qualified with the name of the module. For example, the F# List module has this attribute.

For more information on modules and access control, see [Modules](#) and [Access Control](#).

# do Bindings

12/19/2018 • 2 minutes to read • [Edit Online](#)

A `do` binding is used to execute code without defining a function or value. Also, do bindings can be used in classes, see [do Bindings in Classes](#).

## Syntax

```
[ attributes ]  
[ do ]expression
```

## Remarks

Use a `do` binding when you want to execute code independently of a function or value definition. The expression in a `do` binding must return `unit`. Code in a top-level `do` binding is executed when the module is initialized. The keyword `do` is optional.

Attributes can be applied to a top-level `do` binding. For example, if your program uses COM interop, you might want to apply the `[STAThread]` attribute to your program. You can do this by using an attribute on a `do` binding, as shown in the following code.

```
open System  
open System.Windows.Forms  
  
let form1 = new Form()  
form1.Text <- "XYZ"  
  
[<STAThread>]  
do  
    Application.Run(form1)
```

# Lambda Expressions: The fun Keyword (F#)

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `fun` keyword is used to define a lambda expression, that is, an anonymous function.

## Syntax

```
fun parameter-list -> expression
```

## Remarks

The *parameter-list* typically consists of names and, optionally, types of parameters. More generally, the *parameter-list* can be composed of any F# patterns. For a full list of possible patterns, see [Pattern Matching](#). Lists of valid parameters include the following examples.

```
// Lambda expressions with parameter lists.  
fun a b c -> ...  
fun (a: int) b c -> ...  
fun (a : int) (b : string) (c:float) -> ...  
  
// A lambda expression with a tuple pattern.  
fun (a, b) -> ...  
  
// A lambda expression with a list pattern.  
fun head :: tail -> ...
```

The *expression* is the body of the function, the last expression of which generates a return value. Examples of valid lambda expressions include the following:

```
fun x -> x + 1  
fun a b c -> printfn "%A %A %A" a b c  
fun (a: int) (b: int) (c: int) -> a + b * c  
fun x y -> let swap (a, b) = (b, a) in swap (x, y)
```

## Using Lambda Expressions

Lambda expressions are especially useful when you want to perform operations on a list or other collection and want to avoid the extra work of defining a function. Many F# library functions take function values as arguments, and it can be especially convenient to use a lambda expression in those cases. The following code applies a lambda expression to elements of a list. In this case, the anonymous function adds 1 to every element of a list.

```
let list = List.map (fun i -> i + 1) [1;2;3]  
printfn "%A" list
```

# Recursive Functions: The rec Keyword

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `rec` keyword is used together with the `let` keyword to define a recursive function.

## Syntax

```
// Recursive function:  
let rec function-nameparameter-list =  
    function-body  
  
// Mutually recursive functions:  
let rec function1-nameparameter-list =  
    function1-body  
and function2-nameparameter-list =  
    function2-body  
...  
...
```

## Remarks

Recursive functions, functions that call themselves, are identified explicitly in the F# language. This makes the identifier that is being defined available in the scope of the function.

The following code illustrates a recursive function that computes the  $n^{\text{th}}$  Fibonacci number.

```
let rec fib n =  
    if n <= 2 then 1  
    else fib (n - 1) + fib (n - 2)
```

### NOTE

In practice, code like that above is wasteful of memory and processor time because it involves the recomputation of previously computed values.

Methods are implicitly recursive within the type; there is no need to add the `rec` keyword. Let bindings within classes are not implicitly recursive.

## Mutually Recursive Functions

Sometimes functions are *mutually recursive*, meaning that calls form a circle, where one function calls another which in turn calls the first, with any number of calls in between. You must define such functions together in the one `let` binding, using the `and` keyword to link them together.

The following example shows two mutually recursive functions.

```
let rec Even x =
  if x = 0 then true
  else Odd (x-1)
and Odd x =
  if x = 0 then false
  else Even (x-1)
```

# Entry Point

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic describes the method that you use to set the entry point to an F# program.

## Syntax

```
[<EntryPoint>]  
let-function-binding
```

## Remarks

In the previous syntax, *let-function-binding* is the definition of a function in a `let` binding.

The entry point to a program that is compiled as an executable file is where execution formally starts. You specify the entry point to an F# application by applying the `EntryPoint` attribute to the program's `main` function. This function (created by using a `let` binding) must be the last function in the last compiled file. The last compiled file is the last file in the project or the last file that is passed to the command line.

The entry point function has type `string array -> int`. The arguments provided on the command line are passed to the `main` function in the array of strings. The first element of the array is the first argument; the name of the executable file is not included in the array, as it is in some other languages. The return value is used as the exit code for the process. Zero usually indicates success; nonzero values indicate an error. There is no convention for the specific meaning of nonzero return codes; the meanings of the return codes are application-specific.

The following example illustrates a simple `main` function.

```
[<EntryPoint>]  
let main args =  
    printfn "Arguments passed to function : %A" args  
    // Return 0. This indicates success.  
    0
```

When this code is executed with the command line `EntryPoint.exe 1 2 3`, the output is as follows.

```
Arguments passed to function : [|"1"; "2"; "3"|]
```

## Implicit Entry Point

When a program has no **EntryPoint** attribute that explicitly indicates the entry point, the top level bindings in the last file to be compiled are used as the entry point.

# External Functions

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic describes F# language support for calling functions in native code.

## Syntax

```
[<DllImport( arguments )>]  
extern declaration
```

## Remarks

In the previous syntax, *arguments* represents arguments that are supplied to the `System.Runtime.InteropServices.DllImportAttribute` attribute. The first argument is a string that represents the name of the DLL that contains this function, without the .dll extension. Additional arguments can be supplied for any of the public properties of the `System.Runtime.InteropServices.DllImportAttribute` class, such as the calling convention.

Assume you have a native C++ DLL that contains the following exported function.

```
#include <stdio.h>  
extern "C" void __declspec(dllexport) HelloWorld()  
{  
    printf("Hello world, invoked by F#\n");  
}
```

You can call this function from F# by using the following code.

```
open System.Runtime.InteropServices  
  
module InteropWithNative =  
    [<DllImport(@"C:\bin\nativeddll", CallingConvention = CallingConvention.Cdecl)>]  
    extern void HelloWorld()  
  
InteropWithNative.HelloWorld()
```

Interoperability with native code is referred to as *platform invoke* and is a feature of the CLR. For more information, see [Interoperating with Unmanaged Code](#). The information in that section is applicable to F#.

- [Functions](#)

# Inline Functions

12/19/2018 • 2 minutes to read • [Edit Online](#)

*Inline functions* are functions that are integrated directly into the calling code.

## Using Inline Functions

When you use static type parameters, any functions that are parameterized by type parameters must be inline.

This guarantees that the compiler can resolve these type parameters. When you use ordinary generic type parameters, there is no such restriction.

Other than enabling the use of member constraints, inline functions can be helpful in optimizing code. However, overuse of inline functions can cause your code to be less resistant to changes in compiler optimizations and the implementation of library functions. For this reason, you should avoid using inline functions for optimization unless you have tried all other optimization techniques. Making a function or method inline can sometimes improve performance, but that is not always the case. Therefore, you should also use performance measurements to verify that making any given function inline does in fact have a positive effect.

The `inline` modifier can be applied to functions at the top level, at the module level, or at the method level in a class.

The following code example illustrates an inline function at the top level, an inline instance method, and an inline static method.

```
let inline increment x = x + 1
type WrapInt32() =
    member inline this.incrementByOne(x) = x + 1
    static member inline Increment(x) = x + 1
```

## Inline Functions and Type Inference

The presence of `inline` affects type inference. This is because inline functions can have statically resolved type parameters, whereas non-inline functions cannot. The following code example shows a case where `inline` is helpful because you are using a function that has a statically resolved type parameter, the `float` conversion operator.

```
let inline printAsFloatingPoint number =
    printfn "%f" (float number)
```

Without the `inline` modifier, type inference forces the function to take a specific type, in this case `int`. But with the `inline` modifier, the function is also inferred to have a statically resolved type parameter. With the `inline` modifier, the type is inferred to be the following:

```
^a -> unit when ^a : (static member op_Explicit : ^a -> float)
```

This means that the function accepts any type that supports a conversion to `float`.

## See also

- Functions
- Constraints
- Statically Resolved Type Parameters

# Values

12/19/2018 • 3 minutes to read • [Edit Online](#)

Values in F# are quantities that have a specific type; values can be integral or floating point numbers, characters or text, lists, sequences, arrays, tuples, discriminated unions, records, class types, or function values.

## Binding a Value

The term *binding* means associating a name with a definition. The `let` keyword binds a value, as in the following examples:

```
let a = 1
let b = 100u
let str = "text"

// A function value binding.

let f x = x + 1
```

The type of a value is inferred from the definition. For a primitive type, such as an integral or floating point number, the type is determined from the type of the literal. Therefore, in the previous example, the compiler infers the type of `b` to be `unsigned int`, whereas the compiler infers the type of `a` to be `int`. The type of a function value is determined from the return value in the function body. For more information about function value types, see [Functions](#). For more information about literal types, see [Literals](#).

The compiler does not issue diagnostics about unused bindings by default. To receive these messages, enable warning 1182 in your project file or when invoking the compiler (see `--warnon` under [Compiler Options](#)).

## Why Immutable?

Immutable values are values that cannot be changed throughout the course of a program's execution. If you are used to languages such as C++, Visual Basic, or C#, you might find it surprising that F# puts primacy over immutable values rather than variables that can be assigned new values during the execution of a program. Immutable data is an important element of functional programming. In a multithreaded environment, shared mutable variables that can be changed by many different threads are difficult to manage. Also, with mutable variables, it can sometimes be hard to tell if a variable might be changed when it is passed to another function.

In pure functional languages, there are no variables, and functions behave strictly as mathematical functions. Where code in a procedural language uses a variable assignment to alter a value, the equivalent code in a functional language has an immutable value that is the input, an immutable function, and different immutable values as the output. This mathematical strictness allows for tighter reasoning about the behavior of the program. This tighter reasoning is what enables compilers to check code more stringently and to optimize more effectively, and helps make it easier for developers to understand and write correct code. Functional code is therefore likely to be easier to debug than ordinary procedural code.

F# is not a pure functional language, yet it fully supports functional programming. Using immutable values is a good practice because doing this allows your code to benefit from an important aspect of functional programming.

## Mutable Variables

You can use the keyword `mutable` to specify a variable that can be changed. Mutable variables in F# should generally have a limited scope, either as a field of a type or as a local value. Mutable variables with a limited scope are easier to control and are less likely to be modified in incorrect ways.

You can assign an initial value to a mutable variable by using the `let` keyword in the same way as you would define a value. However, the difference is that you can subsequently assign new values to mutable variables by using the `<-` operator, as in the following example.

```
let mutable x = 1
x <- x + 1
```

Values marked `mutable` may be automatically promoted to `'a ref` if captured by a closure, including forms that create closures, such as `seq` builders. If you wish to be notified when this occurs, enable warning 3180 in your project file or when invoking the compiler.

# Null Values

3/25/2019 • 3 minutes to read • [Edit Online](#)

This topic describes how the null value is used in F#.

## Null Value

The null value is not normally used in F# for values or variables. However, null appears as an abnormal value in certain situations. If a type is defined in F#, null is not permitted as a regular value unless the [AllowNullLiteral](#) attribute is applied to the type. If a type is defined in some other .NET language, null is a possible value, and when you are interoperating with such types, your F# code might encounter null values.

For a type defined in F# and used strictly from F#, the only way to create a null value using the F# library directly is to use [Unchecked.defaultof](#) or [Array.zeroCreate](#). However, for an F# type that is used from other .NET languages, or if you are using that type with an API that is not written in F#, such as the .NET Framework, null values can occur.

You can use the `option` type in F# when you might use a reference variable with a possible null value in another .NET language. Instead of null, with an F# `option` type, you use the option value `None` if there is no object. You use the option value `Some(obj)` with an object `obj` when there is an object. For more information, see [Options](#). Note that you can still pack a `null` value into an Option if, for `Some x`, `x` happens to be `null`. Because of this, it is important you use `None` when a value is `null`.

The `null` keyword is a valid keyword in the F# language, and you have to use it when you are working with .NET Framework APIs or other APIs that are written in another .NET language. The two situations in which you might need a null value are when you call a .NET API and pass a null value as an argument, and when you interpret the return value or an output parameter from a .NET method call.

To pass a null value to a .NET method, just use the `null` keyword in the calling code. The following code example illustrates this.

```
open System

// Pass a null value to a .NET method.
let ParseDateTime (str: string) =
    let (success, res) = DateTime.TryParse(str, null, System.Globalization.DateTimeStyles.AssumeUniversal)
    if success then
        Some(res)
    else
        None
```

To interpret a null value that is obtained from a .NET method, use pattern matching if you can. The following code example shows how to use pattern matching to interpret the null value that is returned from `ReadLine` when it tries to read past the end of an input stream.

```

// Open a file and create a stream reader.
let fileStream1 =
    try
        System.IO.File.OpenRead("TextFile1.txt")
    with
        | :? System.IO.FileNotFoundException -> printfn "Error: TextFile1.txt not found."; exit(1)

let streamReader = new System.IO.StreamReader(fileStream1)

// ProcessNextLine returns false when there is no more input;
// it returns true when there is more input.
let ProcessNextLine nextLine =
    match nextLine with
    | null -> false
    | inputString ->
        match ParseDateTime inputString with
        | Some(date) -> printfn "%s" (date.ToLocalTime().ToString())
        | None -> printfn "Failed to parse the input."
        true

// A null value returned from .NET method ReadLine when there is
// no more input.
while ProcessNextLine (streamReader.ReadLine()) do ()

```

Null values for F# types can also be generated in other ways, such as when you use `Array.zeroCreate`, which calls `Unchecked.defaultof`. You must be careful with such code to keep the null values encapsulated. In a library intended only for F#, you do not have to check for null values in every function. If you are writing a library for interoperation with other .NET languages, you might have to add checks for null input parameters and throw an `ArgumentNullException`, just as you do in C# or Visual Basic code.

You can use the following code to check if an arbitrary value is null.

```

match box value with
| null -> printf "The value is null."
| _ -> printf "The value is not null."

```

# Literals

2/12/2019 • 2 minutes to read • [Edit Online](#)

## NOTE

The API reference links in this article will take you to MSDN (for now).

This topic provides a table that shows how to specify the type of a literal in F#.

## Literal Types

The following table shows the literal types in F#. Characters that represent digits in hexadecimal notation are not case-sensitive; characters that identify the type are case-sensitive.

TYPE	DESCRIPTION	SUFFIX OR PREFIX	EXAMPLES
sbyte	signed 8-bit integer	y	<code>86y</code> <code>0b00000101y</code>
byte	unsigned 8-bit natural number	uy	<code>86uy</code> <code>0b00000101uy</code>
int16	signed 16-bit integer	s	<code>86s</code>
uint16	unsigned 16-bit natural number	us	<code>86us</code>
int	signed 32-bit integer	l or none	<code>86</code>
int32			<code>86l</code>
uint	unsigned 32-bit natural number	u or ul	<code>86u</code>
uint32			<code>86ul</code>
unativeint	native pointer as an unsigned natural number	un	<code>0x00002D3Fun</code>
int64	signed 64-bit integer	L	<code>86L</code>
uint64	unsigned 64-bit natural number	UL	<code>86UL</code>
single, float32	32-bit floating point number	F or f	<code>4.14F</code> or <code>4.14f</code>
		If	<code>0x00000000001f</code>

TYPE	DESCRIPTION	SUFFIX OR PREFIX	EXAMPLES
float; double	64-bit floating point number	none	4.14 or 2.3E+32 or 2.3e+32
		LF	0x0000000000000000LF
bigint	integer not limited to 64-bit representation	I	99999999999999999999999999999999I
decimal	fractional number represented as a fixed point or rational number	M or m	0.7833M or 0.7833m
Char	Unicode character	none	'a'
String	Unicode string	none	"text\n" or @"c :\filename" or """<book title="Paradise Lost">""" or "string1" + "string2"
			See also <a href="#">Strings</a> .
byte	ASCII character	B	'a' B
byte[]	ASCII string	B	"text" B
String or byte[]	verbatim string	@ prefix	@"\server\share" (Unicode) @"\\server\\share" B (ASCII)

## Remarks

Unicode strings can contain explicit encodings that you can specify by using `\u` followed by a 16-bit hexadecimal code or UTF-32 encodings that you can specify by using `\u` followed by a 32-bit hexadecimal code that represents a Unicode surrogate pair.

As of F# 3.1, you can use the `+` sign to combine string literals. You can also use the bitwise or (`|||`) operator to combine enum flags. For example, the following code is legal in F# 3.1:

```
[<Literal>]
let Literal1 = "a" + "b"

[<Literal>]
let FileLocation = __SOURCE_DIRECTORY__ + "/" + __SOURCE_FILE__

[<Literal>]
let Literal2 = 1 ||| 64

[<Literal>]
let Literal3 = System.IO.FileAccess.Read ||| System.IO.FileAccess.Write
```

The use of other bitwise operators isn't allowed.

## Named Literals

Values that are intended to be constants can be marked with the [Literal](#) attribute. This attribute has the effect of causing a value to be compiled as a constant.

In pattern matching expressions, identifiers that begin with lowercase characters are always treated as variables to be bound, rather than as literals, so you should generally use initial capitals when you define literals.

## Integers In Other Bases

Signed 32-bit integers can also be specified in hexadecimal, octal, or binary using a `0x`, `0o` or `0b` prefix respectively.

```
let numbers = (0x9F, 0o77, 0b1010)
// Result: numbers : int * int * int = (159, 63, 10)
```

## Underscores in Numeric Literals

Starting with F# 4.1, you can separate digits with the underscore character (`_`).

```
let value = 0xDEAD_BEEF

let valueAsBits = 0b1101_1110_1010_1101_1011_1110_1110_1111

let exampleSSN = 123_456_7890
```

# F# Types

5/4/2018 • 4 minutes to read • [Edit Online](#)

This topic describes the types that are used in F# and how F# types are named and described.

## Summary of F# Types

Some types are considered *primitive types*, such as the Boolean type `bool` and integral and floating point types of various sizes, which include types for bytes and characters. These types are described in [Primitive Types](#).

Other types that are built into the language include tuples, lists, arrays, sequences, records, and discriminated unions. If you have experience with other .NET languages and are learning F#, you should read the topics for each of these types. Links to more information about these types are included in the [Related Topics](#) section of this topic. These F#-specific types support styles of programming that are common to functional programming languages. Many of these types have associated modules in the F# library that support common operations on these types.

The type of a function includes information about the parameter types and return type.

The .NET Framework is the source of object types, interface types, delegate types, and others. You can define your own object types just as you can in any other .NET language.

Also, F# code can define aliases, which are named *type abbreviations*, that are alternative names for types. You might use type abbreviations when the type might change in the future and you want to avoid changing the code that depends on the type. Or, you might use a type abbreviation as a friendly name for a type that can make code easier to read and understand.

F# provides useful collection types that are designed with functional programming in mind. Using these collection types helps you write code that is more functional in style. For more information, see [F# Collection Types](#).

## Syntax for Types

In F# code, you often have to write out the names of types. Every type has a syntactic form, and you use these syntactic forms in type annotations, abstract method declarations, delegate declarations, signatures, and other constructs. Whenever you declare a new program construct in the interpreter, the interpreter prints the name of the construct and the syntax for its type. This syntax might be just an identifier for a user-defined type or a built-in identifier such as for `int` or `string`, but for more complex types, the syntax is more complex.

The following table shows aspects of the type syntax for F# types.

TYPE	TYPE SYNTAX	EXAMPLES
primitive type	<i>type-name</i>	<code>int</code> <code>float</code> <code>string</code>
aggregate type (class, structure, union, record, enum, and so on)	<i>type-name</i>	<code>System.DateTime</code> <code>Color</code>

TYPE	TYPE SYNTAX	EXAMPLES
type abbreviation	<i>type-abbreviation-name</i>	<code>bigint</code>
fully qualified type	<i>namespaces.type-name</i> or <i>modules.type-name</i> or <i>namespaces.modules.type-name</i>	<code>System.IO.StreamWriter</code>
array	<i>type-name[]</i> or <i>type-name array</i>	<code>int[]</code> <code>array&lt;int&gt;</code> <code>int array</code>
two-dimensional array	<i>type-name[,]</i>	<code>int[,]</code> <code>float[,]</code>
three-dimensional array	<i>type-name[,,]</i>	<code>float[,,]</code>
tuple	<i>type-name1 * type-name2 ...</i>	For example, <code>(1, 'b', 3)</code> has type <code>int * char * int</code>
generic type	<i>type-parameter generic-type-name</i> or <i>generic-type-name&lt;type-parameter-list&gt;</i>	<code>'a list</code> <code>list&lt;'a&gt;</code> <code>Dictionary&lt;'key, 'value&gt;</code>
constructed type (a generic type that has a specific type argument supplied)	<i>type-argument generic-type-name</i> or <i>generic-type-name&lt;type-argument-list&gt;</i>	<code>int option</code> <code>string list</code> <code>int ref</code> <code>option&lt;int&gt;</code> <code>list&lt;string&gt;</code> <code>ref&lt;int&gt;</code> <code>Dictionary&lt;int, string&gt;</code>
function type that has a single parameter	<i>parameter-type1 -&gt; return-type</i>	A function that takes an <code>int</code> and returns a <code>string</code> has type <code>int -&gt; string</code>
function type that has multiple parameters	<i>parameter-type1 -&gt; parameter-type2 -&gt; ... -&gt; return-type</i>	A function that takes an <code>int</code> and a <code>float</code> and returns a <code>string</code> has type <code>int -&gt; float -&gt; string</code>

TYPE	TYPE SYNTAX	EXAMPLES
higher order function as a parameter	( <i>function-type</i> )	<code>List.map</code> has type <code>('a -&gt; 'b) -&gt; 'a list -&gt; 'b list</code>
delegate	delegate of <i>function-type</i>	<code>delegate of unit -&gt; int</code>
flexible type	# <i>type-name</i>	<code>#System.Windows.Forms.Control</code> <code>#seq&lt;int&gt;</code>

# Type Inference

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic describes how the F# compiler infers the types of values, variables, parameters and return values.

## Type Inference in General

The idea of type inference is that you do not have to specify the types of F# constructs except when the compiler cannot conclusively deduce the type. Omitting explicit type information does not mean that F# is a dynamically typed language or that values in F# are weakly typed. F# is a statically typed language, which means that the compiler deduces an exact type for each construct during compilation. If there is not enough information for the compiler to deduce the types of each construct, you must supply additional type information, typically by adding explicit type annotations somewhere in the code.

## Inference of Parameter and Return Types

In a parameter list, you do not have to specify the type of each parameter. And yet, F# is a statically typed language, and therefore every value and expression has a definite type at compile time. For those types that you do not specify explicitly, the compiler infers the type based on the context. If the type is not otherwise specified, it is inferred to be generic. If the code uses a value inconsistently, in such a way that there is no single inferred type that satisfies all the uses of a value, the compiler reports an error.

The return type of a function is determined by the type of the last expression in the function.

For example, in the following code, the parameter types `a` and `b` and the return type are all inferred to be `int` because the literal `100` is of type `int`.

```
let f a b = a + b + 100
```

You can influence type inference by changing the literals. If you make the `100` a `uint32` by appending the suffix `u`, the types of `a`, `b`, and the return value are inferred to be `uint32`.

You can also influence type inference by using other constructs that imply restrictions on the type, such as functions and methods that work with only a particular type.

Also, you can apply explicit type annotations to function or method parameters or to variables in expressions, as shown in the following examples. Errors result if conflicts occur between different constraints.

```
// Type annotations on a parameter.  
let addu1 (x : uint32) y =  
    x + y  
  
// Type annotations on an expression.  
let addu2 x y =  
    (x : uint32) + y
```

You can also explicitly specify the return value of a function by providing a type annotation after all the parameters.

```
let addu1 x y : uint32 =
    x + y
```

A common case where a type annotation is useful on a parameter is when the parameter is an object type and you want to use a member.

```
let replace(str: string) =
    str.Replace("A", "a")
```

## Automatic Generalization

If the function code is not dependent on the type of a parameter, the compiler considers the parameter to be generic. This is called *automatic generalization*, and it can be a powerful aid to writing generic code without increasing complexity.

For example, the following function combines two parameters of any type into a tuple.

```
let makeTuple a b = (a, b)
```

The type is inferred to be

```
'a -> 'b -> 'a * 'b
```

## Additional Information

Type inference is described in more detail in the F# Language Specification.

# Basic types

12/19/2018 • 2 minutes to read • [Edit Online](#)

This topic lists the basic types that are defined in the F# language. These types are the most fundamental in F#, forming the basis of nearly every F# program. They are a superset of .NET primitive types.

TYPE	.NET TYPE	DESCRIPTION
<code>bool</code>	<code>Boolean</code>	Possible values are <code>true</code> and <code>false</code> .
<code>byte</code>	<code>Byte</code>	Values from 0 to 255.
<code>sbyte</code>	<code>SByte</code>	Values from -128 to 127.
<code>int16</code>	<code>Int16</code>	Values from -32768 to 32767.
<code>uint16</code>	<code>UInt16</code>	Values from 0 to 65535.
<code>int</code>	<code>Int32</code>	Values from -2,147,483,648 to 2,147,483,647.
<code>uint32</code>	<code>UInt32</code>	Values from 0 to 4,294,967,295.
<code>int64</code>	<code>Int64</code>	Values from -9,223,372,036,854,775,808 to 9,223,372,036,854,775,807.
<code>uint64</code>	<code>UInt64</code>	Values from 0 to 18,446,744,073,709,551,615.
<code>nativeint</code>	<code>IntPtr</code>	A native pointer as a signed integer.
<code>unativeint</code>	<code>UIntPtr</code>	A native pointer as an unsigned integer.
<code>char</code>	<code>Char</code>	Unicode character values.
<code>string</code>	<code>String</code>	Unicode text.
<code>decimal</code>	<code>Decimal</code>	A floating point data type that has at least 28 significant digits.
<code>unit</code>	not applicable	Indicates the absence of an actual value. The type has only one formal value, which is denoted <code>()</code> . The unit value, <code>()</code> , is often used as a placeholder where a value is needed but no real value is available or makes sense.
<code>void</code>	<code>Void</code>	Indicates no type or value.

TYPE	.NET TYPE	DESCRIPTION
<code>float32</code> , <code>single</code>	<code>Single</code>	A 32-bit floating point type.
<code>float</code> , <code>double</code>	<code>Double</code>	A 64-bit floating point type.

#### NOTE

You can perform computations with integers too big for the 64-bit integer type by using the `bigint` type. `bigint` is not considered a basic type; it is an abbreviation for `System.Numerics.BigInteger`.

# Unit Type

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `unit` type is a type that indicates the absence of a specific value; the `unit` type has only a single value, which acts as a placeholder when no other value exists or is needed.

## Syntax

```
// The value of the unit type.  
()
```

## Remarks

Every F# expression must evaluate to a value. For expressions that do not generate a value that is of interest, the value of type `unit` is used. The `unit` type resembles the `void` type in languages such as C# and C++.

The `unit` type has a single value, and that value is indicated by the token `()`.

The value of the `unit` type is often used in F# programming to hold the place where a value is required by the language syntax, but when no value is needed or desired. An example might be the return value of a `printf` function. Because the important actions of the `printf` operation occur in the function, the function does not have to return an actual value. Therefore, the return value is of type `unit`.

Some constructs expect a `unit` value. For example, a `do` binding or any code at the top level of a module is expected to evaluate to a `unit` value. The compiler reports a warning when a `do` binding or code at the top level of a module produces a result other than the `unit` value that is not used, as shown in the following example.

```
let function1 x y = x + y  
// The next line results in a compiler warning.  
function1 10 20  
// Changing the code to one of the following eliminates the warning.  
// Use this when you do want the return value.  
let result = function1 10 20  
// Use this if you are only calling the function for its side effects,  
// and do not want the return value.  
function1 10 20 |> ignore
```

This warning is a characteristic of functional programming; it does not appear in other .NET programming languages. In a purely functional program, in which functions do not have any side effects, the final return value is the only result of a function call. Therefore, when the result is ignored, it is a possible programming error. Although F# is not a purely functional programming language, it is a good practice to follow functional programming style whenever possible.

# Strings

12/19/2018 • 3 minutes to read • [Edit Online](#)

## NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

The `string` type represents immutable text as a sequence of Unicode characters. `string` is an alias for `System.String` in the .NET Framework.

## Remarks

String literals are delimited by the quotation mark ("") character. The backslash character (\) is used to encode certain special characters. The backslash and the next character together are known as an *escape sequence*. Escape sequences supported in F# string literals are shown in the following table.

CHARACTER	ESCAPE SEQUENCE
Backspace	\b
Newline	\n
Carriage return	\r
Tab	\t
Backslash	\\\
Quotation mark	\"
Apostrophe	\'
Unicode character	\uXXXX or \uXXXX (where X indicates a hexadecimal digit)

If preceded by the @ symbol, the literal is a verbatim string. This means that any escape sequences are ignored, except that two quotation mark characters are interpreted as one quotation mark character.

Additionally, a string may be enclosed by triple quotes. In this case, all escape sequences are ignored, including double quotation mark characters. To specify a string that contains an embedded quoted string, you can either use a verbatim string or a triple-quoted string. If you use a verbatim string, you must specify two quotation mark characters to indicate a single quotation mark character. If you use a triple-quoted string, you can use the single quotation mark characters without them being parsed as the end of the string. This technique can be useful when you work with XML or other structures that include embedded quotation marks.

```
// Using a verbatim string
let xmlFragment1 = @<book author="Milton, John" title="Paradise Lost">"

// Using a triple-quoted string
let xmlFragment2 = """<book author="Milton, John" title="Paradise Lost">"""
```

In code, strings that have line breaks are accepted and the line breaks are interpreted literally as newlines, unless a backslash character is the last character before the line break. Leading white space on the next line is ignored when the backslash character is used. The following code produces a string `str1` that has value `"abc\ndef"` and a string `str2` that has value `"abcdef"`.

```
let str1 = "abc
def"
let str2 = "abc\
def"
```

You can access individual characters in a string by using array-like syntax, as follows.

```
printfn "%c" str1.[1]
```

The output is `b`.

Or you can extract substrings by using array slice syntax, as shown in the following code.

```
printfn "%s" (str1.[0..2])
printfn "%s" (str2.[3..5])
```

The output is as follows.

```
abc
def
```

You can represent ASCII strings by arrays of unsigned bytes, type `byte[]`. You add the suffix `B` to a string literal to indicate that it is an ASCII string. ASCII string literals used with byte arrays support the same escape sequences as Unicode strings, except for the Unicode escape sequences.

```
// "abc" interpreted as a Unicode string.
let str1 : string = "abc"
// "abc" interpreted as an ASCII byte array.
let bytarray : byte[] = "abc"B
```

## String Operators

There are two ways to concatenate strings: by using the `+` operator or by using the `^` operator. The `+` operator maintains compatibility with the .NET Framework string handling features.

The following example illustrates string concatenation.

```
let string1 = "Hello, " + "world"
```

## String Class

Because the string type in F# is actually a .NET Framework `System.String` type, all the `System.String` members are available. This includes the `+` operator, which is used to concatenate strings, the `Length` property, and the `Chars` property, which returns the string as an array of Unicode characters. For more information about strings, see [System.String](#).

By using the `Chars` property of `System.String`, you can access the individual characters in a string by specifying an index, as is shown in the following code.

```
let printChar (str : string) (index : int) =
    printfn "First character: %c" (str.Chars(index))
```

## String Module

Additional functionality for string handling is included in the `String` module in the `FSharp.Core` namespace. For more information, see [Core.String Module](#).

- [F# Language Reference](#)

# Tuples

12/19/2018 • 5 minutes to read • [Edit Online](#)

A *tuple* is a grouping of unnamed but ordered values, possibly of different types. Tuples can either be reference types or structs.

## Syntax

```
(element, ... , element)  
struct(element, ... ,element )
```

## Remarks

Each *element* in the previous syntax can be any valid F# expression.

## Examples

Examples of tuples include pairs, triples, and so on, of the same or different types. Some examples are illustrated in the following code.

```
(1, 2)  
  
// Triple of strings.  
("one", "two", "three")  
  
// Tuple of generic types.  
(a, b)  
  
// Tuple that has mixed types.  
("one", 1, 2.0)  
  
// Tuple of integer expressions.  
(a + 1, b + 1)  
  
// Struct Tuple of floats  
struct (1.025f, 1.5f)
```

## Obtaining Individual Values

You can use pattern matching to access and assign names for tuple elements, as shown in the following code.

```
let print tuple1 =  
  match tuple1 with  
  | (a, b) -> printfn "Pair %A %A" a b
```

You can also deconstruct a tuple via pattern matching outside of a `match` expression via `let` binding:

```
let (a, b) = (1, 2)  
  
// Or as a struct  
let struct (c, d) = struct (1, 2)
```

Or you can pattern match on tuples as inputs to functions:

```
let getDistance ((x1,y1): float*float) ((x2,y2): float*float) =
    // Note the ability to work on individual elements
    (x1*x2 - y1*y2)
    |> abs
    |> sqrt
```

If you need only one element of the tuple, the wildcard character (the underscore) can be used to avoid creating a new name for a value that you do not need.

```
let (a, _) = (1, 2)
```

Copying elements from a reference tuple into a struct tuple is also simple:

```
// Create a reference tuple
let (a, b) = (1, 2)

// Construct a struct tuple from it
let struct (c, d) = struct (a, b)
```

The functions `fst` and `snd` (reference tuples only) return the first and second elements of a tuple, respectively.

```
let c = fst (1, 2)
let d = snd (1, 2)
```

There is no built-in function that returns the third element of a triple, but you can easily write one as follows.

```
let third (_, _, c) = c
```

Generally, it is better to use pattern matching to access individual tuple elements.

## Using Tuples

Tuples provide a convenient way to return multiple values from a function, as shown in the following example. This example performs integer division and returns the rounded result of the operation as a first member of a tuple pair and the remainder as a second member of the pair.

```
let divRem a b =
    let x = a / b
    let y = a % b
    (x, y)
```

Tuples can also be used as function arguments when you want to avoid the implicit currying of function arguments that is implied by the usual function syntax.

```
let sumNoCurry (a, b) = a + b
```

The usual syntax for defining the function `let sum a b = a + b` enables you to define a function that is the partial application of the first argument of the function, as shown in the following code.

```
let sum a b = a + b

let addTen = sum 10
let result = addTen 95
// Result is 105.
```

Using a tuple as the parameter disables currying. For more information, see "Partial Application of Arguments" in [Functions](#).

## Names of Tuple Types

When you write out the name of a type that is a tuple, you use the `*` symbol to separate elements. For a tuple that consists of an `int`, a `float`, and a `string`, such as `(10, 10.0, "ten")`, the type would be written as follows.

```
int * float * string
```

## Interoperation with C# Tuples

C# 7.0 introduced tuples to the language. Tuples in C# are structs, and are equivalent to struct tuples in F#. If you need to interoperate with C#, you must use struct tuples.

This is easy to do. For example, imagine you have to pass a tuple to a C# class and then consume its result, which is also a tuple:

```
namespace CSharpTupleInterop
{
    public static class Example
    {
        public static (int, int) AddOneToXAndY((int x, int y) a) =>
            (a.x + 1, a.y + 1);
    }
}
```

In your F# code, you can then pass a struct tuple as the parameter and consume the result as a struct tuple.

```
open TupleInterop

let struct (newX, newY) = Example.AddOneToXAndY(struct (1, 2))
// newX is now 2, and newY is now 3
```

## Converting between Reference Tuples and Struct Tuples

Because Reference Tuples and Struct Tuples have a completely different underlying representation, they are not implicitly convertible. That is, code such as the following won't compile:

```
// Will not compile!
let (a, b) = struct (1, 2)

// Will not compile!
let struct (c, d) = (1, 2)

// Won't compile!
let f(t: struct(int*int)): int*int = t
```

You must pattern match on one tuple and construct the other with the constituent parts. For example:

```
// Pattern match on the result.  
let (a, b) = (1, 2)  
  
// Construct a new tuple from the parts you pattern matched on.  
let struct (c, d) = struct (a, b)
```

## Compiled Form of Reference Tuples

This section explains the form of tuples when they're compiled. The information here isn't necessary to read unless you are targeting .NET Framework 3.5 or lower.

Tuples are compiled into objects of one of several generic types, all named `System.Tuple`, that are overloaded on the arity, or number of type parameters. Tuple types appear in this form when you view them from another language, such as C# or Visual Basic, or when you are using a tool that is not aware of F# constructs. The `Tuple` types were introduced in .NET Framework 4. If you are targeting an earlier version of the .NET Framework, the compiler uses versions of `System.Tuple` from the 2.0 version of the F# Core Library. The types in this library are used only for applications that target the 2.0, 3.0, and 3.5 versions of the .NET Framework. Type forwarding is used to ensure binary compatibility between .NET Framework 2.0 and .NET Framework 4 F# components.

### Compiled Form of Struct Tuples

Struct tuples (for example, `struct (x, y)`), are fundamentally different from reference tuples. They are compiled into the `ValueTuple` type, overloaded by arity, or the number of type parameters. They are equivalent to [C# 7.0 Tuples](#) and [Visual Basic 2017 Tuples](#), and interoperate bidirectionally.

# F# Collection Types

9/5/2018 • 15 minutes to read • [Edit Online](#)

By reviewing this topic, you can determine which F# collection type best suits a particular need. These collection types differ from the collection types in the .NET Framework, such as those in the `System.Collections.Generic` namespace, in that the F# collection types are designed from a functional programming perspective rather than an object-oriented perspective. More specifically, only the array collection has mutable elements. Therefore, when you modify a collection, you create an instance of the modified collection instead of altering the original collection.

Collection types also differ in the type of data structure in which objects are stored. Data structures such as hash tables, linked lists, and arrays have different performance characteristics and a different set of available operations.

## F# Collection Types

The following table shows F# collection types.

Type	Description	Related Links
List	An ordered, immutable series of elements of the same type. Implemented as a linked list.	<a href="#">Lists</a> <a href="#">List Module</a>
Array	A fixed-size, zero-based, mutable collection of consecutive data elements that are all of the same type.	<a href="#">Arrays</a> <a href="#">Array Module</a> <a href="#">Array2D Module</a> <a href="#">Array3D Module</a>
seq	A logical series of elements that are all of one type. Sequences are particularly useful when you have a large, ordered collection of data but don't necessarily expect to use all the elements. Individual sequence elements are computed only as required, so a sequence can perform better than a list if not all the elements are used. Sequences are represented by the <code>seq&lt;'T&gt;</code> type, which is an alias for <code>IEnumerable&lt;T&gt;</code> . Therefore, any .NET Framework type that implements <code>System.Collections.Generic.IEnumerable&lt;'T&gt;</code> can be used as a sequence.	<a href="#">Sequences</a> <a href="#">Seq Module</a>
Map	An immutable dictionary of elements. Elements are accessed by key.	<a href="#">Map Module</a>
Set	An immutable set that's based on binary trees, where comparison is the F# structural comparison function, which potentially uses implementations of the <code>System.IComparable</code> interface on key values.	<a href="#">Set Module</a>

### Table of Functions

This section compares the functions that are available on F# collection types. The computational complexity of the function is given, where N is the size of the first collection, and M is the size of the second collection, if any. A dash (-) indicates that this function isn't available on the collection. Because sequences are lazily evaluated, a function such as Seq.distinct may be O(1) because it returns immediately, although it still affects the performance of the sequence when enumerated.

Function	Array	List	Sequence	Map	Set	Description
-	-	-	-	-	-	-

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
append	O(M)	O(N)	O(N)	-	-	Returns a new collection that contains the elements of the first collection followed by elements of the second collection.
add	-	-	-	O(log N)	O(log N)	Returns a new collection with the element added.
average	O(N)	O(N)	O(N)	-	-	Returns the average of the elements in the collection.
averageBy	O(N)	O(N)	O(N)	-	-	Returns the average of the results of the provided function applied to each element.
blit	O(N)	-	-	-	-	Copies a section of an array.
cache	-	-	O(N)	-	-	Computes and stores elements of a sequence.
cast	-	-	O(N)	-	-	Converts the elements to the specified type.
choose	O(N)	O(N)	O(N)	-	-	Applies the given function <code>f</code> to each element <code>x</code> of the list. Returns the list that contains the results for each element where the function returns <code>Some(f(x))</code> .
collect	O(N)	O(N)	O(N)	-	-	Applies the given function to each element of the collection, concatenates all the results, and returns the combined list.
compareWith	-	-	O(N)	-	-	Compares two sequences by using the given comparison function, element by element.
concat	O(N)	O(N)	O(N)	-	-	Combines the given enumeration-of-enumerations as a single concatenated enumeration.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
contains	-	-	-	-	O(log N)	Returns true if the set contains the specified element.
containsKey	-	-	-	O(log N)	-	Tests whether an element is in the domain of a map.
count	-	-	-	-	O(N)	Returns the number of elements in the set.
countBy	-	-	O(N)	-	-	Applies a key-generating function to each element of a sequence, and returns a sequence that yields unique keys and their number of occurrences in the original sequence.
copy	O(N)	-	O(N)	-	-	Copies the collection.
create	O(N)	-	-	-	-	Creates an array of whole elements that are all initially the given value.
delay	-	-	O(1)	-	-	Returns a sequence that's built from the given delayed specification of a sequence.
difference	-	-	-	-	O(M * log N)	Returns a new set with the elements of the second set removed from the first set.
distinct			O(1)*			Returns a sequence that contains no duplicate entries according to generic hash and equality comparisons on the entries. If an element occurs multiple times in the sequence, later occurrences are discarded.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
distinctBy			O(1)*			Returns a sequence that contains no duplicate entries according to the generic hash and equality comparisons on the keys that the given key-generating function returns. If an element occurs multiple times in the sequence, later occurrences are discarded.
empty	O(1)	O(1)	O(1)	O(1)	O(1)	Creates an empty collection.
exists	O(N)	O(N)	O(N)	O(log N)	O(log N)	Tests whether any element of the sequence satisfies the given predicate.
exists2	O(min(N,M))	-	O(min(N,M))			Tests whether any pair of corresponding elements of the input sequences satisfies the given predicate.
fill	O(N)					Sets a range of elements of the array to the given value.
filter	O(N)	O(N)	O(N)	O(N)	O(N)	Returns a new collection that contains only the elements of the collection for which the given predicate returns <code>true</code> .
find	O(N)	O(N)	O(N)	O(log N)	-	Returns the first element for which the given function returns <code>true</code> . Returns <code>System.Collections.Generic.IEnumerable&lt;T&gt;</code> if no such element exists.
findIndex	O(N)	O(N)	O(N)	-	-	Returns the index of the first element in the array that satisfies the given predicate. Raises <code>System.Collections.Generic.KeyNotFoundException</code> if no element satisfies the predicate.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
findKey	-	-	-	O(log N)	-	Evaluates the function on each mapping in the collection, and returns the key for the first mapping where the function returns <code>true</code> . If no such element exists, this function raises <code>InvalidOperationException</code> .
fold	O(N)	O(N)	O(N)	O(N)	O(N)	Applies a function to each element of the collection, threading an accumulator argument through the computation. If the input function is <code>f</code> and the elements are $i_0 \dots i_N$ , this function computes $f(\dots(f(s(i_0)) \dots) i_N)$ .
fold2	O(N)	O(N)	-	-	-	Applies a function to corresponding elements of two collections, threading an accumulator argument through the computation. The collections must have identical sizes. If the input function is <code>f</code> and the elements are $i_0 \dots i_N$ and $j_0 \dots j_N$ , this function computes $f(\dots(f(s(i_0) j_0) \dots) i_N j_N)$ .
foldBack	O(N)	O(N)	-	O(N)	O(N)	Applies a function to each element of the collection, threading an accumulator argument through the computation. If the input function is <code>f</code> and the elements are $i_0 \dots i_N$ , this function computes $f(i_0 (\dots(f(i_N s)))$ .

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
foldBack2	O(N)	O(N)	-	-	-	Applies a function to corresponding elements of two collections, threading an accumulator argument through the computation. The collections must have identical sizes. If the input function is $f$ and the elements are $i_0..i_N$ and $j_0..j_N$ , this function computes $f i_0 j_0 \dots (f i_N j_N s)$ .
forall	O(N)	O(N)	O(N)	O(N)	O(N)	Tests whether all elements of the collection satisfy the given predicate.
forall2	O(N)	O(N)	O(N)	-	-	Tests whether all corresponding elements of the collection satisfy the given predicate pairwise.
get / nth	O(1)	O(N)	O(N)	-	-	Returns an element from the collection given its index.
head	-	O(1)	O(1)	-	-	Returns the first element of the collection.
init	O(N)	O(N)	O(1)	-	-	Creates a collection given the dimension and a generator function to compute the elements.
initInfinite	-	-	O(1)	-	-	Generates a sequence that, when iterated, returns successive elements by calling the given function.
intersect	-	-	-	-	O(log N * log M)	Computes the intersection of two sets.
intersectMany	-	-	-	-	O(N1 * N2 ...)	Computes the intersection of a sequence of sets. The sequence must not be empty.
isEmpty	O(1)	O(1)	O(1)	O(1)	-	Returns <code>true</code> if the collection is empty.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
isProperSubset	-	-	-	-	$O(M * \log N)$	Returns <code>true</code> if all elements of the first set are in the second set, and at least one element of the second set isn't in the first set.
isProperSuperset	-	-	-	-	$O(M * \log N)$	Returns <code>true</code> if all elements of the second set are in the first set, and at least one element of the first set isn't in the second set.
isSubset	-	-	-	-	$O(M * \log N)$	Returns <code>true</code> if all elements of the first set are in the second set.
isSuperset	-	-	-	-	$O(M * \log N)$	Returns <code>true</code> if all elements of the second set are in the first set.
iter	$O(N)$	$O(N)$	$O(N)$	$O(N)$	$O(N)$	Applies the given function to each element of the collection.
iteri	$O(N)$	$O(N)$	$O(N)$	-	-	Applies the given function to each element of the collection. The integer that's passed to the function indicates the index of the element.
iteri2	$O(N)$	$O(N)$	-	-	-	Applies the given function to a pair of elements that are drawn from matching indices in two arrays. The integer that's passed to the function indicates the index of the elements. The two arrays must have the same length.
iter2	$O(N)$	$O(N)$	$O(N)$	-	-	Applies the given function to a pair of elements that are drawn from matching indices in two arrays. The two arrays must have the same length.
length	$O(1)$	$O(N)$	$O(N)$	-	-	Returns the number of elements in the collection.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
map	O(N)	O(N)	O(1)	-	-	Builds a collection whose elements are the results of applying the given function to each element of the array.
map2	O(N)	O(N)	O(1)	-	-	Builds a collection whose elements are the results of applying the given function to the corresponding elements of the two collections pairwise. The two input arrays must have the same length.
map3	-	O(N)	-	-	-	Builds a collection whose elements are the results of applying the given function to the corresponding elements of the three collections simultaneously.
mapi	O(N)	O(N)	O(N)	-	-	Builds an array whose elements are the results of applying the given function to each element of the array. The integer index that's passed to the function indicates the index of the element that's being transformed.
mapi2	O(N)	O(N)	-	-	-	Builds a collection whose elements are the results of applying the given function to the corresponding elements of the two collections pairwise, also passing the index of the elements. The two input arrays must have the same length.
max	O(N)	O(N)	O(N)	-	-	Returns the greatest element in the collection, compared by using the <a href="#">max</a> operator.
maxBy	O(N)	O(N)	O(N)	-	-	Returns the greatest element in the collection, compared by using <a href="#">max</a> on the function result.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
maxElement	-	-	-	-	O(log N)	Returns the greatest element in the set according to the ordering that's used for the set.
min	O(N)	O(N)	O(N)	-	-	Returns the least element in the collection, compared by using the <a href="#">min</a> operator.
minBy	O(N)	O(N)	O(N)	-	-	Returns the least element in the collection, compared by using the <a href="#">min</a> operator on the function result.
minElement	-	-	-	-	O(log N)	Returns the lowest element in the set according to the ordering that's used for the set.
ofArray	-	O(N)	O(1)	O(N)	O(N)	Creates a collection that contains the same elements as the given array.
ofList	O(N)	-	O(1)	O(N)	O(N)	Creates a collection that contains the same elements as the given list.
ofSeq	O(N)	O(N)	-	O(N)	O(N)	Creates a collection that contains the same elements as the given sequence.
pairwise	-	-	O(N)	-	-	Returns a sequence of each element in the input sequence and its predecessor except for the first element, which is returned only as the predecessor of the second element.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
partition	O(N)	O(N)	-	O(N)	O(N)	Splits the collection into two collections. The first collection contains the elements for which the given predicate returns <code>true</code> , and the second collection contains the elements for which the given predicate returns <code>false</code> .
permute	O(N)	O(N)	-	-	-	Returns an array with all elements permuted according to the specified permutation.
pick	O(N)	O(N)	O(N)	O(log N)	-	Applies the given function to successive elements, returning the first result where the function returns <code>Some</code> . If the function never returns <code>Some</code> , <code>System.Collections.Generic</code> is raised.
readonly	-	-	O(N)	-	-	Creates a sequence object that delegates to the given sequence object. This operation ensures that a type cast can't rediscover and mutate the original sequence. For example, if given an array, the returned sequence will return the elements of the array, but you can't cast the returned sequence object to an array.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
reduce	O(N)	O(N)	O(N)	-	-	Applies a function to each element of the collection, threading an accumulator argument through the computation. This function starts by applying the function to the first two elements, passes this result into the function along with the third element, and so on. The function returns the final result.
reduceBack	O(N)	O(N)	-	-	-	Applies a function to each element of the collection, threading an accumulator argument through the computation. If the input function is f and the elements are i0...iN, this function computes f i0 (...(f iN-1 iN)).
remove	-	-	-	O(log N)	O(log N)	Removes an element from the domain of the map. No exception is raised if the element isn't present.
replicate	-	O(N)	-	-	-	Creates a list of a specified length with every element set to the given value.
rev	O(N)	O(N)	-	-	-	Returns a new list with the elements in reverse order.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
scan	O(N)	O(N)	O(N)	-	-	Applies a function to each element of the collection, threading an accumulator argument through the computation. This operation applies the function to the second argument and the first element of the list. The operation then passes this result into the function along with the second element and so on. Finally, the operation returns the list of intermediate results and the final result.
scanBack	O(N)	O(N)	-	-	-	Resembles the foldBack operation but returns both the intermediate and final results.
singleton	-	-	O(1)	-	O(1)	Returns a sequence that yields only one item.
set	O(1)	-	-	-	-	Sets an element of an array to the specified value.
skip	-	-	O(N)	-	-	Returns a sequence that skips N elements of the underlying sequence and then yields the remaining elements of the sequence.
skipWhile	-	-	O(N)	-	-	Returns a sequence that, when iterated, skips elements of the underlying sequence while the given predicate returns <code>true</code> and then yields the remaining elements of the sequence.
sort	O(N log N) average  O(N^2) worst case	O(N log N)	O(N log N)	-	-	Sorts the collection by element value. Elements are compared using <code>compare</code> .

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
sortBy	O(N log N) average  O(N^2) worst case	O(N log N)	O(N log N)	-	-	Sorts the given list by using keys that the given projection provides. Keys are compared using <a href="#">compare</a> .
sortInPlace	O(N log N) average  O(N^2) worst case	-	-	-	-	Sorts the elements of an array by mutating it in place and using the given comparison function. Elements are compared by using <a href="#">compare</a> .
sortInPlaceBy	O(N log N) average  O(N^2) worst case	-	-	-	-	Sorts the elements of an array by mutating it in place and using the given projection for the keys. Elements are compared by using <a href="#">compare</a> .
sortInPlaceWith	O(N log N) average  O(N^2) worst case	-	-	-	-	Sorts the elements of an array by mutating it in place and using the given comparison function as the order.
sortWith	O(N log N) average  O(N^2) worst case	O(N log N)	-	-	-	Sorts the elements of a collection, using the given comparison function as the order and returning a new collection.
sub	O(N)	-	-	-	-	Builds an array that contains the given subrange that's specified by starting index and length.
sum	O(N)	O(N)	O(N)	-	-	Returns the sum of the elements in the collection.
sumBy	O(N)	O(N)	O(N)	-	-	Returns the sum of the results that are generated by applying the function to each element of the collection.
tail	-	O(1)	-	-	-	Returns the list without its first element.

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
take	-	-	O(N)	-	-	Returns the elements of the sequence up to a specified count.
takeWhile	-	-	O(1)	-	-	Returns a sequence that, when iterated, yields elements of the underlying sequence while the given predicate returns <code>true</code> and then returns no more elements.
toArray	-	O(N)	O(N)	O(N)	O(N)	Creates an array from the given collection.
toList	O(N)	-	O(N)	O(N)	O(N)	Creates a list from the given collection.
toSeq	O(1)	O(1)	-	O(1)	O(1)	Creates a sequence from the given collection.
truncate	-	-	O(1)	-	-	Returns a sequence that, when enumerated, returns no more than N elements.
tryFind	O(N)	O(N)	O(N)	O(log N)	-	Searches for an element that satisfies a given predicate.
tryFindIndex	O(N)	O(N)	O(N)	-	-	Searches for the first element that satisfies a given predicate and returns the index of the matching element, or <code>None</code> if no such element exists.
tryFindKey	-	-	-	O(log N)	-	Returns the key of the first mapping in the collection that satisfies the given predicate, or returns <code>None</code> if no such element exists.
tryPick	O(N)	O(N)	O(N)	O(log N)	-	Applies the given function to successive elements, returning the first result where the function returns <code>Some</code> for some value. If no such element exists, the operation returns <code>None</code> .

FUNCTION	ARRAY	LIST	SEQUENCE	MAP	SET	DESCRIPTION
unfold	-	-	O(N)	-	-	Returns a sequence that contains the elements that the given computation generates.
union	-	-	-	-	O(M * log N)	Computes the union of the two sets.
unionMany	-	-	-	-	O(N1 * N2 ...)	Computes the union of a sequence of sets.
unzip	O(N)	O(N)	O(N)	-	-	Splits a list of pairs into two lists.
unzip3	O(N)	O(N)	O(N)	-	-	Splits a list of triples into three lists.
windowed	-	-	O(N)	-	-	Returns a sequence that yields sliding windows of containing elements that are drawn from the input sequence. Each window is returned as a fresh array.
zip	O(N)	O(N)	O(N)	-	-	Combines the two collections into a list of pairs. The two lists must have equal lengths.
zip3	O(N)	O(N)	O(N)	-	-	Combines the three collections into a list of triples. The lists must have equal lengths.

# Lists

12/20/2018 • 23 minutes to read • [Edit Online](#)

## NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

A list in F# is an ordered, immutable series of elements of the same type. To perform basic operations on lists, use the functions in the [List module](#).

## Creating and Initializing Lists

You can define a list by explicitly listing out the elements, separated by semicolons and enclosed in square brackets, as shown in the following line of code.

```
let list123 = [ 1; 2; 3 ]
```

You can also put line breaks between elements, in which case the semicolons are optional. The latter syntax can result in more readable code when the element initialization expressions are longer, or when you want to include a comment for each element.

```
let list123 = [  
    1  
    2  
    3 ]
```

Normally, all list elements must be the same type. An exception is that a list in which the elements are specified to be a base type can have elements that are derived types. Thus the following is acceptable, because both [Button](#) and [CheckBox](#) derive from [Control](#).

```
let myControlList : Control list = [ new Button(); new CheckBox() ]
```

You can also define list elements by using a range indicated by integers separated by the range operator (`..`), as shown in the following code.

```
let list1 = [ 1 .. 10 ]
```

An empty list is specified by a pair of square brackets with nothing in between them.

```
// An empty list.  
let listEmpty = []
```

You can also use a sequence expression to create a list. See [Sequence Expressions](#) for more information. For example, the following code creates a list of squares of integers from 1 to 10.

```
let listOfSquares = [ for i in 1 .. 10 -> i*i ]
```

# Operators for Working with Lists

You can attach elements to a list by using the `::` (cons) operator. If `list1` is `[2; 3; 4]`, the following code creates `list2` as `[100; 2; 3; 4]`.

```
let list2 = 100 :: list1
```

You can concatenate lists that have compatible types by using the `@` operator, as in the following code. If `list1` is `[2; 3; 4]` and `list2` is `[100; 2; 3; 4]`, this code creates `list3` as `[2; 3; 4; 100; 2; 3; 4]`.

```
let list3 = list1 @ list2
```

Functions for performing operations on lists are available in the [List module](#).

Because lists in F# are immutable, any modifying operations generate new lists instead of modifying existing lists.

Lists in F# are implemented as singly linked lists, which means that operations that access only the head of the list are O(1), and element access is O( $n$ ).

## Properties

The list type supports the following properties:

PROPERTY	TYPE	DESCRIPTION
<code>Head</code>	<code>'T</code>	The first element.
<code>Empty</code>	<code>'T list</code>	A static property that returns an empty list of the appropriate type.
<code>IsEmpty</code>	<code>bool</code>	<code>true</code> if the list has no elements.
<code>Item</code>	<code>'T</code>	The element at the specified index (zero-based).
<code>Length</code>	<code>int</code>	The number of elements.
<code>Tail</code>	<code>'T list</code>	The list without the first element.

Following are some examples of using these properties.

```
let list1 = [ 1; 2; 3 ]

// Properties
printfn "list1.IsEmpty is %b" (list1.IsEmpty)
printfn "list1.Length is %d" (list1.Length)
printfn "list1.Head is %d" (list1.Head)
printfn "list1.Tail.Head is %d" (list1.Tail.Head)
printfn "list1.Tail.Tail.Head is %d" (list1.Tail.Tail.Head)
printfn "list1.Item(1) is %d" (list1.Item(1))
```

## Using Lists

Programming with lists enables you to perform complex operations with a small amount of code. This section describes common operations on lists that are important to functional programming.

## Recursion with Lists

Lists are uniquely suited to recursive programming techniques. Consider an operation that must be performed on every element of a list. You can do this recursively by operating on the head of the list and then passing the tail of the list, which is a smaller list that consists of the original list without the first element, back again to the next level of recursion.

To write such a recursive function, you use the cons operator (`::`) in pattern matching, which enables you to separate the head of a list from the tail.

The following code example shows how to use pattern matching to implement a recursive function that performs operations on a list.

```
let rec sum list =
    match list with
    | head :: tail -> head + sum tail
    | [] -> 0
```

The previous code works well for small lists, but for larger lists, it could overflow the stack. The following code improves on this code by using an accumulator argument, a standard technique for working with recursive functions. The use of the accumulator argument makes the function tail recursive, which saves stack space.

```
let sum list =
    let rec loop list acc =
        match list with
        | head :: tail -> loop tail (acc + head)
        | [] -> acc
    loop list 0
```

The function `RemoveAllMultiples` is a recursive function that takes two lists. The first list contains the numbers whose multiples will be removed, and the second list is the list from which to remove the numbers. The code in the following example uses this recursive function to eliminate all the non-prime numbers from a list, leaving a list of prime numbers as the result.

```
let IsPrimeMultipleTest n x =
    x = n || x % n <> 0

let rec RemoveAllMultiples listn listx =
    match listn with
    | head :: tail -> RemoveAllMultiples tail (List.filter (IsPrimeMultipleTest head) listx)
    | [] -> listx

let GetPrimesUpTo n =
    let max = int (sqrt (float n))
    RemoveAllMultiples [ 2 .. max ] [ 1 .. n ]

printfn "Primes Up To %d:\n%A" 100 (GetPrimesUpTo 100)
```

The output is as follows:

```
Primes Up To 100:
[2; 3; 5; 7; 11; 13; 17; 19; 23; 29; 31; 37; 41; 43; 47; 53; 59; 61; 67; 71; 73; 79; 83; 89; 97]
```

# Module Functions

The [List module](#) provides functions that access the elements of a list. The head element is the fastest and easiest to access. Use the property [Head](#) or the module function [List.head](#). You can access the tail of a list by using the [Tail](#) property or the [List.tail](#) function. To find an element by index, use the [List.nth](#) function. [List.nth](#) traverses the list. Therefore, it is  $O(n)$ . If your code uses [List.nth](#) frequently, you might want to consider using an array instead of a list. Element access in arrays is  $O(1)$ .

## Boolean Operations on Lists

The [List.isEmpty](#) function determines whether a list has any elements.

The [List.exists](#) function applies a Boolean test to elements of a list and returns [true](#) if any element satisfies the test. [List.exists2](#) is similar but operates on successive pairs of elements in two lists.

The following code demonstrates the use of [List.exists](#).

```
// Use List.exists to determine whether there is an element of a list satisfies a given Boolean expression.  
// containsNumber returns true if any of the elements of the supplied list match  
// the supplied number.  
let containsNumber number list = List.exists (fun elem -> elem = number) list  
let list0to3 = [0 .. 3]  
printfn "For list %A, contains zero is %b" list0to3 (containsNumber 0 list0to3)
```

The output is as follows:

```
For list [0; 1; 2; 3], contains zero is true
```

The following example demonstrates the use of [List.exists2](#).

```
// Use List.exists2 to compare elements in two lists.  
// isEqualElement returns true if any elements at the same position in two supplied  
// lists match.  
let isEqualElement list1 list2 = List.exists2 (fun elem1 elem2 -> elem1 = elem2) list1 list2  
let list1to5 = [ 1 .. 5 ]  
let list5to1 = [ 5 .. -1 .. 1 ]  
if (isEqualElement list1to5 list5to1) then  
    printfn "Lists %A and %A have at least one equal element at the same position." list1to5 list5to1  
else  
    printfn "Lists %A and %A do not have an equal element at the same position." list1to5 list5to1
```

The output is as follows:

```
Lists [1; 2; 3; 4; 5] and [5; 4; 3; 2; 1] have at least one equal element at the same position.
```

You can use [List.forall](#) if you want to test whether all the elements of a list meet a condition.

```
let isAllZeroes list = List.forall (fun elem -> elem = 0.0) list  
printfn "%b" (isAllZeroes [0.0; 0.0])  
printfn "%b" (isAllZeroes [0.0; 1.0])
```

The output is as follows:

```
true  
false
```

Similarly, `List.forall2` determines whether all elements in the corresponding positions in two lists satisfy a Boolean expression that involves each pair of elements.

```
let listEqual list1 list2 = List.forall2 (fun elem1 elem2 -> elem1 = elem2) list1 list2
printfn "%b" (listEqual [0; 1; 2] [0; 1; 2])
printfn "%b" (listEqual [0; 0; 0] [0; 1; 0])
```

The output is as follows:

```
true
false
```

## Sort Operations on Lists

The `List.sort`, `List.sortBy`, and `List.sortWith` functions sort lists. The sorting function determines which of these three functions to use. `List.sort` uses default generic comparison. Generic comparison uses global operators based on the generic compare function to compare values. It works efficiently with a wide variety of element types, such as simple numeric types, tuples, records, discriminated unions, lists, arrays, and any type that implements `System.IComparable`. For types that implement `System.IComparable`, generic comparison uses the `System.IComparable.CompareTo()` function. Generic comparison also works with strings, but uses a culture-independent sorting order. Generic comparison should not be used on unsupported types, such as function types. Also, the performance of the default generic comparison is best for small structured types; for larger structured types that need to be compared and sorted frequently, consider implementing `System.IComparable` and providing an efficient implementation of the `System.IComparable.CompareTo()` method.

`List.sortBy` takes a function that returns a value that is used as the sort criterion, and `List.sortWith` takes a comparison function as an argument. These latter two functions are useful when you are working with types that do not support comparison, or when the comparison requires more complex comparison semantics, as in the case of culture-aware strings.

The following example demonstrates the use of `List.sort`.

```
let sortedList1 = List.sort [1; 4; 8; -2; 5]
printfn "%A" sortedList1
```

The output is as follows:

```
[-2; 1; 4; 5; 8]
```

The following example demonstrates the use of `List.sortBy`.

```
let sortedList2 = List.sortBy (fun elem -> abs elem) [1; 4; 8; -2; 5]
printfn "%A" sortedList2
```

The output is as follows:

```
[1; -2; 4; 5; 8]
```

The next example demonstrates the use of `List.sortWith`. In this example, the custom comparison function `compareWidgets` is used to first compare one field of a custom type, and then another when the values of the first field are equal.

```

type Widget = { ID: int; Rev: int }

let compareWidgets widget1 widget2 =
    if widget1.ID < widget2.ID then -1 else
    if widget1.ID > widget2.ID then 1 else
    if widget1.Rev < widget2.Rev then -1 else
    if widget1.Rev > widget2.Rev then 1 else
    0

let listToCompare =
    [ { ID = 92; Rev = 1 }
    { ID = 110; Rev = 1 }
    { ID = 100; Rev = 5 }
    { ID = 100; Rev = 2 }
    { ID = 92; Rev = 1 }
    ]

let sortedWidgetList = List.sortWith compareWidgets listToCompare
printfn "%A" sortedWidgetList

```

The output is as follows:

```
[{ID = 92;
Rev = 1}; {ID = 92;
Rev = 1}; {ID = 100;
Rev = 2}; {ID = 100;
Rev = 5}; {ID = 110;
Rev = 1}]
```

## Search Operations on Lists

Numerous search operations are supported for lists. The simplest, [List.find](#), enables you to find the first element that matches a given condition.

The following code example demonstrates the use of [List.find](#) to find the first number that is divisible by 5 in a list.

```

let isDivisibleBy number elem = elem % number = 0
let result = List.find (isDivisibleBy 5) [ 1 .. 100 ]
printfn "%d" result

```

The result is 5.

If the elements must be transformed first, call [List.pick](#), which takes a function that returns an option, and looks for the first option value that is `Some(x)`. Instead of returning the element, [List.pick](#) returns the result `x`. If no matching element is found, [List.pick](#) throws [System.Collections.Generic.KeyNotFoundException](#). The following code shows the use of [List.pick](#).

```

let valuesList = [ ("a", 1); ("b", 2); ("c", 3) ]

let resultPick = List.pick (fun elem ->
    match elem with
    | (value, 2) -> Some value
    | _ -> None) valuesList
printfn "%A" resultPick

```

The output is as follows:

```
"b"
```

Another group of search operations, [List.tryFind](#) and related functions, return an option value. The `List.tryFind` function returns the first element of a list that satisfies a condition if such an element exists, but the option value `None` if not. The variation `List.tryFindIndex` returns the index of the element, if one is found, rather than the element itself. These functions are illustrated in the following code.

```
let list1d = [1; 3; 7; 9; 11; 13; 15; 19; 22; 29; 36]
let isEven x = x % 2 = 0
match List.tryFind isEven list1d with
| Some value -> printfn "The first even value is %d." value
| None -> printfn "There is no even value in the list."

match List.tryFindIndex isEven list1d with
| Some value -> printfn "The first even value is at position %d." value
| None -> printfn "There is no even value in the list."
```

The output is as follows:

```
The first even value is 22.
The first even value is at position 8.
```

## Arithmetic Operations on Lists

Common arithmetic operations such as sum and average are built into the [List module](#). To work with `List.sum`, the list element type must support the `+` operator and have a zero value. All built-in arithmetic types satisfy these conditions. To work with `List.average`, the element type must support division without a remainder, which excludes integral types but allows for floating point types. The `List.sumBy` and `List.averageBy` functions take a function as a parameter, and this function's results are used to calculate the values for the sum or average.

The following code demonstrates the use of `List.sum`, `List.sumBy`, and `List.average`.

```
// Compute the sum of the first 10 integers by using List.sum.
let sum1 = List.sum [1 .. 10]

// Compute the sum of the squares of the elements of a list by using List.sumBy.
let sum2 = List.sumBy (fun elem -> elem*elem) [1 .. 10]

// Compute the average of the elements of a list by using List.average.
let avg1 = List.average [0.0; 1.0; 1.0; 2.0]

printfn "%f" avg1
```

The output is `1.000000`.

The following code shows the use of `List.averageBy`.

```
let avg2 = List.averageBy (fun elem -> float elem) [1 .. 10]
printfn "%f" avg2
```

The output is `5.5`.

## Lists and Tuples

Lists that contain tuples can be manipulated by `zip` and `unzip` functions. These functions combine two lists of single values into one list of tuples or separate one list of tuples into two lists of single values. The simplest `List.zip` function takes two lists of single elements and produces a single list of tuple pairs. Another version,

[List.zip3](#), takes three lists of single elements and produces a single list of tuples that have three elements. The following code example demonstrates the use of [List.zip](#).

```
let list1 = [ 1; 2; 3 ]
let list2 = [ -1; -2; -3 ]
let listZip = List.zip list1 list2
printfn "%A" listZip
```

The output is as follows:

```
[(1, -1); (2, -2); (3, -3)]
```

The following code example demonstrates the use of [List.zip3](#).

```
let list3 = [ 0; 0; 0]
let listZip3 = List.zip3 list1 list2 list3
printfn "%A" listZip3
```

The output is as follows:

```
[(1, -1, 0); (2, -2, 0); (3, -3, 0)]
```

The corresponding unzip versions, [List.unzip](#) and [List.unzip3](#), take lists of tuples and return lists in a tuple, where the first list contains all the elements that were first in each tuple, and the second list contains the second element of each tuple, and so on.

The following code example demonstrates the use of [List.unzip](#).

```
let lists = List.unzip [(1,2); (3,4)]
printfn "%A" lists
printfn "%A %A" (fst lists) (snd lists)
```

The output is as follows:

```
([1; 3], [2; 4])
[1; 3] [2; 4]
```

The following code example demonstrates the use of [List.unzip3](#).

```
let listsUnzip3 = List.unzip3 [(1,2,3); (4,5,6)]
printfn "%A" listsUnzip3
```

The output is as follows:

```
([1; 4], [2; 5], [3; 6])
```

## Operating on List Elements

F# supports a variety of operations on list elements. The simplest is [List.iter](#), which enables you to call a function on every element of a list. Variations include [List.iter2](#), which enables you to perform an operation on elements of two lists, [List.iteri](#), which is like [List.iter](#) except that the index of each element is passed as an argument to the function that is called for each element, and [List.iteri2](#), which is a combination of the

functionality of `List.iter2` and `List.iteri`. The following code example illustrates these functions.

```
let list1 = [1; 2; 3]
let list2 = [4; 5; 6]
List.iter (fun x -> printfn "List.iter: element is %d" x) list1
List.iteri(fun i x -> printfn "List.iteri: element %d is %d" i x) list1
List.iter2 (fun x y -> printfn "List.iter2: elements are %d %d" x y) list1 list2
List.iteri2 (fun i x y ->
    printfn "List.iteri2: element %d of list1 is %d element %d of list2 is %d"
    i x i y)
list1 list2
```

The output is as follows:

```
List.iter: element is 1
List.iter: element is 2
List.iter: element is 3
List.iteri: element 0 is 1
List.iteri: element 1 is 2
List.iteri: element 2 is 3
List.iter2: elements are 1 4
List.iter2: elements are 2 5
List.iter2: elements are 3 6
List.iteri2: element 0 of list1 is 1; element 0 of list2 is 4
List.iteri2: element 1 of list1 is 2; element 1 of list2 is 5
List.iteri2: element 2 of list1 is 3; element 2 of list2 is 6
```

Another frequently used function that transforms list elements is `List.map`, which enables you to apply a function to each element of a list and put all the results into a new list. `List.map2` and `List.map3` are variations that take multiple lists. You can also use `List.mapi` and `List.mapi2`, if, in addition to the element, the function needs to be passed the index of each element. The only difference between `List.mapi2` and `List.mapi` is that `List.mapi2` works with two lists. The following example illustrates `List.map`.

```
let list1 = [1; 2; 3]
let newList = List.map (fun x -> x + 1) list1
printfn "%A" newList
```

The output is as follows:

```
[2; 3; 4]
```

The following example shows the use of `List.map2`.

```
let list1 = [1; 2; 3]
let list2 = [4; 5; 6]
let sumList = List.map2 (fun x y -> x + y) list1 list2
printfn "%A" sumList
```

The output is as follows:

```
[5; 7; 9]
```

The following example shows the use of `List.map3`.

```
let newList2 = List.map3 (fun x y z -> x + y + z) list1 list2 [2; 3; 4]
printfn "%A" newList2
```

The output is as follows:

```
[7; 10; 13]
```

The following example shows the use of `List.mapi`.

```
let newListAddIndex = List.mapi (fun i x -> x + i) list1
printfn "%A" newListAddIndex
```

The output is as follows:

```
[1; 3; 5]
```

The following example shows the use of `List.mapi2`.

```
let listAddTimesIndex = List.mapi2 (fun i x y -> (x + y) * i) list1 list2
printfn "%A" listAddTimesIndex
```

The output is as follows:

```
[0; 7; 18]
```

`List.collect` is like `List.map`, except that each element produces a list and all these lists are concatenated into a final list. In the following code, each element of the list generates three numbers. These are all collected into one list.

```
let collectList = List.collect (fun x -> [for i in 1..3 -> x * i]) list1
printfn "%A" collectList
```

The output is as follows:

```
[1; 2; 3; 2; 4; 6; 3; 6; 9]
```

You can also use `List.filter`, which takes a Boolean condition and produces a new list that consists only of elements that satisfy the given condition.

```
let evenOnlyList = List.filter (fun x -> x % 2 = 0) [1; 2; 3; 4; 5; 6]
```

The resulting list is `[2; 4; 6]`.

A combination of map and filter, `List.choose` enables you to transform and select elements at the same time.

`List.choose` applies a function that returns an option to each element of a list, and returns a new list of the results for elements when the function returns the option value `Some`.

The following code demonstrates the use of `List.choose` to select capitalized words out of a list of words.

```
let listWords = [ "and"; "Rome"; "Bob"; "apple"; "zebra" ]
let isCapitalized (string1:string) = System.Char.IsUpper string1.[0]
let results = List.choose (fun elem ->
    match elem with
    | elem when isCapitalized elem -> Some(elem + "'s")
    | _ -> None) listWords
printfn "%A" results
```

The output is as follows:

```
["Rome's"; "Bob's"]
```

## Operating on Multiple Lists

Lists can be joined together. To join two lists into one, use [List.append](#). To join more than two lists, use [List.concat](#).

```
let list1to10 = List.append [1; 2; 3] [4; 5; 6; 7; 8; 9; 10]
let listResult = List.concat [ [1; 2; 3]; [4; 5; 6]; [7; 8; 9] ]
List.iter (fun elem -> printf "%d " elem) list1to10
printfn ""
List.iter (fun elem -> printf "%d " elem) listResult
```

## Fold and Scan Operations

Some list operations involve interdependencies between all of the list elements. The fold and scan operations are like [List.iter](#) and [List.map](#) in that you invoke a function on each element, but these operations provide an additional parameter called the *accumulator* that carries information through the computation.

Use [List.fold](#) to perform a calculation on a list.

The following code example demonstrates the use of [List.fold](#) to perform various operations.

The list is traversed; the accumulator `acc` is a value that is passed along as the calculation proceeds. The first argument takes the accumulator and the list element, and returns the interim result of the calculation for that list element. The second argument is the initial value of the accumulator.

```

let sumList list = List.fold (fun acc elem -> acc + elem) 0 list
printfn "Sum of the elements of list %A is %d." [ 1 .. 3 ] (sumList [ 1 .. 3 ])

// The following example computes the average of a list.
let averageList list = (List.fold (fun acc elem -> acc + float elem) 0.0 list / float list.Length)

// The following example computes the standard deviation of a list.
// The standard deviation is computed by taking the square root of the
// sum of the variances, which are the differences between each value
// and the average.
let stdDevList list =
    let avg = averageList list
    sqrt (List.fold (fun acc elem -> acc + (float elem - avg) ** 2.0 ) 0.0 list / float list.Length)

let testList listTest =
    printfn "List %A average: %f stddev: %f" listTest (averageList listTest) (stdDevList listTest)

testList [1; 1; 1]
testList [1; 2; 1]
testList [1; 2; 3]

// List.fold is the same as to List.iter when the accumulator is not used.
let printList list = List.fold (fun acc elem -> printfn "%A" elem) () list
printList [0.0; 1.0; 2.5; 5.1 ]

// The following example uses List.fold to reverse a list.
// The accumulator starts out as the empty list, and the function uses the cons operator
// to add each successive element to the head of the accumulator list, resulting in a
// reversed form of the list.
let reverseList list = List.fold (fun acc elem -> elem::acc) [] list
printfn "%A" (reverseList [1 .. 10])

```

The versions of these functions that have a digit in the function name operate on more than one list. For example, [List.fold2](#) performs computations on two lists.

The following example demonstrates the use of [List.fold2](#).

```

// Use List.fold2 to perform computations over two lists (of equal size) at the same time.
// Example: Sum the greater element at each list position.
let sumGreatest list1 list2 = List.fold2 (fun acc elem1 elem2 ->
                                            acc + max elem1 elem2) 0 list1 list2

let sum = sumGreatest [1; 2; 3] [3; 2; 1]
printfn "The sum of the greater of each pair of elements in the two lists is %d." sum

```

[List.fold](#) and [List.scan](#) differ in that [List.fold](#) returns the final value of the extra parameter, but [List.scan](#) returns the list of the intermediate values (along with the final value) of the extra parameter.

Each of these functions includes a reverse variation, for example, [List.foldBack](#), which differs in the order in which the list is traversed and the order of the arguments. Also, [List.fold](#) and [List.foldBack](#) have variations, [List.fold2](#) and [List.foldBack2](#), that take two lists of equal length. The function that executes on each element can use corresponding elements of both lists to perform some action. The element types of the two lists can be different, as in the following example, in which one list contains transaction amounts for a bank account, and the other list contains the type of transaction: deposit or withdrawal.

```

// Discriminated union type that encodes the transaction type.
type Transaction =
    | Deposit
    | Withdrawal

let transactionTypes = [Deposit; Deposit; Withdrawal]
let transactionAmounts = [100.00; 1000.00; 95.00 ]
let initialBalance = 200.00

// Use fold2 to perform a calculation on the list to update the account balance.
let endingBalance = List.fold2 (fun acc elem1 elem2 ->
    match elem1 with
    | Deposit -> acc + elem2
    | Withdrawal -> acc - elem2)
    initialBalance
    transactionTypes
    transactionAmounts

printfn "%f" endingBalance

```

For a calculation like summation, `List.fold` and `List.foldBack` have the same effect because the result does not depend on the order of traversal. In the following example, `List.foldBack` is used to add the elements in a list.

```

let sumListBack list = List.foldBack (fun acc elem -> acc + elem) list 0
printfn "%d" (sumListBack [1; 2; 3])

// For a calculation in which the order of traversal is important, fold and foldBack have different
// results. For example, replacing fold with foldBack in the listReverse function
// produces a function that copies the list, rather than reversing it.
let copyList list = List.foldBack (fun elem acc -> elem::acc) list []
printfn "%A" (copyList [1 .. 10])

```

The following example returns to the bank account example. This time a new transaction type is added: an interest calculation. The ending balance now depends on the order of transactions.

```

type Transaction2 =
    | Deposit
    | Withdrawal
    | Interest

let transactionTypes2 = [Deposit; Deposit; Withdrawal; Interest]
let transactionAmounts2 = [100.00; 1000.00; 95.00; 0.05 / 12.0 ]
let initialBalance2 = 200.00

// Because fold2 processes the lists by starting at the head element,
// the interest is calculated last, on the balance of 1205.00.
let endingBalance2 = List.fold2 (fun acc elem1 elem2 ->
    match elem1 with
    | Deposit -> acc + elem2
    | Withdrawal -> acc - elem2
    | Interest -> acc * (1.0 + elem2))
    initialBalance2
    transactionTypes2
    transactionAmounts2

printfn "%f" endingBalance2

// Because foldBack2 processes the lists by starting at end of the list,
// the interest is calculated first, on the balance of only 200.00.
let endingBalance3 = List.foldBack2 (fun elem1 elem2 acc ->
    match elem1 with
    | Deposit -> acc + elem2
    | Withdrawal -> acc - elem2
    | Interest -> acc * (1.0 + elem2))
    transactionTypes2
    transactionAmounts2
    initialBalance2

printfn "%f" endingBalance3

```

The function `List.reduce` is somewhat like `List.fold` and `List.scan`, except that instead of passing around a separate accumulator, `List.reduce` takes a function that takes two arguments of the element type instead of just one, and one of those arguments acts as the accumulator, meaning that it stores the intermediate result of the computation. `List.reduce` starts by operating on the first two list elements, and then uses the result of the operation along with the next element. Because there is not a separate accumulator that has its own type, `List.reduce` can be used in place of `List.fold` only when the accumulator and the element type have the same type. The following code demonstrates the use of `List.reduce`. `List.reduce` throws an exception if the list provided has no elements.

In the following code, the first call to the lambda expression is given the arguments 2 and 4, and returns 6, and the next call is given the arguments 6 and 10, so the result is 16.

```

let sumAList list =
    try
        List.reduce (fun acc elem -> acc + elem) list
    with
    | :? System.ArgumentException as exc -> 0

let resultSum = sumAList [2; 4; 10]
printfn "%d" resultSum

```

## Converting Between Lists and Other Collection Types

The `List` module provides functions for converting to and from both sequences and arrays. To convert to or from a sequence, use `List.toSeq` or `List.ofSeq`. To convert to or from an array, use `List.toArray` or `List.ofArray`.

## Additional Operations

For information about additional operations on lists, see the library reference topic [Collections.List Module](#).

# Arrays

12/19/2018 • 17 minutes to read • [Edit Online](#)

## NOTE

The API reference link will take you to MSDN. The docs.microsoft.com API reference is not complete.

Arrays are fixed-size, zero-based, mutable collections of consecutive data elements that are all of the same type.

## Creating Arrays

You can create arrays in several ways. You can create a small array by listing consecutive values between `[]` and `[]` and separated by semicolons, as shown in the following examples.

```
let array1 = [| 1; 2; 3 |]
```

You can also put each element on a separate line, in which case the semicolon separator is optional.

```
let array1 =
  [
    1
    2
    3
  ]
```

The type of the array elements is inferred from the literals used and must be consistent. The following code causes an error because 1.0 is a float and 2 and 3 are integers.

```
// Causes an error.
// let array2 = [| 1.0; 2; 3 |]
```

You can also use sequence expressions to create arrays. Following is an example that creates an array of squares of integers from 1 to 10.

```
let array3 = [| for i in 1 .. 10 -> i * i |]
```

To create an array in which all the elements are initialized to zero, use `Array.zeroCreate`.

```
let arrayOfTenZeroes : int array = Array.zeroCreate 10
```

## Accessing Elements

You can access array elements by using a dot operator (`.`) and brackets (`[` and `]`).

```
array1.[0]
```

Array indexes start at 0.

You can also access array elements by using slice notation, which enables you to specify a subrange of the array. Examples of slice notation follow.

```
// Accesses elements from 0 to 2.  
  
array1.[0..2]  
  
// Accesses elements from the beginning of the array to 2.  
  
array1.[..2]  
  
// Accesses elements from 2 to the end of the array.  
  
array1.[2..]
```

When slice notation is used, a new copy of the array is created.

## Array Types and Modules

The type of all F# arrays is the .NET Framework type [System.Array](#). Therefore, F# arrays support all the functionality available in [System.Array](#).

The library module [Microsoft.FSharp.Collections.Array](#) supports operations on one-dimensional arrays. The modules [Array2D](#), [Array3D](#), and [Array4D](#) contain functions that support operations on arrays of two, three, and four dimensions, respectively. You can create arrays of rank greater than four by using [System.Array](#).

### Simple Functions

[Array.get](#) gets an element. [Array.length](#) gives the length of an array. [Array.set](#) sets an element to a specified value. The following code example illustrates the use of these functions.

```
let array1 = Array.create 10 ""  
for i in 0 .. array1.Length - 1 do  
    Array.set array1 i (i.ToString())  
for i in 0 .. array1.Length - 1 do  
    printf "%s " (Array.get array1 i)
```

The output is as follows.

```
0 1 2 3 4 5 6 7 8 9
```

### Functions That Create Arrays

Several functions create arrays without requiring an existing array. [Array.empty](#) creates a new array that does not contain any elements. [Array.create](#) creates an array of a specified size and sets all the elements to provided values. [Array.init](#) creates an array, given a dimension and a function to generate the elements.

[Array.zeroCreate](#) creates an array in which all the elements are initialized to the zero value for the array's type. The following code demonstrates these functions.

```

let myEmptyArray = Array.empty
printfn "Length of empty array: %d" myEmptyArray.Length

printfn "Array of floats set to 5.0: %A" (Array.create 10 5.0)

printfn "Array of squares: %A" (Array.init 10 (fun index -> index * index))

let (myZeroArray : float array) = Array.zeroCreate 10

```

The output is as follows.

```

Length of empty array: 0
Area of floats set to 5.0: [|5.0; 5.0; 5.0; 5.0; 5.0; 5.0; 5.0; 5.0; 5.0|]
Array of squares: [|0; 1; 4; 9; 16; 25; 36; 49; 64; 81|]

```

[Array.copy](#) creates a new array that contains elements that are copied from an existing array. Note that the copy is a shallow copy, which means that if the element type is a reference type, only the reference is copied, not the underlying object. The following code example illustrates this.

```

open System.Text

let firstArray : StringBuilder array = Array.init 3 (fun index -> new StringBuilder(""))
let secondArray = Array.copy firstArray
// Reset an element of the first array to a new value.
firstArray.[0] <- new StringBuilder("Test1")
// Change an element of the first array.
firstArray.[1].Insert(0, "Test2") |> ignore
printfn "%A" firstArray
printfn "%A" secondArray

```

The output of the preceding code is as follows:

```

[|Test1; Test2; |]
[; Test2; |]

```

The string `Test1` appears only in the first array because the operation of creating a new element overwrites the reference in `firstArray` but does not affect the original reference to an empty string that is still present in `secondArray`. The string `Test2` appears in both arrays because the `Insert` operation on the [System.Text.StringBuilder](#) type affects the underlying [System.Text.StringBuilder](#) object, which is referenced in both arrays.

[Array.sub](#) generates a new array from a subrange of an array. You specify the subrange by providing the starting index and the length. The following code demonstrates the use of `Array.sub`.

```

let a1 = [| 0 .. 99 |]
let a2 = Array.sub a1 5 10
printfn "%A" a2

```

The output shows that the subarray starts at element 5 and contains 10 elements.

```

[|5; 6; 7; 8; 9; 10; 11; 12; 13; 14|]

```

`Array.append` creates a new array by combining two existing arrays.

The following code demonstrates `Array.append`.

```
printfn "%A" (Array.append [| 1; 2; 3|] [| 4; 5; 6|])
```

The output of the preceding code is as follows.

```
[|1; 2; 3; 4; 5; 6|]
```

`Array.choose` selects elements of an array to include in a new array. The following code demonstrates `Array.choose`. Note that the element type of the array does not have to match the type of the value returned in the option type. In this example, the element type is `int` and the option is the result of a polynomial function, `elem*elem - 1`, as a floating point number.

```
printfn "%A" (Array.choose (fun elem -> if elem % 2 = 0 then
                                         Some(float (elem*elem - 1))
                                         else
                                         None) [| 1 .. 10 |])
```

The output of the preceding code is as follows.

```
[|3.0; 15.0; 35.0; 63.0; 99.0|]
```

`Array.collect` runs a specified function on each array element of an existing array and then collects the elements generated by the function and combines them into a new array. The following code demonstrates `Array.collect`.

```
printfn "%A" (Array.collect (fun elem -> [| 0 .. elem |]) [| 1; 5; 10|])
```

The output of the preceding code is as follows.

```
[|0; 1; 0; 1; 2; 3; 4; 5; 0; 1; 2; 3; 4; 5; 6; 7; 8; 9; 10|]
```

`Array.concat` takes a sequence of arrays and combines them into a single array. The following code demonstrates `Array.concat`.

```
Array.concat [ [|0..3|] ; [|4|] ]
//output [|0; 1; 2; 3; 4|]

Array.concat [| [|0..3|] ; [|4|] |]
//output [|0; 1; 2; 3; 4|]
```

The output of the preceding code is as follows.

```
[|(1, 1, 1); (1, 2, 2); (1, 3, 3); (2, 1, 2); (2, 2, 4); (2, 3, 6); (3, 1, 3);
(3, 2, 6); (3, 3, 9)|]
```

`Array.filter` takes a Boolean condition function and generates a new array that contains only those elements from the input array for which the condition is true. The following code demonstrates `Array.filter`.

```
printfn "%A" (Array.filter (fun elem -> elem % 2 = 0) [| 1 .. 10 |])
```

The output of the preceding code is as follows.

```
[|2; 4; 6; 8; 10|]
```

`Array.rev` generates a new array by reversing the order of an existing array. The following code demonstrates `Array.rev`.

```
let stringReverse (s: string) =
    System.String(Array.rev (s.ToCharArray()))

printfn "%A" (stringReverse("!dlrow olleH"))
```

The output of the preceding code is as follows.

```
"Hello world!"
```

You can easily combine functions in the array module that transform arrays by using the pipeline operator (`|>`), as shown in the following example.

```
[| 1 .. 10 |]
|> Array.filter (fun elem -> elem % 2 = 0)
|> Array.choose (fun elem -> if (elem <> 8) then Some(elem*elem) else None)
|> Array.rev
|> printfn "%A"
```

The output is

```
[|100; 36; 16; 4|]
```

## Multidimensional Arrays

A multidimensional array can be created, but there is no syntax for writing a multidimensional array literal. Use the operator `array2D` to create an array from a sequence of sequences of array elements. The sequences can be array or list literals. For example, the following code creates a two-dimensional array.

```
let my2DArray = array2D [ [ 1; 0]; [0; 1] ]
```

You can also use the function `Array2D.init` to initialize arrays of two dimensions, and similar functions are available for arrays of three and four dimensions. These functions take a function that is used to create the elements. To create a two-dimensional array that contains elements set to an initial value instead of specifying a function, use the `Array2D.create` function, which is also available for arrays up to four dimensions. The following code example first shows how to create an array of arrays that contain the desired elements, and then uses `Array2D.init` to generate the desired two-dimensional array.

```
let arrayOfArrays = [ [ | 1.0; 0.0 |]; [|0.0; 1.0 |] ]
let twoDimensionalArray = Array2D.init 2 2 (fun i j -> arrayOfArrays.[i].[j])
```

Array indexing and slicing syntax is supported for arrays up to rank 4. When you specify an index in multiple dimensions, you use commas to separate the indexes, as illustrated in the following code example.

```
twoDimensionalArray.[0, 1] <- 1.0
```

The type of a two-dimensional array is written out as `<type>[, ]` (for example, `int[, ]`, `double[, ]`), and the type of a three-dimensional array is written as `<type>[,, ]`, and so on for arrays of higher dimensions.

Only a subset of the functions available for one-dimensional arrays is also available for multidimensional arrays. For more information, see [Collections.Array Module](#), [Collections.Array2D Module](#), [Collections.Array3D Module](#), and [Collections.Array4D Module](#).

## Array Slicing and Multidimensional Arrays

In a two-dimensional array (a matrix), you can extract a sub-matrix by specifying ranges and using a wildcard (`*`) character to specify whole rows or columns.

```
/ Get rows 1 to N from an NxM matrix (returns a matrix):
matrix.[1.., *]

// Get rows 1 to 3 from a matrix (returns a matrix):
matrix.[1..3, *]

// Get columns 1 to 3 from a matrix (returns a matrix):
matrix.[*, 1..3]

// Get a 3x3 submatrix:
matrix.[1..3, 1..3]
```

As of F# 3.1, you can decompose a multidimensional array into subarrays of the same or lower dimension. For example, you can obtain a vector from a matrix by specifying a single row or column.

```
// Get row 3 from a matrix as a vector:
matrix.[3, *]

// Get column 3 from a matrix as a vector:
matrix.[*, 3]
```

You can use this slicing syntax for types that implement the element access operators and overloaded `GetSlice` methods. For example, the following code creates a `Matrix` type that wraps the F# 2D array, implements an `Item` property to provide support for array indexing, and implements three versions of `GetSlice`. If you can use this code as a template for your matrix types, you can use all the slicing operations that this section describes.

```

type Matrix<'T>(N: int, M: int) =
    let internalArray = Array2D.zeroCreate<'T> N M

    member this.Item
        with get(a: int, b: int) = internalArray.[a, b]
        and set(a: int, b: int) (value:'T) = internalArray.[a, b] <- value

    member this.GetSlice(rowStart: int option, rowFinish : int option, colStart: int option, colFinish : int option) =
        let rowStart =
            match rowStart with
            | Some(v) -> v
            | None -> 0
        let rowFinish =
            match rowFinish with
            | Some(v) -> v
            | None -> internalArray.GetLength(0) - 1
        let colStart =
            match colStart with
            | Some(v) -> v
            | None -> 0
        let colFinish =
            match colFinish with
            | Some(v) -> v
            | None -> internalArray.GetLength(1) - 1
        internalArray.[rowStart..rowFinish, colStart..colFinish]

    member this.GetSlice(row: int, colStart: int option, colFinish: int option) =
        let colStart =
            match colStart with
            | Some(v) -> v
            | None -> 0
        let colFinish =
            match colFinish with
            | Some(v) -> v
            | None -> internalArray.GetLength(1) - 1
        internalArray.[row, colStart..colFinish]

    member this.GetSlice(rowStart: int option, rowFinish: int option, col: int) =
        let rowStart =
            match rowStart with
            | Some(v) -> v
            | None -> 0
        let rowFinish =
            match rowFinish with
            | Some(v) -> v
            | None -> internalArray.GetLength(0) - 1
        internalArray.[rowStart..rowFinish, col]

module test =
    let generateTestMatrix x y =
        let matrix = new Matrix<float>(3, 3)
        for i in 0..2 do
            for j in 0..2 do
                matrix.[i, j] <- float(i) * x - float(j) * y
        matrix

    let test1 = generateTestMatrix 2.3 1.1
    let submatrix = test1.[0..1, 0..1]
    printfn "%A" submatrix

    let firstRow = test1.[0,*]
    let secondRow = test1.[1,*]
    let firstCol = test1.[*,0]
    printfn "%A" firstCol

```

## Boolean Functions on Arrays

The functions `Array.exists` and `Array.exists2` test elements in either one or two arrays, respectively. These functions take a test function and return `true` if there is an element (or element pair for `Array.exists2`) that satisfies the condition.

The following code demonstrates the use of `Array.exists` and `Array.exists2`. In these examples, new functions are created by applying only one of the arguments, in these cases, the function argument.

```
let allNegative = Array.exists (fun elem -> abs (elem) = elem) >> not
printfn "%A" (allNegative [| -1; -2; -3 |])
printfn "%A" (allNegative [| -10; -1; 5 |])
printfn "%A" (allNegative [| 0 |])

let haveEqualElement = Array.exists2 (fun elem1 elem2 -> elem1 = elem2)
printfn "%A" (haveEqualElement [| 1; 2; 3 |] [| 3; 2; 1 |])
```

The output of the preceding code is as follows.

```
true
false
false
true
```

Similarly, the function `Array.forall` tests an array to determine whether every element satisfies a Boolean condition. The variation `Array.forall2` does the same thing by using a Boolean function that involves elements of two arrays of equal length. The following code illustrates the use of these functions.

```
let allPositive = Array.forall (fun elem -> elem > 0)
printfn "%A" (allPositive [| 0; 1; 2; 3 |])
printfn "%A" (allPositive [| 1; 2; 3 |])

let allEqual = Array.forall2 (fun elem1 elem2 -> elem1 = elem2)
printfn "%A" (allEqual [| 1; 2 |] [| 1; 2 |])
printfn "%A" (allEqual [| 1; 2 |] [| 2; 1 |])
```

The output for these examples is as follows.

```
false
true
true
false
```

## Searching Arrays

`Array.find` takes a Boolean function and returns the first element for which the function returns `true`, or raises a `System.Collections.Generic.KeyNotFoundException` if no element that satisfies the condition is found.

`Array.findIndex` is like `Array.find`, except that it returns the index of the element instead of the element itself.

The following code uses `Array.find` and `Array.findIndex` to locate a number that is both a perfect square and perfect cube.

```

let arrayA = [| 2 .. 100 |]
let delta = 1.0e-10
let isPerfectSquare (x:int) =
    let y = sqrt (float x)
    abs(y - round y) < delta
let isPerfectCube (x:int) =
    let y = System.Math.Pow(float x, 1.0/3.0)
    abs(y - round y) < delta
let element = Array.find (fun elem -> isPerfectSquare elem && isPerfectCube elem) arrayA
let index = Array.findIndex (fun elem -> isPerfectSquare elem && isPerfectCube elem) arrayA
printfn "The first element that is both a square and a cube is %d and its index is %d." element index

```

The output is as follows.

```
The first element that is both a square and a cube is 64 and its index is 62.
```

`Array.tryFind` is like `Array.find`, except that its result is an option type, and it returns `None` if no element is found. `Array.tryFind` should be used instead of `Array.find` when you do not know whether a matching element is in the array. Similarly, `Array.tryFindIndex` is like `Array.findIndex` except that the option type is the return value. If no element is found, the option is `None`.

The following code demonstrates the use of `Array.tryFind`. This code depends on the previous code.

```

let delta = 1.0e-10
let isPerfectSquare (x:int) =
    let y = sqrt (float x)
    abs(y - round y) < delta
let isPerfectCube (x:int) =
    let y = System.Math.Pow(float x, 1.0/3.0)
    abs(y - round y) < delta
let lookForCubeAndSquare array1 =
    let result = Array.tryFind (fun elem -> isPerfectSquare elem && isPerfectCube elem) array1
    match result with
    | Some x -> printfn "Found an element: %d" x
    | None -> printfn "Failed to find a matching element."

lookForCubeAndSquare [| 1 .. 10 |]
lookForCubeAndSquare [| 100 .. 1000 |]
lookForCubeAndSquare [| 2 .. 50 |]

```

The output is as follows.

```
Found an element: 1
Found an element: 729
```

Use `Array.tryPick` when you need to transform an element in addition to finding it. The result is the first element for which the function returns the transformed element as an option value, or `None` if no such element is found.

The following code shows the use of `Array.tryPick`. In this case, instead of a lambda expression, several local helper functions are defined to simplify the code.

```

let findPerfectSquareAndCube array1 =
    let delta = 1.0e-10
    let isPerfectSquare (x:int) =
        let y = sqrt (float x)
        abs(y - round y) < delta
    let isPerfectCube (x:int) =
        let y = System.Math.Pow(float x, 1.0/3.0)
        abs(y - round y) < delta
    // intFunction : (float -> float) -> int -> int
    // Allows the use of a floating point function with integers.
    let intFunction function1 number = int (round (function1 (float number)))
    let cubeRoot x = System.Math.Pow(x, 1.0/3.0)
    // testElement: int -> (int * int * int) option
    // Test an element to see whether it is a perfect square and a perfect
    // cube, and, if so, return the element, square root, and cube root
    // as an option value. Otherwise, return None.
    let testElement elem =
        if isPerfectSquare elem && isPerfectCube elem then
            Some(elem, intFunction sqrt elem, intFunction cubeRoot elem)
        else None
    match Array.tryPick testElement array1 with
    | Some (n, sqrt, cuberoot) -> printfn "Found an element %d with square root %d and cube root %d." n sqrt
cuberoot
    | None -> printfn "Did not find an element that is both a perfect square and a perfect cube."

```

findPerfectSquareAndCube [| 1 .. 10 |]  
 findPerfectSquareAndCube [| 2 .. 100 |]  
 findPerfectSquareAndCube [| 100 .. 1000 |]  
 findPerfectSquareAndCube [| 1000 .. 10000 |]  
 findPerfectSquareAndCube [| 2 .. 50 |]

The output is as follows.

```

Found an element 1 with square root 1 and cube root 1.
Found an element 64 with square root 8 and cube root 4.
Found an element 729 with square root 27 and cube root 9.
Found an element 4096 with square root 64 and cube root 16.

```

## Performing Computations on Arrays

The `Array.average` function returns the average of each element in an array. It is limited to element types that support exact division by an integer, which includes floating point types but not integral types. The `Array.averageBy` function returns the average of the results of calling a function on each element. For an array of integral type, you can use `Array.averageBy` and have the function convert each element to a floating point type for the computation.

Use `Array.max` or `Array.min` to get the maximum or minimum element, if the element type supports it. Similarly, `Array.maxBy` and `Array.minBy` allow a function to be executed first, perhaps to transform to a type that supports comparison.

`Array.sum` adds the elements of an array, and `Array.sumBy` calls a function on each element and adds the results together.

To execute a function on each element in an array without storing the return values, use `Array.iter`. For a function involving two arrays of equal length, use `Array.iter2`. If you also need to keep an array of the results of the function, use `Array.map` or `Array.map2`, which operates on two arrays at a time.

The variations `Array.itei` and `Array.itei2` allow the index of the element to be involved in the computation; the same is true for `Array.mapi` and `Array.mapi2`.

The functions `Array.fold`, `Array.foldBack`, `Array.reduce`, `Array.reduceBack`, `Array.scan`, and `Array.scanBack`

execute algorithms that involve all the elements of an array. Similarly, the variations `Array.fold2` and `Array.foldBack2` perform computations on two arrays.

These functions for performing computations correspond to the functions of the same name in the [List module](#). For usage examples, see [Lists](#).

## Modifying Arrays

`Array.set` sets an element to a specified value. `Array.fill` sets a range of elements in an array to a specified value. The following code provides an example of `Array.fill`.

```
let arrayFill1 = [| 1 .. 25 |]
Array.fill arrayFill1 2 20 0
printfn "%A" arrayFill1
```

The output is as follows.

```
[|1; 2; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 0; 23; 24; 25|]
```

You can use `Array.blit` to copy a subsection of one array to another array.

## Converting to and from Other Types

`Array.ofList` creates an array from a list. `Array.ofSeq` creates an array from a sequence. `Array.toList` and `Array.toSeq` convert to these other collection types from the array type.

## Sorting Arrays

Use `Array.sort` to sort an array by using the generic comparison function. Use `Array.sortBy` to specify a function that generates a value, referred to as a *key*, to sort by using the generic comparison function on the key. Use `Array.sortWith` if you want to provide a custom comparison function. `Array.sort`, `Array.sortBy`, and `Array.sortWith` all return the sorted array as a new array. The variations `Array.sortInPlace`, `Array.sortInPlaceBy`, and `Array.sortInPlaceWith` modify the existing array instead of returning a new one.

## Arrays and Tuples

The functions `Array.zip` and `Array.unzip` convert arrays of tuple pairs to tuples of arrays and vice versa. `Array.zip3` and `Array.unzip3` are similar except that they work with tuples of three elements or tuples of three arrays.

## Parallel Computations on Arrays

The module `Array.Parallel` contains functions for performing parallel computations on arrays. This module is not available in applications that target versions of the .NET Framework prior to version 4.

# Sequences

2/21/2019 • 18 minutes to read • [Edit Online](#)

## NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

A *sequence* is a logical series of elements all of one type. Sequences are particularly useful when you have a large, ordered collection of data but do not necessarily expect to use all of the elements. Individual sequence elements are computed only as required, so a sequence can provide better performance than a list in situations in which not all the elements are used. Sequences are represented by the `seq<'T>` type, which is an alias for `System.Collections.Generic.IEnumerable<'T>`. Therefore, any .NET Framework type that implements `System.IEnumerable` can be used as a sequence. The [Seq module](#) provides support for manipulations involving sequences.

## Sequence Expressions

A *sequence expression* is an expression that evaluates to a sequence. Sequence expressions can take a number of forms. The simplest form specifies a range. For example, `seq { 1 .. 5 }` creates a sequence that contains five elements, including the endpoints 1 and 5. You can also specify an increment (or decrement) between two double periods. For example, the following code creates the sequence of multiples of 10.

```
// Sequence that has an increment.  
seq { 0 .. 10 .. 100 }
```

Sequence expressions are made up of F# expressions that produce values of the sequence. They can use the `yield` keyword to produce values that become part of the sequence.

Following is an example.

```
seq { for i in 1 .. 10 do yield i * i }
```

You can use the `->` operator instead of `yield`, in which case you can omit the `do` keyword, as shown in the following example.

```
seq { for i in 1 .. 10 -> i * i }
```

The following code generates a list of coordinate pairs along with an index into an array that represents the grid.

```
let (height, width) = (10, 10)  
seq { for row in 0 .. width - 1 do  
      for col in 0 .. height - 1 do  
        yield (row, col, row*width + col)  
    }
```

An `if` expression used in a sequence is a filter. For example, to generate a sequence of only prime numbers, assuming that you have a function `isprime` of type `int -> bool`, construct the sequence as follows.

```
seq { for n in 1 .. 100 do if isprime n then yield n }
```

When you use `yield` or `->` in an iteration, each iteration is expected to generate a single element of the sequence. If each iteration produces a sequence of elements, use `yield!`. In that case, the elements generated on each iteration are concatenated to produce the final sequence.

You can combine multiple expressions together in a sequence expression. The elements generated by each expression are concatenated together. For an example, see the "Examples" section of this topic.

## Examples

The first example uses a sequence expression that contains an iteration, a filter, and a yield to generate an array. This code prints a sequence of prime numbers between 1 and 100 to the console.

```
// Recursive isprime function.  
let isprime n =  
    let rec check i =  
        i > n/2 || (n % i <> 0 && check (i + 1))  
    check 2  
  
let aSequence = seq { for n in 1..100 do if isprime n then yield n }  
for x in aSequence do  
    printfn "%d" x
```

The following code uses `yield` to create a multiplication table that consists of tuples of three elements, each consisting of two factors and the product.

```
let multiplicationTable =  
    seq { for i in 1..9 do  
        for j in 1..9 do  
            yield (i, j, i*j) }
```

The following example demonstrates the use of `yield!` to combine individual sequences into a single final sequence. In this case, the sequences for each subtree in a binary tree are concatenated in a recursive function to produce the final sequence.

```
// Yield the values of a binary tree in a sequence.  
type Tree<'a> =  
    | Tree of 'a * Tree<'a> * Tree<'a>  
    | Leaf of 'a  
  
// inorder : Tree<'a> -> seq<'a>  
let rec inorder tree =  
    seq {  
        match tree with  
        | Tree(x, left, right) ->  
            yield! inorder left  
            yield x  
            yield! inorder right  
        | Leaf x -> yield x  
    }  
  
let mytree = Tree(6, Tree(2, Leaf(1), Leaf(3)), Leaf(9))  
let seq1 = inorder mytree  
printfn "%A" seq1
```

# Using Sequences

Sequences support many of the same functions as [lists](#). Sequences also support operations such as grouping and counting by using key-generating functions. Sequences also support more diverse functions for extracting subsequences.

Many data types, such as lists, arrays, sets, and maps are implicitly sequences because they are enumerable collections. A function that takes a sequence as an argument works with any of the common F# data types, in addition to any .NET Framework data type that implements `System.Collections.Generic.IEnumerable<'T>`. Contrast this to a function that takes a list as an argument, which can only take lists. The type `seq<'T>` is a type abbreviation for `IEnumerable<'T>`. This means that any type that implements the generic `System.Collections.Generic.IEnumerable<'T>`, which includes arrays, lists, sets, and maps in F#, and also most .NET Framework collection types, is compatible with the `seq` type and can be used wherever a sequence is expected.

## Module Functions

The [Seq module](#) in the [Microsoft.FSharp.Collections namespace](#) contains functions for working with sequences. These functions work with lists, arrays, maps, and sets as well, because all of those types are enumerable, and therefore can be treated as sequences.

## Creating Sequences

You can create sequences by using sequence expressions, as described previously, or by using certain functions.

You can create an empty sequence by using [Seq.empty](#), or you can create a sequence of just one specified element by using [Seq.singleton](#).

```
let seqEmpty = Seq.empty
let seqOne = Seq.singleton 10
```

You can use [Seq.init](#) to create a sequence for which the elements are created by using a function that you provide. You also provide a size for the sequence. This function is just like [List.init](#), except that the elements are not created until you iterate through the sequence. The following code illustrates the use of `Seq.init`.

```
let seqFirst5MultiplesOf10 = Seq.init 5 (fun n -> n * 10)
Seq.iter (fun elem -> printf "%d " elem) seqFirst5MultiplesOf10
```

The output is

```
0 10 20 30 40
```

By using [Seq.ofArray](#) and [Seq.ofList<'T> Function](#), you can create sequences from arrays and lists. However, you can also convert arrays and lists to sequences by using a cast operator. Both techniques are shown in the following code.

```
// Convert an array to a sequence by using a cast.
let seqFromArray1 = [| 1 .. 10 |] :> seq<int>
// Convert an array to a sequence by using Seq.ofArray.
let seqFromArray2 = [| 1 .. 10 |] |> Seq.ofArray
```

By using [Seq.cast](#), you can create a sequence from a weakly typed collection, such as those defined in `System.Collections`. Such weakly typed collections have the element type `System.Object` and are enumerated

by using the non-generic `System.Collections.Generic.IEnumerable<T>` type. The following code illustrates the use of `Seq.cast` to convert an `System.Collections.ArrayList` into a sequence.

```
open System
let mutable arrayList1 = new System.Collections.ArrayList(10)
for i in 1 .. 10 do arrayList1.Add(i) |> ignore
let seqCast : seq<int> = Seq.cast arrayList1
```

You can define infinite sequences by using the `Seq.initInfinite` function. For such a sequence, you provide a function that generates each element from the index of the element. Infinite sequences are possible because of lazy evaluation; elements are created as needed by calling the function that you specify. The following code example produces an infinite sequence of floating point numbers, in this case the alternating series of reciprocals of squares of successive integers.

```
let seqInfinite = Seq.initInfinite (fun index ->
    let n = float(index + 1)
    1.0 / (n * n * (if ((index + 1) % 2 = 0) then 1.0 else -1.0)))
printfn "%A" seqInfinite
```

`Seq.unfold` generates a sequence from a computation function that takes a state and transforms it to produce each subsequent element in the sequence. The state is just a value that is used to compute each element, and can change as each element is computed. The second argument to `Seq.unfold` is the initial value that is used to start the sequence. `Seq.unfold` uses an option type for the state, which enables you to terminate the sequence by returning the `None` value. The following code shows two examples of sequences, `seq1` and `fib`, that are generated by an `unfold` operation. The first, `seq1`, is just a simple sequence with numbers up to 20. The second, `fib`, uses `unfold` to compute the Fibonacci sequence. Because each element in the Fibonacci sequence is the sum of the previous two Fibonacci numbers, the state value is a tuple that consists of the previous two numbers in the sequence. The initial value is `(1,1)`, the first two numbers in the sequence.

```
let seq1 = Seq.unfold (fun state -> if (state > 20) then None else Some(state, state + 1)) 0
printfn "The sequence seq1 contains numbers from 0 to 20."
for x in seq1 do printfn "%d" x
let fib = Seq.unfold (fun state ->
    if (snd state > 1000) then None
    else Some(fst state + snd state, (snd state, fst state + snd state))) (1,1)
printfn "\nThe sequence fib contains Fibonacci numbers."
for x in fib do printfn "%d" x
```

The output is as follows:

```
The sequence seq1 contains numbers from 0 to 20.
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20

The sequence fib contains Fibonacci numbers.
2 3 5 8 13 21 34 55 89 144 233 377 610 987 1597
```

The following code is an example that uses many of the sequence module functions described here to generate and compute the values of infinite sequences. The code might take a few minutes to run.

```

// infiniteSequences.fs
// generateInfiniteSequence generates sequences of floating point
// numbers. The sequences generated are computed from the fDenominator
// function, which has the type (int -> float) and computes the
// denominator of each term in the sequence from the index of that
// term. The isAlternating parameter is true if the sequence has
// alternating signs.
let generateInfiniteSequence fDenominator isAlternating =
    if (isAlternating) then
        Seq.initInfinite (fun index -> 1.0 / (fDenominator index) * (if (index % 2 = 0) then -1.0 else 1.0))
    else
        Seq.initInfinite (fun index -> 1.0 / (fDenominator index))

// The harmonic series is the series of reciprocals of whole numbers.
let harmonicSeries = generateInfiniteSequence (fun index -> float index) false
// The harmonic alternating series is like the harmonic series
// except that it has alternating signs.
let harmonicAlternatingSeries = generateInfiniteSequence (fun index -> float index) true
// This is the series of reciprocals of the odd numbers.
let oddNumberSeries = generateInfiniteSequence (fun index -> float (2 * index - 1)) true
// This is the series of reciprocals of the squares.
let squaresSeries = generateInfiniteSequence (fun index -> float (index * index)) false

// This function sums a sequence, up to the specified number of terms.
let sumSeq length sequence =
    Seq.unfold (fun state ->
        let subtotal = snd state + Seq.nth (fst state + 1) sequence
        if (fst state >= length) then None
        else Some(subtotal,(fst state + 1, subtotal))) (0, 0.0)

// This function sums an infinite sequence up to a given value
// for the difference (epsilon) between subsequent terms,
// up to a maximum number of terms, whichever is reached first.
let infiniteSum infiniteSeq epsilon maxIteration =
    infiniteSeq
    |> sumSeq maxIteration
    |> Seq.pairwise
    |> Seq.takeWhile (fun elem -> abs (snd elem - fst elem) > epsilon)
    |> List.ofSeq
    |> List.rev
    |> List.head
    |> snd

// Compute the sums for three sequences that converge, and compare
// the sums to the expected theoretical values.
let result1 = infiniteSum harmonicAlternatingSeries 0.00001 100000
printfn "Result: %f ln2: %f" result1 (log 2.0)

let pi = Math.PI
let result2 = infiniteSum oddNumberSeries 0.00001 10000
printfn "Result: %f pi/4: %f" result2 (pi/4.0)

// Because this is not an alternating series, a much smaller epsilon
// value and more terms are needed to obtain an accurate result.
let result3 = infiniteSum squaresSeries 0.0000001 1000000
printfn "Result: %f pi*pi/6: %f" result3 (pi*pi/6.0)

```

## Searching and Finding Elements

Sequences support functionality available with lists: [Seq.exists](#), [Seq.exists2](#), [Seq.find](#), [Seq.findIndex](#), [Seq.pick](#), [Seq.tryFind](#), and [Seq.tryFindIndex](#). The versions of these functions that are available for sequences evaluate the sequence only up to the element that is being searched for. For examples, see [Lists](#).

# Obtaining Subsequences

`Seq.filter` and `Seq.choose` are like the corresponding functions that are available for lists, except that the filtering and choosing does not occur until the sequence elements are evaluated.

`Seq.truncate` creates a sequence from another sequence, but limits the sequence to a specified number of elements. `Seq.take` creates a new sequence that contains only a specified number of elements from the start of a sequence. If there are fewer elements in the sequence than you specify to take, `Seq.take` throws a `System.InvalidOperationException`. The difference between `Seq.take` and `Seq.truncate` is that `Seq.truncate` does not produce an error if the number of elements is fewer than the number you specify.

The following code shows the behavior of and differences between `Seq.truncate` and `Seq.take`.

```
let mySeq = seq { for i in 1 .. 10 -> i*i }
let truncatedSeq = Seq.truncate 5 mySeq
let takenSeq = Seq.take 5 mySeq

let truncatedSeq2 = Seq.truncate 20 mySeq
let takenSeq2 = Seq.take 20 mySeq

let printSeq seq1 = Seq.iter (printf "%A ") seq1; printfn ""

// Up to this point, the sequences are not evaluated.
// The following code causes the sequences to be evaluated.
truncatedSeq |> printSeq
truncatedSeq2 |> printSeq
takenSeq |> printSeq
// The following line produces a run-time error (in printSeq):
takenSeq2 |> printSeq
```

The output, before the error occurs, is as follows.

```
1 4 9 16 25
1 4 9 16 25 36 49 64 81 100
1 4 9 16 25
1 4 9 16 25 36 49 64 81 100
```

By using `Seq.takeWhile`, you can specify a predicate function (a Boolean function) and create a sequence from another sequence made up of those elements of the original sequence for which the predicate is `true`, but stop before the first element for which the predicate returns `false`. `Seq.skip` returns a sequence that skips a specified number of the first elements of another sequence and returns the remaining elements. `Seq.skipWhile` returns a sequence that skips the first elements of another sequence as long as the predicate returns `true`, and then returns the remaining elements, starting with the first element for which the predicate returns `false`.

The following code example illustrates the behavior of and differences between `Seq.takeWhile`, `Seq.skip`, and `Seq.skipWhile`.

```
// takeWhile
let mySeqLessThan10 = Seq.takeWhile (fun elem -> elem < 10) mySeq
mySeqLessThan10 |> printSeq

// skip
let mySeqSkipFirst5 = Seq.skip 5 mySeq
mySeqSkipFirst5 |> printSeq

// skipWhile
let mySeqSkipWhileLessThan10 = Seq.skipWhile (fun elem -> elem < 10) mySeq
mySeqSkipWhileLessThan10 |> printSeq
```

The output is as follows.

```
1 4 9  
36 49 64 81 100  
16 25 36 49 64 81 100
```

## Transforming Sequences

[Seq.pairwise](#) creates a new sequence in which successive elements of the input sequence are grouped into tuples.

```
let printSeq seq1 = Seq.iter (printf "%A " ) seq1; printfn ""  
let seqPairwise = Seq.pairwise (seq { for i in 1 .. 10 -> i*i })  
printSeq seqPairwise  
  
printfn ""  
let seqDelta = Seq.map (fun elem -> snd elem - fst elem) seqPairwise  
printSeq seqDelta
```

[Seq.windowed](#) is like [Seq.pairwise](#), except that instead of producing a sequence of tuples, it produces a sequence of arrays that contain copies of adjacent elements (a *window*) from the sequence. You specify the number of adjacent elements you want in each array.

The following code example demonstrates the use of [Seq.windowed](#). In this case the number of elements in the window is 3. The example uses [printSeq](#), which is defined in the previous code example.

```
let seqNumbers = [ 1.0; 1.5; 2.0; 1.5; 1.0; 1.5 ] :> seq<float>  
let seqWindows = Seq.windowed 3 seqNumbers  
let seqMovingAverage = Seq.map Array.average seqWindows  
printfn "Initial sequence: "  
printSeq seqNumbers  
printfn "\nWindows of length 3: "  
printSeq seqWindows  
printfn "\nMoving average: "  
printSeq seqMovingAverage
```

The output is as follows.

Initial sequence:

```
1.0 1.5 2.0 1.5 1.0 1.5  
  
Windows of length 3:  
 [|1.0; 1.5; 2.0|] [|1.5; 2.0; 1.5|] [|2.0; 1.5; 1.0|] [|1.5; 1.0; 1.5|]  
  
Moving average:  
1.5 1.666666667 1.5 1.333333333
```

## Operations with Multiple Sequences

[Seq.zip](#) and [Seq.zip3](#) take two or three sequences and produce a sequence of tuples. These functions are like the corresponding functions available for [lists](#). There is no corresponding functionality to separate one sequence into two or more sequences. If you need this functionality for a sequence, convert the sequence to a list and use [List.unzip](#).

# Sorting, Comparing, and Grouping

The sorting functions supported for lists also work with sequences. This includes [Seq.sort](#) and [Seq.sortBy](#). These functions iterate through the whole sequence.

You compare two sequences by using the [Seq.compareWith](#) function. The function compares successive elements in turn, and stops when it encounters the first unequal pair. Any additional elements do not contribute to the comparison.

The following code shows the use of [Seq.compareWith](#).

```
let sequence1 = seq { 1 .. 10 }
let sequence2 = seq { 10 .. -1 .. 1 }

// Compare two sequences element by element.
let compareSequences = Seq.compareWith (fun elem1 elem2 ->
    if elem1 > elem2 then 1
    elif elem1 < elem2 then -1
    else 0)

let compareResult1 = compareSequences sequence1 sequence2
match compareResult1 with
| 1 -> printfn "Sequence1 is greater than sequence2."
| -1 -> printfn "Sequence1 is less than sequence2."
| 0 -> printfn "Sequence1 is equal to sequence2."
| _ -> failwith("Invalid comparison result.")
```

In the previous code, only the first element is computed and examined, and the result is -1.

[Seq.countBy](#) takes a function that generates a value called a *key* for each element. A key is generated for each element by calling this function on each element. [Seq.countBy](#) then returns a sequence that contains the key values, and a count of the number of elements that generated each value of the key.

```
let mySeq1 = seq { 1.. 100 }
let printSeq seq1 = Seq.iter (printf "%A ") seq1; printfn ""
let seqResult = Seq.countBy (fun elem -> if elem % 3 = 0 then 0
                                elif elem % 3 = 1 then 1
                                else 2) mySeq1

printSeq seqResult
```

The output is as follows.

```
(1, 34) (2, 33) (0, 33)
```

The previous output shows that there were 34 elements of the original sequence that produced the key 1, 33 values that produced the key 2, and 33 values that produced the key 0.

You can group elements of a sequence by calling [Seq.groupBy](#). [Seq.groupBy](#) takes a sequence and a function that generates a key from an element. The function is executed on each element of the sequence. [Seq.groupBy](#) returns a sequence of tuples, where the first element of each tuple is the key and the second is a sequence of elements that produce that key.

The following code example shows the use of [Seq.groupBy](#) to partition the sequence of numbers from 1 to 100 into three groups that have the distinct key values 0, 1, and 2.

```

let sequence = seq { 1 .. 100 }
let printSeq seq1 = Seq.iter (printf "%A") seq1; printfn ""
let sequences3 = Seq.groupBy (fun index ->
    if (index % 3 = 0) then 0
    elif (index % 3 = 1) then 1
    else 2) sequence
sequences3 |> printSeq

```

The output is as follows.

```
(1, seq [1; 4; 7; 10; ...]) (2, seq [2; 5; 8; 11; ...]) (0, seq [3; 6; 9; 12; ...])
```

You can create a sequence that eliminates duplicate elements by calling [Seq.distinct](#). Or you can use [Seq.distinctBy](#), which takes a key-generating function to be called on each element. The resulting sequence contains elements of the original sequence that have unique keys; later elements that produce a duplicate key to an earlier element are discarded.

The following code example illustrates the use of [Seq.distinct](#). [Seq.distinct](#) is demonstrated by generating sequences that represent binary numbers, and then showing that the only distinct elements are 0 and 1.

```

let binary n =
    let rec generateBinary n =
        if (n / 2 = 0) then [n]
        else (n % 2) :: generateBinary (n / 2)
    generateBinary n |> List.rev |> Seq.ofList

printfn "%A" (binary 1024)

let resultSequence = Seq.distinct (binary 1024)
printfn "%A" resultSequence

```

The following code demonstrates [Seq.distinctBy](#) by starting with a sequence that contains negative and positive numbers and using the absolute value function as the key-generating function. The resulting sequence is missing all the positive numbers that correspond to the negative numbers in the sequence, because the negative numbers appear earlier in the sequence and therefore are selected instead of the positive numbers that have the same absolute value, or key.

```

let inputSequence = { -5 .. 10 }
let printSeq seq1 = Seq.iter (printf "%A") seq1; printfn ""
printfn "Original sequence: "
printSeq inputSequence
printfn "\nSequence with distinct absolute values: "
let seqDistinctAbsoluteValue = Seq.distinctBy (fun elem -> abs elem) inputSequence
seqDistinctAbsoluteValue |> printSeq

```

## Readonly and Cached Sequences

[Seq.readonly](#) creates a read-only copy of a sequence. [seq.readonly](#) is useful when you have a read-write collection, such as an array, and you do not want to modify the original collection. This function can be used to preserve data encapsulation. In the following code example, a type that contains an array is created. A property exposes the array, but instead of returning an array, it returns a sequence that is created from the array by using [Seq.readonly](#).

```
type ArrayContainer(start, finish) =
    let internalArray = [| start .. finish |]
    member this.RangeSeq = Seq.readonly internalArray
    member this.RangeArray = internalArray

let newArray = new ArrayContainer(1, 10)
let rangeSeq = newArray.RangeSeq
let rangeArray = newArray.RangeArray
// These lines produce an error:
//let myArray = rangeSeq :> int array
//myArray.[0] <- 0
// The following line does not produce an error.
// It does not preserve encapsulation.
rangeArray.[0] <- 0
```

[Seq.cache](#) creates a stored version of a sequence. Use `seq.cache` to avoid reevaluation of a sequence, or when you have multiple threads that use a sequence, but you must make sure that each element is acted upon only one time. When you have a sequence that is being used by multiple threads, you can have one thread that enumerates and computes the values for the original sequence, and remaining threads can use the cached sequence.

## Performing Computations on Sequences

Simple arithmetic operations are like those of lists, such as [Seq.average](#), [Seq.sum](#), [Seq.averageBy](#), [Seq.sumBy](#), and so on.

[Seq.fold](#), [Seq.reduce](#), and [Seq.scan](#) are like the corresponding functions that are available for lists. Sequences support a subset of the full variations of these functions that lists support. For more information and examples, see [Lists](#).

# Slices

3/8/2019 • 3 minutes to read • [Edit Online](#)

In F#, a slice is a subset of a data type. To be able to take a slice from a data type, the data type must either define a `GetSlice` method or in a [type extension](#) that is in scope. This article explains how to take slices from existing F# types and how to define your own.

Slices are similar to [indexers](#), but instead of yielding a single value from the underlying data structure, they yield multiple ones.

F# currently has intrinsic support for slicing strings, lists, arrays, and 2D arrays.

## Basic slicing with F# lists and arrays

The most common data types that are sliced are F# lists and arrays. The following example demonstrates how to do this with lists:

```
// Generate a list of 100 integers
let fullList = [ 1 .. 100 ]

// Create a slice from indices 1-5 (inclusive)
let smallSlice = fullList.[1..5]
printfn "Small slice: %A" smallSlice

// Create a slice from the beginning to index 5 (inclusive)
let unboundedBeginning = fullList.[..5]
printfn "Unbounded beginning slice: %A" unboundedBeginning

// Create a slice from an index to the end of the list
let unboundedEnd = fullList.[94..]
printfn "Unbounded end slice: %A" unboundedEnd
```

Slicing arrays is just like slicing lists:

```
// Generate an array of 100 integers
let fullArray = [| 1 .. 100 |]

// Create a slice from indices 1-5 (inclusive)
let smallSlice = fullArray.[1..5]
printfn "Small slice: %A" smallSlice

// Create a slice from the beginning to index 5 (inclusive)
let unboundedBeginning = fullArray.[..5]
printfn "Unbounded beginning slice: %A" unboundedBeginning

// Create a slice from an index to the end of the list
let unboundedEnd = fullArray.[94..]
printfn "Unbounded end slice: %A" unboundedEnd
```

## Slicing multidimensional arrays

F# supports multidimensional arrays in the F# core library. As with one-dimensional arrays, slices of multidimensional arrays can also be useful. However, the introduction of additional dimensions mandates a slightly different syntax so that you can take slices of specific rows and columns.

The following examples demonstrate how to slice a 2D array:

```
// Generate a 3x3 2D matrix
let A = array2D [[1;2;3];[4;5;6];[7;8;9]]
printfn "Full matrix:\n%A" A

// Take the first row
let row0 = A.[0,*]
printfn "Row 0: %A" row0

// Take the first column
let col0 = A.[*,0]
printfn "Column 0: %A" col0

// Take all rows but only two columns
let subA = A.[*,0..1]
printfn "%A" subA

// Take two rows and all columns
let subA' = A.[0..1,*]
printfn "%A" subA'

// Slice a 2x2 matrix out of the full 3x3 matrix
let twoByTwo = A.[0..1,0..1]
printfn "%A" twoByTwo
```

The F# core library does not define `GetSlice` for 3D arrays. If you wish to slice those or other arrays of more dimensions, you must define the `GetSlice` member yourself.

## Defining slices for other data structures

The F# core library defines slices for a limited set of types. If you wish to define slices for more data types, you can do so either in the type definition itself or in a type extension.

For example, here's how you might define slices for the `ArraySegment<T>` class to allow for convenient data manipulation:

```
open System

type ArraySegment<'TItem> with
    member segment.GetSlice(?start, ?finish) =
        let start = defaultArg start 0
        let finish = defaultArg finish segment.Count
        ArraySegment(segment.Array, segment.Offset + start, finish - start)

let arr = ArraySegment [| 1 .. 10 |]
let slice = arr.[2..5] // [ 3; 4; 5 ]
```

### Use inlining to avoid boxing if it is necessary

If you are defining slices for a type that is actually a struct, we recommend that you `inline` the `GetSlice` member. The F# compiler optimizes away the optional arguments, avoiding any heap allocations as a result of slicing. This is critically important for slicing constructs such as `Span<T>` that cannot be allocated on the heap.

```
open System

type Span<'T> with
    // Note the 'inline' in the member definition
    member inline sp.GetSlice(startIdx, endIdx) =
        let s = defaultArg startIdx 0
        let e = defaultArg endIdx sp.Length
        sp.Slice(s, e)

    let printSpan (sp: Span<int>) =
        let arr = sp.ToArray()
        printfn "%A" arr

    let sp = [| 1; 2; 3; 4; 5 |].AsSpan()
    printSpan sp.[0..] // [|1; 2; 3; 4; 5|]
    printSpan sp.[..5] // [|1; 2; 3; 4; 5|]
    printSpan sp.[0..3] // [|1; 2; 3|]
    printSpan sp.[1..2] // [|2; 3|]
```

# Options

12/19/2018 • 3 minutes to read • [Edit Online](#)

The option type in F# is used when an actual value might not exist for a named value or variable. An option has an underlying type and can hold a value of that type, or it might not have a value.

## Remarks

The following code illustrates a function which generates an option type.

```
let keepIfPositive (a : int) = if a > 0 then Some(a) else None
```

As you can see, if the input `a` is greater than 0, `Some(a)` is generated. Otherwise, `None` is generated.

The value `None` is used when an option does not have an actual value. Otherwise, the expression `Some( ... )` gives the option a value. The values `Some` and `None` are useful in pattern matching, as in the following function `exists`, which returns `true` if the option has a value and `false` if it does not.

```
let exists (x : int option) =
    match x with
    | Some(x) -> true
    | None -> false
```

## Using Options

Options are commonly used when a search does not return a matching result, as shown in the following code.

```
let rec tryFindMatch pred list =
    match list with
    | head :: tail -> if pred(head)
                          then Some(head)
                          else tryFindMatch pred tail
    | [] -> None

// result1 is Some 100 and its type is int option.
let result1 = tryFindMatch (fun elem -> elem = 100) [ 200; 100; 50; 25 ]

// result2 is None and its type is int option.
let result2 = tryFindMatch (fun elem -> elem = 26) [ 200; 100; 50; 25 ]
```

In the previous code, a list is searched recursively. The function `tryFindMatch` takes a predicate function `pred` that returns a Boolean value, and a list to search. If an element that satisfies the predicate is found, the recursion ends and the function returns the value as an option in the expression `Some(head)`. The recursion ends when the empty list is matched. At that point the value `head` has not been found, and `None` is returned.

Many F# library functions that search a collection for a value that may or may not exist return the `option` type. By convention, these functions begin with the `try` prefix, for example, `Seq.tryFindIndex`.

Options can also be useful when a value might not exist, for example if it is possible that an exception will be thrown when you try to construct a value. The following code example illustrates this.

```

open System.IO
let openFile filename =
    try
        let file = File.Open (filename, FileMode.Create)
        Some(file)
    with
        | ex -> eprintf "An exception occurred with message %s" ex.Message
        None

```

The `openFile` function in the previous example has type `string -> File option` because it returns a `File` object if the file opens successfully and `None` if an exception occurs. Depending on the situation, it may not be an appropriate design choice to catch an exception rather than allowing it to propagate.

## Option Properties and Methods

The option type supports the following properties and methods.

PROPERTY OR METHOD	TYPE	DESCRIPTION
<code>None</code>	<code>'T option</code>	A static property that enables you to create an option value that has the <code>None</code> value.
<code>IsNone</code>	<code>bool</code>	Returns <code>true</code> if the option has the <code>None</code> value.
<code>IsSome</code>	<code>bool</code>	Returns <code>true</code> if the option has a value that is not <code>None</code> .
<code>Some</code>	<code>'T option</code>	A static member that creates an option that has a value that is not <code>None</code> .
<code>Value</code>	<code>'T</code>	Returns the underlying value, or throws a <code>System.NullReferenceException</code> if the value is <code>None</code> .

## Option Module

There is a module, `Option`, that contains useful functions that perform operations on options. Some functions repeat the functionality of the properties but are useful in contexts where a function is needed. `Option.isSome` and `Option.isNone` are both module functions that test whether an option holds a value. `Option.get` obtains the value, if there is one. If there is no value, it throws `System.ArgumentException`.

The `Option.bind` function executes a function on the value, if there is a value. The function must take exactly one argument, and its parameter type must be the option type. The return value of the function is another option type.

The option module also includes functions that correspond to the functions that are available for lists, arrays, sequences, and other collection types. These functions include `Option.map`, `Option.iter`, `Option.forall`, `Option.exists`, `Option.foldBack`, `Option.fold`, and `Option.count`. These functions enable options to be used like a collection of zero or one elements. For more information and examples, see the discussion of collection functions in [Lists](#).

## Converting to Other Types

Options can be converted to lists or arrays. When an option is converted into either of these data structures, the resulting data structure has zero or one element. To convert an option to an array, use `Option.toArray`. To convert an option to a list, use `Option.toList`.

# Value Options

2/7/2019 • 2 minutes to read • [Edit Online](#)

The Value Option type in F# is used when the following two circumstances hold:

1. A scenario is appropriate for an [F# Option](#).
2. Using a struct provides a performance benefit in your scenario.

Not all performance-sensitive scenarios are "solved" by using structs. You must consider the additional cost of copying when using them instead of reference types. However, large F# programs commonly instantiate many optional types that flow through hot paths, and in such cases, structs can often yield better overall performance over the lifetime of a program.

## Definition

Value Option is defined as a [struct discriminated union](#) that is similar to the reference option type. Its definition can be thought of this way:

```
[<StructuralEquality; StructuralComparison>]
[<Struct>]
type ValueOption<'T> =
    | ValueNone
    | ValueSome of 'T
```

Value Option conforms to structural equality and comparison. The main difference is that the compiled name, type name, and case names all indicate that it is a value type.

## Using Value Options

Value Options are used just like [Options](#). `ValueSome` is used to indicate that a value is present, and `ValueNone` is used when a value is not present:

```
let tryParseDateTime (s: string) =
    match System.DateTime.TryParse(s) with
    | (true, dt) -> ValueSome dt
    | (false, _) -> ValueNone

let possibleDateString1 = "1990-12-25"
let possibleDateString2 = "This is not a date"

let result1 = tryParseDateTime possibleDateString1
let result2 = tryParseDateTime possibleDateString2

match (result1, result2) with
| ValueSome d1, ValueSome d2 -> printfn "Both are dates!"
| ValueSome d1, ValueNone -> printfn "Only the first is a date!"
| ValueNone, ValueSome d2 -> printfn "Only the second is a date!"
| ValueNone, ValueNone -> printfn "None of them are dates!"
```

As with [Options](#), the naming convention for a function that returns `ValueOption` is to prefix it with `try`.

## Value Option properties and methods

There is one property for Value Options at this time: `Value`. An `InvalidOperationException` is raised if no value is present when this property is invoked.

## Value Option functions

There is currently one module-bound function for Value Options, `defaultValueArg` :

```
val defaultValueArg : arg:'T option -> defaultValue:'T -> 'T
```

As with the `defaultArg` function, `defaultValueArg` returns the underlying value of the given Value Option if it exists; otherwise, it returns the specified default value.

At this time, there are no other module-bound functions for Value Options.

## See also

- [Options](#)

# Results

12/19/2018 • 2 minutes to read • [Edit Online](#)

Starting with F# 4.1, there is a `Result<'T, 'TFailure>` type which you can use for writing error-tolerant code which can be composed.

## Syntax

```
// The definition of Result in FSharp.Core
[<StructuralEquality; StructuralComparison>]
[<CompiledName("FSharpResult`2")>]
[<Struct>]
type Result<'T, 'TError> =
    | Ok of ResultValue:'T
    | Error of ErrorValue:'TError
```

## Remarks

Note that the result type is a [struct discriminated union](#), which is another feature introduced in F# 4.1. Structural equality semantics apply here.

The `Result` type is typically used in monadic error-handling, which is often referred to as [Railway-oriented Programming](#) within the F# community. The following trivial example demonstrates this approach.

```

// Define a simple type which has fields that can be validated
type Request =
    { Name: string
      Email: string }

// Define some logic for what defines a valid name.
//
// Generates a Result which is an Ok if the name validates;
// otherwise, it generates a Result which is an Error.
let validateName req =
    match req.Name with
    | null -> Error "No name found."
    | "" -> Error "Name is empty."
    | "bananas" -> Error "Bananas is not a name."
    | _ -> Ok req

// Similarly, define some email validation logic.
let validateEmail req =
    match req.Email with
    | null -> Error "No email found."
    | "" -> Error "Email is empty."
    | s when s.EndsWith("bananas.com") -> Error "No email from bananas.com is allowed."
    | _ -> Ok req

let validateRequest reqResult =
    reqResult
    |> Result.bind validateName
    |> Result.bind validateEmail

let test() =
    // Now, create a Request and pattern match on the result.
    let req1 = { Name = "Phillip"; Email = "phillip@contoso.biz" }
    let res1 = validateRequest (Ok req1)
    match res1 with
    | Ok req -> printfn "My request was valid! Name: %s Email %s" req.Name req.Email
    | Error e -> printfn "Error: %s" e
    // Prints: "My request was valid! Name: Phillip Email: phillip@contoso.biz"

    let req2 = { Name = "Phillip"; Email = "phillip@bananas.com" }
    let res2 = validateRequest (Ok req2)
    match res2 with
    | Ok req -> printfn "My request was valid! Name: %s Email %s" req.Name req.Email
    | Error e -> printfn "Error: %s" e
    // Prints: "Error: No email from bananas.com is allowed."

test()

```

As you can see, it's quite easy to chain together various validation functions if you force them all to return a `Result`. This lets you break up functionality like this into small pieces which are as composable as you need them to be. This also has the added value of *enforcing* the use of [pattern matching](#) at the end of a round of validation, which in turns enforces a higher degree of program correctness.

# Generics

12/19/2018 • 6 minutes to read • [Edit Online](#)

F# function values, methods, properties, and aggregate types such as classes, records, and discriminated unions can be *generic*. Generic constructs contain at least one type parameter, which is usually supplied by the user of the generic construct. Generic functions and types enable you to write code that works with a variety of types without repeating the code for each type. Making your code generic can be simple in F#, because often your code is implicitly inferred to be generic by the compiler's type inference and automatic generalization mechanisms.

## Syntax

```
// Explicitly generic function.  
let function-name<type-parameters> parameter-list =  
    function-body  
  
// Explicitly generic method.  
[ static ] member object-identifier.method-name<type-parameters> parameter-list [ return-type ] =  
    method-body  
  
// Explicitly generic class, record, interface, structure,  
// or discriminated union.  
type type-name<type-parameters> type-definition
```

## Remarks

The declaration of an explicitly generic function or type is much like that of a non-generic function or type, except for the specification (and use) of the type parameters, in angle brackets after the function or type name.

Declarations are often implicitly generic. If you do not fully specify the type of every parameter that is used to compose a function or type, the compiler attempts to infer the type of each parameter, value, and variable from the code you write. For more information, see [Type Inference](#). If the code for your type or function does not otherwise constrain the types of parameters, the function or type is implicitly generic. This process is named *automatic generalization*. There are some limits on automatic generalization. For example, if the F# compiler is unable to infer the types for a generic construct, the compiler reports an error that refers to a restriction called the *value restriction*. In that case, you may have to add some type annotations. For more information about automatic generalization and the value restriction, and how to change your code to address the problem, see [Automatic Generalization](#).

In the previous syntax, *type-parameters* is a comma-separated list of parameters that represent unknown types, each of which starts with a single quotation mark, optionally with a constraint clause that further limits what types may be used for that type parameter. For the syntax for constraint clauses of various kinds and other information about constraints, see [Constraints](#).

The *type-definition* in the syntax is the same as the type definition for a non-generic type. It includes the constructor parameters for a class type, an optional `as` clause, the equal symbol, the record fields, the `inherit` clause, the choices for a discriminated union, `let` and `do` bindings, member definitions, and anything else permitted in a non-generic type definition.

The other syntax elements are the same as those for non-generic functions and types. For example, *object-identifier* is an identifier that represents the containing object itself.

Properties, fields, and constructors cannot be more generic than the enclosing type. Also, values in a module

cannot be generic.

## Implicitly Generic Constructs

When the F# compiler infers the types in your code, it automatically treats any function that can be generic as generic. If you specify a type explicitly, such as a parameter type, you prevent automatic generalization.

In the following code example, `makeList` is generic, even though neither it nor its parameters are explicitly declared as generic.

```
let makeList a b =
    [a; b]
```

The signature of the function is inferred to be `'a -> 'a -> 'a list`. Note that `a` and `b` in this example are inferred to have the same type. This is because they are included in a list together, and all elements of a list must be of the same type.

You can also make a function generic by using the single quotation mark syntax in a type annotation to indicate that a parameter type is a generic type parameter. In the following code, `function1` is generic because its parameters are declared in this manner, as type parameters.

```
let function1 (x: 'a) (y: 'a) =
    printfn "%A %A" x y
```

## Explicitly Generic Constructs

You can also make a function generic by explicitly declaring its type parameters in angle brackets (`<type-parameter>`). The following code illustrates this.

```
let function2<'T> x y =
    printfn "%A, %A" x y
```

## Using Generic Constructs

When you use generic functions or methods, you might not have to specify the type arguments. The compiler uses type inference to infer the appropriate type arguments. If there is still an ambiguity, you can supply type arguments in angle brackets, separating multiple type arguments with commas.

The following code shows the use of the functions that are defined in the previous sections.

```
// In this case, the type argument is inferred to be int.
function1 10 20
// In this case, the type argument is float.
function1 10.0 20.0
// Type arguments can be specified, but should only be specified
// if the type parameters are declared explicitly. If specified,
// they have an effect on type inference, so in this example,
// a and b are inferred to have type int.
let function3 a b =
    // The compiler reports a warning:
    function1<int> a b
    // No warning.
    function2<int> a b
```

#### NOTE

There are two ways to refer to a generic type by name. For example, `list<int>` and `int list` are two ways to refer to a generic type `list` that has a single type argument `int`. The latter form is conventionally used only with built-in F# types such as `list` and `option`. If there are multiple type arguments, you normally use the syntax `Dictionary<int, string>` but you can also use the syntax `(int, string) Dictionary`.

## Wildcards as Type Arguments

To specify that a type argument should be inferred by the compiler, you can use the underscore, or wildcard symbol (`_`), instead of a named type argument. This is shown in the following code.

```
let printSequence (sequence1: Collections.seq<_>) =
    Seq.iter (fun elem -> printf "%s " (elem.ToString())) sequence1
```

## Constraints in Generic Types and Functions

In a generic type or function definition, you can use only those constructs that are known to be available on the generic type parameter. This is required to enable the verification of function and method calls at compile time. If you declare your type parameters explicitly, you can apply an explicit constraint to a generic type parameter to notify the compiler that certain methods and functions are available. However, if you allow the F# compiler to infer your generic parameter types, it will determine the appropriate constraints for you. For more information, see [Constraints](#).

## Statically Resolved Type Parameters

There are two kinds of type parameters that can be used in F# programs. The first are generic type parameters of the kind described in the previous sections. This first kind of type parameter is equivalent to the generic type parameters that are used in languages such as Visual Basic and C#. Another kind of type parameter is specific to F# and is referred to as a *statically resolved type parameter*. For information about these constructs, see [Statically Resolved Type Parameters](#).

## Examples

```

// A generic function.
// In this example, the generic type parameter 'a makes function3 generic.
let function3 (x : 'a) (y : 'a) =
    printf "%A %A" x y

// A generic record, with the type parameter in angle brackets.
type GR<'a> =
{
    Field1: 'a;
    Field2: 'a;
}

// A generic class.
type C<'a>(a : 'a, b : 'a) =
    let z = a
    let y = b
    member this.GenericMethod(x : 'a) =
        printfn "%A %A %A" x y z

// A generic discriminated union.
type U<'a> =
| Choice1 of 'a
| Choice2 of 'a * 'a

type Test() =
    // A generic member
    member this.Function1<'a>(x, y) =
        printfn "%A, %A" x y

    // A generic abstract method.
    abstract abstractMethod<'a, 'b> : 'a * 'b -> unit
    override this.abstractMethod<'a, 'b>(x:'a, y:'b) =
        printfn "%A, %A" x y

```

# Automatic Generalization

12/19/2018 • 3 minutes to read • [Edit Online](#)

F# uses type inference to evaluate the types of functions and expressions. This topic describes how F# automatically generalizes the arguments and types of functions so that they work with multiple types when this is possible.

## Automatic Generalization

The F# compiler, when it performs type inference on a function, determines whether a given parameter can be generic. The compiler examines each parameter and determines whether the function has a dependency on the specific type of that parameter. If it does not, the type is inferred to be generic.

The following code example illustrates a function that the compiler infers to be generic.

```
let max a b = if a > b then a else b
```

The type is inferred to be `'a -> 'a -> 'a`.

The type indicates that this is a function that takes two arguments of the same unknown type and returns a value of that same type. One of the reasons that the previous function can be generic is that the greater-than operator (`>`) is itself generic. The greater-than operator has the signature `'a -> 'a -> bool`. Not all operators are generic, and if the code in a function uses a parameter type together with a non-generic function or operator, that parameter type cannot be generalized.

Because `max` is generic, it can be used with types such as `int`, `float`, and so on, as shown in the following examples.

```
let biggestFloat = max 2.0 3.0
let biggestInt = max 2 3
```

However, the two arguments must be of the same type. The signature is `'a -> 'a -> 'a`, not `'a -> 'b -> 'a`. Therefore, the following code produces an error because the types do not match.

```
// Error: type mismatch.
let biggestIntFloat = max 2.0 3
```

The `max` function also works with any type that supports the greater-than operator. Therefore, you could also use it on a string, as shown in the following code.

```
let testString = max "cab" "cat"
```

## Value Restriction

The compiler performs automatic generalization only on complete function definitions that have explicit arguments, and on simple immutable values.

This means that the compiler issues an error if you try to compile code that is not sufficiently constrained to be a specific type, but is also not generalizable. The error message for this problem refers to this restriction on

automatic generalization for values as the *value restriction*.

Typically, the value restriction error occurs either when you want a construct to be generic but the compiler has insufficient information to generalize it, or when you unintentionally omit sufficient type information in a nongeneric construct. The solution to the value restriction error is to provide more explicit information to more fully constrain the type inference problem, in one of the following ways:

- Constrain a type to be nongeneric by adding an explicit type annotation to a value or parameter.
- If the problem is using a nongeneralizable construct to define a generic function, such as a function composition or incompletely applied curried function arguments, try to rewrite the function as an ordinary function definition.
- If the problem is an expression that is too complex to be generalized, make it into a function by adding an extra, unused parameter.
- Add explicit generic type parameters. This option is rarely used.
- The following code examples illustrate each of these scenarios.

Case 1: Too complex an expression. In this example, the list `counter` is intended to be `int option ref`, but it is not defined as a simple immutable value.

```
let counter = ref None
// Adding a type annotation fixes the problem:
let counter : int option ref = ref None
```

Case 2: Using a nongeneralizable construct to define a generic function. In this example, the construct is nongeneralizable because it involves partial application of function arguments.

```
let maxhash = max << hash
// The following is acceptable because the argument for maxhash is explicit:
let maxhash obj = (max << hash) obj
```

Case 3: Adding an extra, unused parameter. Because this expression is not simple enough for generalization, the compiler issues the value restriction error.

```
let emptyList10 = Array.create 10 []
// Adding an extra (unused) parameter makes it a function, which is generalizable.
let emptyList10 () = Array.create 10 []
```

Case 4: Adding type parameters.

```
let arrayOf10Lists = Array.create 10 []
// Adding a type parameter and type annotation lets you write a generic value.
let arrayOf10Lists<'T> = Array.create 10 ([]:'T list)
```

In the last case, the value becomes a type function, which may be used to create values of many different types, for example as follows:

```
let intLists = arrayOf10Lists<int>
let floatLists = arrayOf10Lists<float>
```

# Constraints

12/19/2018 • 4 minutes to read • [Edit Online](#)

This topic describes constraints that you can apply to generic type parameters to specify the requirements for a type argument in a generic type or function.

## Syntax

```
type-parameter-list when constraint1 [ and constraint2]
```

## Remarks

There are several different constraints you can apply to limit the types that can be used in a generic type. The following table lists and describes these constraints.

CONSTRAINT	SYNTAX	DESCRIPTION
Type Constraint	<i>type-parameter</i> :> <i>type</i>	The provided type must be equal to or derived from the type specified, or, if the type is an interface, the provided type must implement the interface.
Null Constraint	<i>type-parameter</i> : null	The provided type must support the null literal. This includes all .NET object types but not F# list, tuple, function, class, record, or union types.
Explicit Member Constraint	[ <i>type-parameter</i> [or ... or <i>type-parameter</i> ]] : ( <i>member-signature</i> )	At least one of the type arguments provided must have a member that has the specified signature; not intended for common use. Members must be either explicitly defined on the type or part of an implicit type extension to be valid targets for an Explicit Member Constraint.
Constructor Constraint	<i>type-parameter</i> : ( new : unit -> 'a )	The provided type must have a default constructor.
Value Type Constraint	: struct	The provided type must be a .NET value type.
Reference Type Constraint	: not struct	The provided type must be a .NET reference type.
Enumeration Type Constraint	: enum< <i>underlying-type</i> >	The provided type must be an enumerated type that has the specified underlying type; not intended for common use.

CONSTRAINT	SYNTAX	DESCRIPTION
Delegate Constraint	: delegate< <i>tuple-parameter-type</i> , <i>return-type</i> >	The provided type must be a delegate type that has the specified arguments and return value; not intended for common use.
Comparison Constraint	: comparison	The provided type must support comparison.
Equality Constraint	: equality	The provided type must support equality.
Unmanaged Constraint	: unmanaged	The provided type must be an unmanaged type. Unmanaged types are either certain primitive types ( <code>sbyte</code> , <code>byte</code> , <code>char</code> , <code>nativeint</code> , <code>unativeint</code> , <code>float32</code> , <code>float</code> , <code>int16</code> , <code>uint16</code> , <code>int32</code> , <code>uint32</code> , <code>int64</code> , <code>uint64</code> , or <code>decimal</code> ), enumeration types, <code>nativeptr&lt;_&gt;</code> , or a non-generic structure whose fields are all unmanaged types.

You have to add a constraint when your code has to use a feature that is available on the constraint type but not on types in general. For example, if you use the type constraint to specify a class type, you can use any one of the methods of that class in the generic function or type.

Specifying constraints is sometimes required when writing type parameters explicitly, because without a constraint, the compiler has no way of verifying that the features that you are using will be available on any type that might be supplied at run time for the type parameter.

The most common constraints you use in F# code are type constraints that specify base classes or interfaces. The other constraints are either used by the F# library to implement certain functionality, such as the explicit member constraint, which is used to implement operator overloading for arithmetic operators, or are provided mainly because F# supports the complete set of constraints that is supported by the common language runtime.

During the type inference process, some constraints are inferred automatically by the compiler. For example, if you use the `+` operator in a function, the compiler infers an explicit member constraint on variable types that are used in the expression.

The following code illustrates some constraint declarations.

```

// Base Type Constraint
type Class1<'T when 'T :> System.Exception> =
class end

// Interface Type Constraint
type Class2<'T when 'T :> System.IComparable> =
class end

// Null constraint
type Class3<'T when 'T : null> =
class end

// Member constraint with static member
type Class4<'T when 'T : (static member staticMethod1 : unit -> 'T) > =
class end

// Member constraint with instance member
type Class5<'T when 'T : (member Method1 : 'T -> int)> =
class end

// Member constraint with property
type Class6<'T when 'T : (member Property1 : int)> =
class end

// Constructor constraint
type Class7<'T when 'T : (new : unit -> 'T)>() =
member val Field = new 'T()

// Reference type constraint
type Class8<'T when 'T : not struct> =
class end

// Enumeration constraint with underlying value specified
type Class9<'T when 'T : enum<uint32>> =
class end

// 'T must implement IComparable, or be an array type with comparable
// elements, or be System.IntPtr or System.UIntPtr. Also, 'T must not have
// the NoComparison attribute.
type Class10<'T when 'T : comparison> =
class end

// 'T must support equality. This is true for any type that does not
// have the NoEquality attribute.
type Class11<'T when 'T : equality> =
class end

type Class12<'T when 'T : delegate<obj * System.EventArgs, unit>> =
class end

type Class13<'T when 'T : unmanaged> =
class end

// Member constraints with two type parameters
// Most often used with static type parameters in inline functions
let inline add(value1 : ^T when ^T : (static member (+) : ^T * ^T -> ^T), value2: ^T) =
value1 + value2

// ^T and ^U must support operator +
let inline heterogenousAdd(value1 : ^T when (^T or ^U) : (static member (+) : ^T * ^U -> ^T), value2 : ^U) =
value1 + value2

// If there are multiple constraints, use the and keyword to separate them.
type Class14<'T,'U when 'T : equality and 'U : equality> =
class end

```

# Statically Resolved Type Parameters

12/19/2018 • 3 minutes to read • [Edit Online](#)

A *statically resolved type parameter* is a type parameter that is replaced with an actual type at compile time instead of at run time. They are preceded by a caret (^) symbol.

## Syntax

```
^type-parameter
```

## Remarks

In the F# language, there are two distinct kinds of type parameters. The first kind is the standard generic type parameter. These are indicated by an apostrophe ('), as in `'T` and `'U`. They are equivalent to generic type parameters in other .NET Framework languages. The other kind is statically resolved and is indicated by a caret symbol, as in `^T` and `^U`.

Statically resolved type parameters are primarily useful in conjunction with member constraints, which are constraints that allow you to specify that a type argument must have a particular member or members in order to be used. There is no way to create this kind of constraint by using a regular generic type parameter.

The following table summarizes the similarities and differences between the two kinds of type parameters.

FEATURE	GENERIC	STATICALLY RESOLVED
Syntax	<code>'T</code> , <code>'U</code>	<code>^T</code> , <code>^U</code>
Resolution time	Run time	Compile time
Member constraints	Cannot be used with member constraints.	Can be used with member constraints.
Code generation	A type (or method) with standard generic type parameters results in the generation of a single generic type or method.	Multiple instantiations of types and methods are generated, one for each type that is needed.
Use with types	Can be used on types.	Cannot be used on types.
Use with inline functions	No. An inline function cannot be parameterized with a standard generic type parameter.	Yes. Statically resolved type parameters cannot be used on functions or methods that are not inline.

Many F# core library functions, especially operators, have statically resolved type parameters. These functions and operators are inline, and result in efficient code generation for numeric computations.

Inline methods and functions that use operators, or use other functions that have statically resolved type parameters, can also use statically resolved type parameters themselves. Often, type inference infers such inline functions to have statically resolved type parameters. The following example illustrates an operator definition that is inferred to have a statically resolved type parameter.

```

let inline (+@) x y = x + x * y
// Call that uses int.
printfn "%d" (1 +@ 1)
// Call that uses float.
printfn "%f" (1.0 +@ 0.5)

```

The resolved type of `(+@)` is based on the use of both `(+)` and `(*)`, both of which cause type inference to infer member constraints on the statically resolved type parameters. The resolved type, as shown in the F# interpreter, is as follows.

```

^a -> ^c -> ^d
when (^a or ^b) : (static member (+) : ^a * ^b -> ^d) and
(^a or ^c) : (static member (* ) : ^a * ^c -> ^b)

```

The output is as follows.

```

2
1.500000

```

Starting with F# 4.1, you can also specify concrete type names in statically resolved type parameter signatures. In previous versions of the language, the type name could actually be inferred by the compiler, but could not actually be specified in the signature. As of F# 4.1, you may also specify concrete type names in statically resolved type parameter signatures. Here's an example:

```

let inline konst x _ = x

type CFunctor() =
    static member inline fmap (f: ^a -> ^b, a: ^a list) = List.map f a
    static member inline fmap (f: ^a -> ^b, a: ^a option) =
        match a with
        | None -> None
        | Some x -> Some (f x)

    // default implementation of replace
    static member inline replace< ^a, ^b, ^c, ^d, ^e when ^a :> CFunctor and (^a or ^d): (static member fmap: (^b -> ^c) * ^d -> ^e) > (a, f) =
        ((^a or ^d) : (static member fmap : (^b -> ^c) * ^d -> ^e) (konst a, f))

    // call overridden replace if present
    static member inline replace< ^a, ^b, ^c when ^b: (static member replace: ^a * ^b -> ^c)>(a: ^a, f: ^b) =
        (^b : (static member replace: ^a * ^b -> ^c) (a, f))

let inline replace_instance< ^a, ^b, ^c, ^d when (^a or ^c): (static member replace: ^b * ^c -> ^d)> (a: ^b, f: ^c) =
    ((^a or ^c): (static member replace: ^b * ^c -> ^d) (a, f))

// Note the concrete type 'CFunctor' specified in the signature
let inline replace (a: ^a) (f: ^b): ^a0 when (CFunctor or ^b): (static member replace: ^a * ^b -> ^a0) =
    replace_instance<CFunctor, _, _, _> (a, f)

```

# Records

12/20/2018 • 6 minutes to read • [Edit Online](#)

Records represent simple aggregates of named values, optionally with members. Starting with F# 4.1, they can either be structs or reference types. They are reference types by default.

## Syntax

```
[ attributes ]
type [accessibility-modifier] typename =
{ [ mutable ] label1 : type1;
  [ mutable ] label2 : type2;
  ...
[ member-list ]
```

## Remarks

In the previous syntax, *typename* is the name of the record type, *label1* and *label2* are names of values, referred to as *labels*, and *type1* and *type2* are the types of these values. *member-list* is the optional list of members for the type. You can use the `[<Struct>]` attribute to create a struct record rather than a record which is a reference type.

Following are some examples.

```
// Labels are separated by semicolons when defined on the same line.
type Point = { X: float; Y: float; Z: float; }

// You can define labels on their own line with a semicolon.
type Customer =
{ First: string
  Last: string
  SSN: uint32
  AccountNumber: uint32; }

// A struct record.
[<Struct>]
type StructPoint =
{ X: float
  Y: float
  Z: float }
```

When each label is on a separate line, the semicolon is optional.

You can set values in expressions known as *record expressions*. The compiler infers the type from the labels used (if the labels are sufficiently distinct from those of other record types). Braces (`{ }` ) enclose the record expression. The following code shows a record expression that initializes a record with three float elements with labels `x`, `y` and `z`.

```
let mypoint = { X = 1.0; Y = 1.0; Z = -1.0; }
```

Do not use the shortened form if there could be another type that also has the same labels.

```
type Point = { X: float; Y: float; Z: float; }
type Point3D = { X: float; Y: float; Z: float }
// Ambiguity: Point or Point3D?
let mypoint3D = { X = 1.0; Y = 1.0; Z = 0.0; }
```

The labels of the most recently declared type take precedence over those of the previously declared type, so in the preceding example, `mypoint3D` is inferred to be `Point3D`. You can explicitly specify the record type, as in the following code.

```
let myPoint1 = { Point.X = 1.0; Y = 1.0; Z = 0.0; }
```

Methods can be defined for record types just as for class types.

## Creating Records by Using Record Expressions

You can initialize records by using the labels that are defined in the record. An expression that does this is referred to as a *record expression*. Use braces to enclose the record expression and use the semicolon as a delimiter.

The following example shows how to create a record.

```
type MyRecord =
{ X: int
  Y: int
  Z: int }

let myRecord1 = { X = 1; Y = 2; Z = 3; }
```

The semicolons after the last field in the record expression and in the type definition are optional, regardless of whether the fields are all in one line.

When you create a record, you must supply values for each field. You cannot refer to the values of other fields in the initialization expression for any field.

In the following code, the type of `myRecord2` is inferred from the names of the fields. Optionally, you can specify the type name explicitly.

```
let myRecord2 = { MyRecord.X = 1; MyRecord.Y = 2; MyRecord.Z = 3 }
```

Another form of record construction can be useful when you have to copy an existing record, and possibly change some of the field values. The following line of code illustrates this.

```
let myRecord3 = { myRecord2 with Y = 100; Z = 2 }
```

This form of the record expression is called the *copy and update record expression*.

Records are immutable by default; however, you can easily create modified records by using a copy and update expression. You can also explicitly specify a mutable field.

```

type Car =
    { Make : string
      Model : string
      mutable Odometer : int }

let myCar = { Make = "Fabrikam"; Model = "Coupe"; Odometer = 108112 }
myCar.Odometer <- myCar.Odometer + 21

```

Don't use the `<DefaultValue>` attribute with record fields. A better approach is to define default instances of records with fields that are initialized to default values and then use a copy and update record expression to set any fields that differ from the default values.

```

// Rather than use [<DefaultValue>], define a default record.
type MyRecord =
    { Field1 : int
      Field2 : int }

let defaultRecord1 = { Field1 = 0; Field2 = 0 }
let defaultRecord2 = { Field1 = 1; Field2 = 25 }

// Use the with keyword to populate only a few chosen fields
// and leave the rest with default values.
let rr3 = { defaultRecord1 with Field2 = 42 }

```

## Creating Mutually Recursive Records

Sometime when creating a record, you may want to have it depend on another type that you would like to define afterwards. This is a compile error unless you define the record types to be mutually recursive.

Defining mutually recursive records is done with the `and` keyword. This lets you link 2 or more record types together.

For example, the following code defines a `Person` and `Address` type as mutually recursive:

```

// Create a Person type and use the Address type that is not defined
type Person =
    { Name: string
      Age: int
      Address: Address }
// Define the Address type which is used in the Person record
and Address =
    { Line1: string
      Line2: string
      PostCode: string }

```

If you were to define the previous example without the `and` keyword, then it would not compile. The `and` keyword is required for mutually recursive definitions.

## Pattern Matching with Records

Records can be used with pattern matching. You can specify some fields explicitly and provide variables for other fields that will be assigned when a match occurs. The following code example illustrates this.

```

type Point3D = { X: float; Y: float; Z: float }
let evaluatePoint (point: Point3D) =
    match point with
    | { X = 0.0; Y = 0.0; Z = 0.0 } -> printfn "Point is at the origin."
    | { X = xVal; Y = 0.0; Z = 0.0 } -> printfn "Point is on the x-axis. Value is %f." xVal
    | { X = 0.0; Y = yVal; Z = 0.0 } -> printfn "Point is on the y-axis. Value is %f." yVal
    | { X = 0.0; Y = 0.0; Z = zVal } -> printfn "Point is on the z-axis. Value is %f." zVal
    | { X = xVal; Y = yVal; Z = zVal } -> printfn "Point is at (%f, %f, %f)." xVal yVal zVal

evaluatePoint { X = 0.0; Y = 0.0; Z = 0.0 }
evaluatePoint { X = 100.0; Y = 0.0; Z = 0.0 }
evaluatePoint { X = 10.0; Y = 0.0; Z = -1.0 }

```

The output of this code is as follows.

```

Point is at the origin.
Point is on the x-axis. Value is 100.000000.
Point is at (10.000000, 0.000000, -1.000000).

```

## Differences Between Records and Classes

Record fields differ from classes in that they are automatically exposed as properties, and they are used in the creation and copying of records. Record construction also differs from class construction. In a record type, you cannot define a constructor. Instead, the construction syntax described in this topic applies. Classes have no direct relationship between constructor parameters, fields, and properties.

Like union and structure types, records have structural equality semantics. Classes have reference equality semantics. The following code example demonstrates this.

```

type RecordTest = { X: int; Y: int }

let record1 = { X = 1; Y = 2 }
let record2 = { X = 1; Y = 2 }

if (record1 = record2) then
    printfn "The records are equal."
else
    printfn "The records are unequal."

```

The output of this code is as follows:

```

The records are equal.

```

If you write the same code with classes, the two class objects would be unequal because the two values would represent two objects on the heap and only the addresses would be compared (unless the class type overrides the `System.Object.Equals` method).

If you need reference equality for records, add the attribute `[<ReferenceEquality>]` above the record.

# Discriminated Unions

12/19/2018 • 8 minutes to read • [Edit Online](#)

Discriminated unions provide support for values that can be one of a number of named cases, possibly each with different values and types. Discriminated unions are useful for heterogeneous data; data that can have special cases, including valid and error cases; data that varies in type from one instance to another; and as an alternative for small object hierarchies. In addition, recursive discriminated unions are used to represent tree data structures.

## Syntax

```
[ attributes ]
type [accessibility-modifier] type-name =
    | case-identifier1 [of [fieldname1 : ] type1 [ * [fieldname2 : ] type2 ...]
    | case-identifier2 [of [fieldname3 : ] type3 [ * [fieldname4 : ] type4 ...]

[ member-list ]
```

## Remarks

Discriminated unions are similar to union types in other languages, but there are differences. As with a union type in C++ or a variant type in Visual Basic, the data stored in the value is not fixed; it can be one of several distinct options. Unlike unions in these other languages, however, each of the possible options is given a *case identifier*. The case identifiers are names for the various possible types of values that objects of this type could be; the values are optional. If values are not present, the case is equivalent to an enumeration case. If values are present, each value can either be a single value of a specified type, or a tuple that aggregates multiple fields of the same or different types. You can give an individual field a name, but the name is optional, even if other fields in the same case are named.

Accessibility for discriminated unions defaults to `public`.

For example, consider the following declaration of a Shape type.

```
type Shape =
    | Rectangle of width : float * length : float
    | Circle of radius : float
    | Prism of width : float * float * height : float
```

The preceding code declares a discriminated union Shape, which can have values of any of three cases: Rectangle, Circle, and Prism. Each case has a different set of fields. The Rectangle case has two named fields, both of type `float`, that have the names width and length. The Circle case has just one named field, radius. The Prism case has three fields, two of which (width and height) are named fields. Unnamed fields are referred to as anonymous fields.

You construct objects by providing values for the named and anonymous fields according to the following examples.

```
let rect = Rectangle(length = 1.3, width = 10.0)
let circ = Circle (1.0)
let prism = Prism(5., 2.0, height = 3.0)
```

This code shows that you can either use the named fields in the initialization, or you can rely on the ordering of the fields in the declaration and just provide the values for each field in turn. The constructor call for `rect` in the previous code uses the named fields, but the constructor call for `circ` uses the ordering. You can mix the ordered fields and named fields, as in the construction of `prism`.

The `option` type is a simple discriminated union in the F# core library. The `option` type is declared as follows.

```
// The option type is a discriminated union.
type Option<'a> =
    | Some of 'a
    | None
```

The previous code specifies that the type `Option` is a discriminated union that has two cases, `Some` and `None`. The `Some` case has an associated value that consists of one anonymous field whose type is represented by the type parameter `'a`. The `None` case has no associated value. Thus the `option` type specifies a generic type that either has a value of some type or no value. The type `option` also has a lowercase type alias, `option`, that is more commonly used.

The case identifiers can be used as constructors for the discriminated union type. For example, the following code is used to create values of the `option` type.

```
let myOption1 = Some(10.0)
let myOption2 = Some("string")
let myOption3 = None
```

The case identifiers are also used in pattern matching expressions. In a pattern matching expression, identifiers are provided for the values associated with the individual cases. For example, in the following code, `x` is the identifier given the value that is associated with the `Some` case of the `option` type.

```
let printValue opt =
    match opt with
    | Some x -> printfn "%A" x
    | None -> printfn "No value."
```

In pattern matching expressions, you can use named fields to specify discriminated union matches. For the `Shape` type that was declared previously, you can use the named fields as the following code shows to extract the values of the fields.

```
let getShapeHeight shape =
    match shape with
    | Rectangle(height = h) -> h
    | Circle(radius = r) -> 2. * r
    | Prism(height = h) -> h
```

Normally, the case identifiers can be used without qualifying them with the name of the union. If you want the name to always be qualified with the name of the union, you can apply the `RequireQualifiedAccess` attribute to the union type definition.

## Unwrapping Discriminated Unions

In F# Discriminated Unions are often used in domain-modeling for wrapping a single type. It's easy to extract the underlying value via pattern matching as well. You don't need to use a `match` expression for a single case:

```
let ([UnionCaseName] [values]) = [UnionValue]
```

The following example demonstrates this:

```
type ShaderProgram = | ShaderProgram of id:int

let someFunctionUsingShaderProgram shaderProgram =
    let (ShaderProgram id) = shaderProgram
    // Use the unwrapped value
    ...
```

Pattern matching is also allowed directly in function parameters, so you can unwrap a single case there:

```
let someFunctionUsingShaderProgram (ShaderProgram id) =
    // Use the unwrapped value
    ...
```

## Struct Discriminated Unions

Starting with F# 4.1, you can also represent Discriminated Unions as structs. This is done with the [`<Struct>`]

```
[<Struct>]
type SingleCase = Case of string

[<Struct>]
type Multicase =
    | Case1 of Case1 : string
    | Case2 of Case2 : int
    | Case3 of Case3 : double
```

Because these are value types and not reference types, there are extra considerations compared with reference discriminated unions:

1. They are copied as value types and have value type semantics.
2. You cannot use a recursive type definition with a multicase struct Discriminated Union.
3. You must provide unique case names for a multicase struct Discriminated Union.

## Using Discriminated Unions Instead of Object Hierarchies

You can often use a discriminated union as a simpler alternative to a small object hierarchy. For example, the following discriminated union could be used instead of a `Shape` base class that has derived types for circle, square, and so on.

```
type Shape =
    // The value here is the radius.
    | Circle of float
    // The value here is the side length.
    | EquilateralTriangle of double
    // The value here is the side length.
    | Square of double
    // The values here are the height and width.
    | Rectangle of double * double
```

Instead of a virtual method to compute an area or perimeter, as you would use in an object-oriented implementation, you can use pattern matching to branch to appropriate formulas to compute these quantities. In the following example, different formulas are used to compute the area, depending on the shape.

```

let pi = 3.141592654

let area myShape =
    match myShape with
    | Circle radius -> pi * radius * radius
    | EquilateralTriangle s -> (sqrt 3.0) / 4.0 * s * s
    | Square s -> s * s
    | Rectangle (h, w) -> h * w

let radius = 15.0
let myCircle = Circle(radius)
printfn "Area of circle that has radius %f: %f" radius (area myCircle)

let squareSide = 10.0
let mySquare = Square(squareSide)
printfn "Area of square that has side %f: %f" squareSide (area mySquare)

let height, width = 5.0, 10.0
let myRectangle = Rectangle(height, width)
printfn "Area of rectangle that has height %f and width %f is %f" height width (area myRectangle)

```

The output is as follows:

```

Area of circle that has radius 15.000000: 706.858347
Area of square that has side 10.000000: 100.000000
Area of rectangle that has height 5.000000 and width 10.000000 is 50.000000

```

## Using Discriminated Unions for Tree Data Structures

Discriminated unions can be recursive, meaning that the union itself can be included in the type of one or more cases. Recursive discriminated unions can be used to create tree structures, which are used to model expressions in programming languages. In the following code, a recursive discriminated union is used to create a binary tree data structure. The union consists of two cases, `Node`, which is a node with an integer value and left and right subtrees, and `Tip`, which terminates the tree.

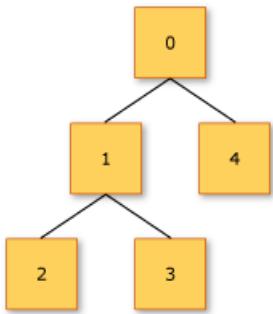

```

type Tree =
    | Tip
    | Node of int * Tree * Tree

let rec sumTree tree =
    match tree with
    | Tip -> 0
    | Node(value, left, right) ->
        value + sumTree(left) + sumTree(right)
let myTree = Node(0, Node(1, Node(2, Tip, Tip), Node(3, Tip, Tip)), Node(4, Tip, Tip))
let resultSumTree = sumTree myTree

```

In the previous code, `resultSumTree` has the value 10. The following illustration shows the tree structure for `myTree`.

Discriminated unions work well if the nodes in the tree are heterogeneous. In the following code, the type `Expression` represents the abstract syntax tree of an expression in a simple programming language that supports addition and multiplication of numbers and variables. Some of the union cases are not recursive and represent either numbers (`Number`) or variables (`Variable`). Other cases are recursive, and represent operations (`Add` and `Multiply`), where the operands are also expressions. The `Evaluate` function uses a match expression to recursively process the syntax tree.

```

type Expression =
| Number of int
| Add of Expression * Expression
| Multiply of Expression * Expression
| Variable of string

let rec Evaluate (env:Map<string,int>) exp =
  match exp with
  | Number n -> n
  | Add (x, y) -> Evaluate env x + Evaluate env y
  | Multiply (x, y) -> Evaluate env x * Evaluate env y
  | Variable id    -> env.[id]

let environment = Map.ofList [ "a", 1 ;
                                "b", 2 ;
                                "c", 3 ]

// Create an expression tree that represents
// the expression: a + 2 * b.
let expressionTree1 = Add(Variable "a", Multiply(Number 2, Variable "b"))

// Evaluate the expression a + 2 * b, given the
// table of values for the variables.
let result = Evaluate environment expressionTree1
  
```

When this code is executed, the value of `result` is 5.

## Common Attributes

The following attributes are commonly seen in discriminated unions:

- `[RequireQualifiedAccess]`
- `[NoEquality]`
- `[NoComparison]`
- `[Struct]`

## See also

- [F# Language Reference](#)

# Enumerations

12/19/2018 • 2 minutes to read • [Edit Online](#)

*Enumerations*, also known as *enums*, are integral types where labels are assigned to a subset of the values. You can use them in place of literals to make code more readable and maintainable.

## Syntax

```
type enum-name =
| value1 = integer-literal1
| value2 = integer-literal2
...
```

## Remarks

An enumeration looks much like a discriminated union that has simple values, except that the values can be specified. The values are typically integers that start at 0 or 1, or integers that represent bit positions. If an enumeration is intended to represent bit positions, you should also use the [Flags](#) attribute.

The underlying type of the enumeration is determined from the literal that is used, so that, for example, you can use literals with a suffix, such as `1u`, `2u`, and so on, for an unsigned integer (`uint32`) type.

When you refer to the named values, you must use the name of the enumeration type itself as a qualifier, that is, `enum-name.value1`, not just `value1`. This behavior differs from that of discriminated unions. This is because enumerations always have the [RequireQualifiedAccess](#) attribute.

The following code shows the declaration and use of an enumeration.

```
// Declaration of an enumeration.
type Color =
| Red = 0
| Green = 1
| Blue = 2
// Use of an enumeration.
let col1 : Color = Color.Red
```

You can easily convert enumerations to the underlying type by using the appropriate operator, as shown in the following code.

```
// Conversion to an integral type.
let n = int col1
```

Enumerated types can have one of the following underlying types: `sbyte`, `byte`, `int16`, `uint16`, `int32`, `uint32`, `int64`, `uint64`, `uint64`, and `char`. Enumeration types are represented in the .NET Framework as types that are inherited from `System.Enum`, which in turn is inherited from `System.ValueType`. Thus, they are value types that are located on the stack or inline in the containing object, and any value of the underlying type is a valid value of the enumeration. This is significant when pattern matching on enumeration values, because you have to provide a pattern that catches the unnamed values.

The `enum` function in the F# library can be used to generate an enumeration value, even a value other than one of

the predefined, named values. You use the `enum` function as follows.

```
let col2 = enum<Color>(3)
```

The default `enum` function works with type `int32`. Therefore, it cannot be used with enumeration types that have other underlying types. Instead, use the following.

```
type uColor =
| Red = 0u
| Green = 1u
| Blue = 2u
let col3 = Microsoft.FSharp.Core.LanguagePrimitives.EnumOfValue<uint32, uColor>(2u)
```

Additionally, cases for enums are always emitted as `public`. This is so that they align with C# and the rest of the .NET platform.

# Type Abbreviations

12/19/2018 • 2 minutes to read • [Edit Online](#)

A *type abbreviation* is an alias or alternate name for a type.

## Syntax

```
type [accessibility-modifier] type-abbreviation = type-name
```

## Remarks

You can use type abbreviations to give a type a more meaningful name, in order to make code easier to read. You can also use them to create an easy to use name for a type that is otherwise cumbersome to write out.

Additionally, you can use type abbreviations to make it easier to change an underlying type without changing all the code that uses the type. The following is a simple type abbreviation.

Accessibility of type abbreviations defaults to `public`.

```
type SizeType = uint32
```

Type abbreviations can include generic parameters, as in the following code.

```
type Transform<'a> = 'a -> 'a
```

In the previous code, `Transform` is a type abbreviation that represents a function that takes a single argument of any type and that returns a single value of that same type.

Type abbreviations are not preserved in the .NET Framework MSIL code. Therefore, when you use an F# assembly from another .NET Framework language, you must use the underlying type name for a type abbreviation.

Type abbreviations can also be used on units of measure. For more information, see [Units of Measure](#).

## See also

- [F# Language Reference](#)

# Classes

12/19/2018 • 8 minutes to read • [Edit Online](#)

Classes are types that represent objects that can have properties, methods, and events.

## Syntax

```
// Class definition:  
type [access-modifier] type-name [type-params] [access-modifier] ( parameter-list ) [ as identifier ] =  
[ class ]  
[ inherit base-type-name(base-constructor-args) ]  
[ let-bindings ]  
[ do-bindings ]  
member-list  
...  
[ end ]  
// Mutually recursive class definitions:  
type [access-modifier] type-name1 ...  
and [access-modifier] type-name2 ...  
...
```

## Remarks

Classes represent the fundamental description of .NET object types; the class is the primary type concept that supports object-oriented programming in F#.

In the preceding syntax, the `type-name` is any valid identifier. The `type-params` describes optional generic type parameters. It consists of type parameter names and constraints enclosed in angle brackets (`<` and `>`). For more information, see [Generics](#) and [Constraints](#). The `parameter-list` describes constructor parameters. The first access modifier pertains to the type; the second pertains to the primary constructor. In both cases, the default is `public`.

You specify the base class for a class by using the `inherit` keyword. You must supply arguments, in parentheses, for the base class constructor.

You declare fields or function values that are local to the class by using `let` bindings, and you must follow the general rules for `let` bindings. The `do-bindings` section includes code to be executed upon object construction.

The `member-list` consists of additional constructors, instance and static method declarations, interface declarations, abstract bindings, and property and event declarations. These are described in [Members](#).

The `identifier` that is used with the optional `as` keyword gives a name to the instance variable, or self identifier, which can be used in the type definition to refer to the instance of the type. For more information, see the section [Self Identifiers](#) later in this topic.

The keywords `class` and `end` that mark the start and end of the definition are optional.

Mutually recursive types, which are types that reference each other, are joined together with the `and` keyword just as mutually recursive functions are. For an example, see the section [Mutually Recursive Types](#).

## Constructors

The constructor is code that creates an instance of the class type. Constructors for classes work somewhat

differently in F# than they do in other .NET languages. In an F# class, there is always a primary constructor whose arguments are described in the `parameter-list` that follows the type name, and whose body consists of the `let` (and `let rec`) bindings at the start of the class declaration and the `do` bindings that follow. The arguments of the primary constructor are in scope throughout the class declaration.

You can add additional constructors by using the `new` keyword to add a member, as follows:

```
new ( argument-list ) = constructor-body
```

The body of the new constructor must invoke the primary constructor that is specified at the top of the class declaration.

The following example illustrates this concept. In the following code, `MyClass` has two constructors, a primary constructor that takes two arguments and another constructor that takes no arguments.

```
type MyClass1(x: int, y: int) =
    do printfn "%d %d" x y
new() = MyClass1(0, 0)
```

## let and do Bindings

The `let` and `do` bindings in a class definition form the body of the primary class constructor, and therefore they run whenever a class instance is created. If a `let` binding is a function, then it is compiled into a member. If the `let` binding is a value that is not used in any function or member, then it is compiled into a variable that is local to the constructor. Otherwise, it is compiled into a field of the class. The `do` expressions that follow are compiled into the primary constructor and execute initialization code for every instance. Because any additional constructors always call the primary constructor, the `let` bindings and `do` bindings always execute regardless of which constructor is called.

Fields that are created by `let` bindings can be accessed throughout the methods and properties of the class; however, they cannot be accessed from static methods, even if the static methods take an instance variable as a parameter. They cannot be accessed by using the `self` identifier, if one exists.

## Self Identifiers

A *self identifier* is a name that represents the current instance. Self identifiers resemble the `this` keyword in C# or C++ or `Me` in Visual Basic. You can define a self identifier in two different ways, depending on whether you want the self identifier to be in scope for the whole class definition or just for an individual method.

To define a self identifier for the whole class, use the `as` keyword after the closing parentheses of the constructor parameter list, and specify the identifier name.

To define a self identifier for just one method, provide the self identifier in the member declaration, just before the method name and a period (.) as a separator.

The following code example illustrates the two ways to create a self identifier. In the first line, the `as` keyword is used to define the self identifier. In the fifth line, the identifier `this` is used to define a self identifier whose scope is restricted to the method `PrintMessage`.

```
type MyClass2(dataIn) as self =
    let data = dataIn
    do
        self.PrintMessage()
    member this.PrintMessage() =
        printf "Creating MyClass2 with Data %d" data
```

Unlike in other .NET languages, you can name the self identifier however you want; you are not restricted to names such as `self`, `Me`, or `this`.

The self identifier that is declared with the `as` keyword is not initialized until after the `let` bindings are executed. Therefore, it cannot be used in the `let` bindings. You can use the self identifier in the `do` bindings section.

## Generic Type Parameters

Generic type parameters are specified in angle brackets (`<` and `>`), in the form of a single quotation mark followed by an identifier. Multiple generic type parameters are separated by commas. The generic type parameter is in scope throughout the declaration. The following code example shows how to specify generic type parameters.

```
type MyGenericClass<'a> (x: 'a) =
    do printfn "%A" x
```

Type arguments are inferred when the type is used. In the following code, the inferred type is a sequence of tuples.

```
let g1 = MyGenericClass( seq { for i in 1 .. 10 -> (i, i*i) } )
```

## Specifying Inheritance

The `inherit` clause identifies the direct base class, if there is one. In F#, only one direct base class is allowed. Interfaces that a class implements are not considered base classes. Interfaces are discussed in the [Interfaces](#) topic.

You can access the methods and properties of the base class from the derived class by using the language keyword `base` as an identifier, followed by a period (.) and the name of the member.

For more information, see [Inheritance](#).

## Members Section

You can define static or instance methods, properties, interface implementations, abstract members, event declarations, and additional constructors in this section. Let and do bindings cannot appear in this section. Because members can be added to a variety of F# types in addition to classes, they are discussed in a separate topic, [Members](#).

## Mutually Recursive Types

When you define types that reference each other in a circular way, you string together the type definitions by using the `and` keyword. The `and` keyword replaces the `type` keyword on all except the first definition, as follows.

```

open System.IO

type Folder(pathIn: string) =
    let path = pathIn
    let filenameArray : string array = Directory.GetFiles(path)
    member this.FileArray = Array.map (fun elem -> new File(elem, this)) filenameArray

and File(filename: string, containingFolder: Folder) =
    member this.Name = filename
    member this.ContainingFolder = containingFolder

let folder1 = new Folder(".")
for file in folder1.FileArray do
    printfn "%s" file.Name

```

The output is a list of all the files in the current directory.

## When to Use Classes, Unions, Records, and Structures

Given the variety of types to choose from, you need to have a good understanding of what each type is designed for to select the appropriate type for a particular situation. Classes are designed for use in object-oriented programming contexts. Object-oriented programming is the dominant paradigm used in applications that are written for the .NET Framework. If your F# code has to work closely with the .NET Framework or another object-oriented library, and especially if you have to extend from an object-oriented type system such as a UI library, classes are probably appropriate.

If you are not interoperating closely with object-oriented code, or if you are writing code that is self-contained and therefore protected from frequent interaction with object-oriented code, you should consider using records and discriminated unions. A single, well thought-out discriminated union, together with appropriate pattern matching code, can often be used as a simpler alternative to an object hierarchy. For more information about discriminated unions, see [Discriminated Unions](#).

Records have the advantage of being simpler than classes, but records are not appropriate when the demands of a type exceed what can be accomplished with their simplicity. Records are basically simple aggregates of values, without separate constructors that can perform custom actions, without hidden fields, and without inheritance or interface implementations. Although members such as properties and methods can be added to records to make their behavior more complex, the fields stored in a record are still a simple aggregate of values. For more information about records, see [Records](#).

Structures are also useful for small aggregates of data, but they differ from classes and records in that they are .NET value types. Classes and records are .NET reference types. The semantics of value types and reference types are different in that value types are passed by value. This means that they are copied bit for bit when they are passed as a parameter or returned from a function. They are also stored on the stack or, if they are used as a field, embedded inside the parent object instead of stored in their own separate location on the heap. Therefore, structures are appropriate for frequently accessed data when the overhead of accessing the heap is a problem. For more information about structures, see [Structures](#).

# Structures

12/19/2018 • 4 minutes to read • [Edit Online](#)

A *structure* is a compact object type that can be more efficient than a class for types that have a small amount of data and simple behavior.

## Syntax

```
[ attributes ]
type [accessibility-modifier] type-name =
    struct
        type-definition-elements-and-members
    end
// or
[ attributes ]
[<StructAttribute>]
type [accessibility-modifier] type-name =
    type-definition-elements-and-members
```

## Remarks

Structures are *value types*, which means that they are stored directly on the stack or, when they are used as fields or array elements, inline in the parent type. Unlike classes and records, structures have pass-by-value semantics. This means that they are useful primarily for small aggregates of data that are accessed and copied frequently.

In the previous syntax, two forms are shown. The first is not the lightweight syntax, but it is nevertheless frequently used because, when you use the `struct` and `end` keywords, you can omit the `StructAttribute` attribute, which appears in the second form. You can abbreviate `structAttribute` to just `Struct`.

The *type-definition-elements-and-members* in the previous syntax represents member declarations and definitions. Structures can have constructors and mutable and immutable fields, and they can declare members and interface implementations. For more information, see [Members](#).

Structures cannot participate in inheritance, cannot contain `let` or `do` bindings, and cannot recursively contain fields of their own type (although they can contain reference cells that reference their own type).

Because structures do not allow `let` bindings, you must declare fields in structures by using the `val` keyword. The `val` keyword defines a field and its type but does not allow initialization. Instead, `val` declarations are initialized to zero or null. For this reason, structures that have an implicit constructor (that is, parameters that are given immediately after the structure name in the declaration) require that `val` declarations be annotated with the `DefaultValue` attribute. Structures that have a defined constructor still support zero-initialization. Therefore, the `DefaultValue` attribute is a declaration that such a zero value is valid for the field. Implicit constructors for structures do not perform any actions because `let` and `do` bindings aren't allowed on the type, but the implicit constructor parameter values passed in are available as private fields.

Explicit constructors might involve initialization of field values. When you have a structure that has an explicit constructor, it still supports zero-initialization; however, you do not use the `DefaultValue` attribute on the `val` declarations because it conflicts with the explicit constructor. For more information about `val` declarations, see [Explicit Fields: The `val` Keyword](#).

Attributes and accessibility modifiers are allowed on structures, and follow the same rules as those for other types. For more information, see [Attributes](#) and [Access Control](#).

The following code examples illustrate structure definitions.

```
// In Point3D, three immutable values are defined.  
// x, y, and z will be initialized to 0.0.  
type Point3D =  
    struct  
        val x: float  
        val y: float  
        val z: float  
    end  
  
// In Point2D, two immutable values are defined.  
// It also has a member which computes a distance between itself and another Point2D.  
// Point2D has an explicit constructor.  
// You can create zero-initialized instances of Point2D, or you can  
// pass in arguments to initialize the values.  
type Point2D =  
    struct  
        val X: float  
        val Y: float  
        new(x: float, y: float) = { X = x; Y = y }  
  
        member this.GetDistanceFrom(p: Point2D) =  
            let dX = (p.X - this.X) ** 2.0  
            let dY = (p.Y - this.Y) ** 2.0  
  
            dX + dY  
            |> sqrt  
    end
```

## ByRefLike structs

You can define your own structs that can adhere to `byref`-like semantics: see [Byrefs](#) for more information. This is done with the `IsByRefLikeAttribute` attribute:

```
open System  
open System.Runtime.CompilerServices  
  
[<IsByRefLike; Struct>]  
type S(count1: Span<int>, count2: Span<int>) =  
    member x.Count1 = count1  
    member x.Count2 = count2
```

`IsByRefLike` does not imply `Struct`. Both must be present on the type.

A "`byref`-like" struct in F# is a stack-bound value type. It is never allocated on the managed heap. A `byref`-like struct is useful for high-performance programming, as it is enforced with set of strong checks about lifetime and non-capture. The rules are:

- They can be used as function parameters, method parameters, local variables, method returns.
- They cannot be static or instance members of a class or normal struct.
- They cannot be captured by any closure construct (`async` methods or lambda expressions).
- They cannot be used as a generic parameter.

Although these rules very strongly restrict usage, they do so to fulfill the promise of high-performance computing in a safe manner.

## ReadOnly structs

You can annotate structs with the [IsReadOnlyAttribute](#) attribute. For example:

```
[<IsReadOnly; Struct>]
type S(count1: int, count2: int) =
    member x.Count1 = count1
    member x.Count2 = count2
```

`IsReadOnly` does not imply `Struct`. You must add both to have an `IsReadOnly` struct.

Use of this attribute emits metadata letting F# and C# know to treat it as `inref<'T>` and `in ref`, respectively.

Defining a mutable value inside of a readonly struct produces an error.

## Struct Records and Discriminated Unions

You can represent [Records](#) and [Discriminated Unions](#) as structs with the `[<struct>]` attribute. See each article to learn more.

# Inheritance

12/19/2018 • 3 minutes to read • [Edit Online](#)

Inheritance is used to model the "is-a" relationship, or subtyping, in object-oriented programming.

## Specifying Inheritance Relationships

You specify inheritance relationships by using the `inherit` keyword in a class declaration. The basic syntactical form is shown in the following example.

```
type MyDerived(...) =  
    inherit MyBase(...)
```

A class can have at most one direct base class. If you do not specify a base class by using the `inherit` keyword, the class implicitly inherits from `System.Object`.

## Inherited Members

If a class inherits from another class, the methods and members of the base class are available to users of the derived class as if they were direct members of the derived class.

Any let bindings and constructor parameters are private to a class and, therefore, cannot be accessed from derived classes.

The keyword `base` is available in derived classes and refers to the base class instance. It is used like the self-identifier.

## Virtual Methods and Overrides

Virtual methods (and properties) work somewhat differently in F# as compared to other .NET languages. To declare a new virtual member, you use the `abstract` keyword. You do this regardless of whether you provide a default implementation for that method. Thus a complete definition of a virtual method in a base class follows this pattern:

```
abstract member [method-name] : [type]  
  
default [self-identifier].[method-name] [argument-list] = [method-body]
```

And in a derived class, an override of this virtual method follows this pattern:

```
override [self-identifier].[method-name] [argument-list] = [method-body]
```

If you omit the default implementation in the base class, the base class becomes an abstract class.

The following code example illustrates the declaration of a new virtual method `function1` in a base class and how to override it in a derived class.

```

type MyClassBase1() =
    let mutable z = 0
    abstract member function1 : int -> int
    default u.function1(a : int) = z <- z + a; z

type MyClassDerived1() =
    inherit MyClassBase1()
    override u.function1(a: int) = a + 1

```

## Constructors and Inheritance

The constructor for the base class must be called in the derived class. The arguments for the base class constructor appear in the argument list in the `inherit` clause. The values that are used must be determined from the arguments supplied to the derived class constructor.

The following code shows a base class and a derived class, where the derived class calls the base class constructor in the `inherit` clause:

```

type MyClassBase2(x: int) =
    let mutable z = x * x
    do for i in 1..z do printf "%d " i

type MyClassDerived2(y: int) =
    inherit MyClassBase2(y * 2)
    do for i in 1..y do printf "%d " i

```

In the case of multiple constructors, the following code can be used. The first line of the derived class constructors is the `inherit` clause, and the fields appear as explicit fields that are declared with the `val` keyword. For more information, see [Explicit Fields: The `val` Keyword](#).

```

type BaseClass =
    val string1 : string
    new (str) = { string1 = str }
    new () = { string1 = "" }

type DerivedClass =
    inherit BaseClass

    val string2 : string
    new (str1, str2) = { inherit BaseClass(str1); string2 = str2 }
    new (str2) = { inherit BaseClass(); string2 = str2 }

let obj1 = DerivedClass("A", "B")
let obj2 = DerivedClass("A")

```

## Alternatives to Inheritance

In cases where a minor modification of a type is required, consider using an object expression as an alternative to inheritance. The following example illustrates the use of an object expression as an alternative to creating a new derived type:

```
open System

let object1 = { new Object() with
    override this.ToString() = "This overrides object.ToString()"
}

printfn "%s" (object1.ToString())
```

For more information about object expressions, see [Object Expressions](#).

When you are creating object hierarchies, consider using a discriminated union instead of inheritance. Discriminated unions can also model varied behavior of different objects that share a common overall type. A single discriminated union can often eliminate the need for a number of derived classes that are minor variations of each other. For information about discriminated unions, see [Discriminated Unions](#).

- [Object Expressions](#)
- [F# Language Reference](#)

# Interfaces

12/19/2018 • 3 minutes to read • [Edit Online](#)

*Interfaces* specify sets of related members that other classes implement.

## Syntax

```
// Interface declaration:  
[ attributes ]  
type [accessibility-modifier] interface-name =  
    [ interface ]      [ inherit base-interface-name ... ]  
    abstract member1 : [ argument-types1 -> ] return-type1  
    abstract member2 : [ argument-types2 -> ] return-type2  
    ...  
[ end ]  
  
// Implementing, inside a class type definition:  
interface interface-name with  
    member self-identifier.member1argument-list = method-body1  
    member self-identifier.member2argument-list = method-body2  
  
// Implementing, by using an object expression:  
[ attributes ]  
let class-name (argument-list) =  
    { new interface-name with  
        member self-identifier.member1argument-list = method-body1  
        member self-identifier.member2argument-list = method-body2  
        [ base-interface-definitions ]  
    }  
member-list
```

## Remarks

Interface declarations resemble class declarations except that no members are implemented. Instead, all the members are abstract, as indicated by the keyword `abstract`. You do not provide a method body for abstract methods. However, you can provide a default implementation by also including a separate definition of the member as a method together with the `default` keyword. Doing so is equivalent to creating a virtual method in a base class in other .NET languages. Such a virtual method can be overridden in classes that implement the interface.

The default accessibility for interfaces is `public`.

You can optionally give each method parameter a name using normal F# syntax:

```
type ISprintable =  
    abstract member Print : format:string -> unit
```

In the above `ISprintable` example, the `Print` method has a single parameter of the type `string` with the name `format`.

There are two ways to implement interfaces: by using object expressions, and by using class types. In either case, the class type or object expression provides method bodies for abstract methods of the interface.

Implementations are specific to each type that implements the interface. Therefore, interface methods on different types might be different from each other.

The keywords `interface` and `end`, which mark the start and end of the definition, are optional when you use lightweight syntax. If you do not use these keywords, the compiler attempts to infer whether the type is a class or an interface by analyzing the constructs that you use. If you define a member or use other class syntax, the type is interpreted as a class.

The .NET coding style is to begin all interfaces with a capital `I`.

## Implementing Interfaces by Using Class Types

You can implement one or more interfaces in a class type by using the `interface` keyword, the name of the interface, and the `with` keyword, followed by the interface member definitions, as shown in the following code.

```
type IPrintable =
    abstract member Print : unit -> unit

type SomeClass1(x: int, y: float) =
    interface IPrintable with
        member this.Print() = printfn "%d %f" x y
```

Interface implementations are inherited, so any derived classes do not need to reimplement them.

## Calling Interface Methods

Interface methods can be called only through the interface, not through any object of the type that implements the interface. Thus, you might have to upcast to the interface type by using the `:>` operator or the `upcast` operator in order to call these methods.

To call the interface method when you have an object of type `SomeClass`, you must upcast the object to the interface type, as shown in the following code.

```
let x1 = new SomeClass1(1, 2.0)
(x1 :> IPrintable).Print()
```

An alternative is to declare a method on the object that upcasts and calls the interface method, as in the following example.

```
type SomeClass2(x: int, y: float) =
    member this.Print() = (this :> IPrintable).Print()
    interface IPrintable with
        member this.Print() = printfn "%d %f" x y

let x2 = new SomeClass2(1, 2.0)
x2.Print()
```

## Implementing Interfaces by Using Object Expressions

Object expressions provide a short way to implement an interface. They are useful when you do not have to create a named type, and you just want an object that supports the interface methods, without any additional methods. An object expression is illustrated in the following code.

```
let makePrintable(x: int, y: float) =
    { new IPrintable with
        member this.Print() = printfn "%d %f" x y }
let x3 = makePrintable(1, 2.0)
x3.Print()
```

## Interface Inheritance

Interfaces can inherit from one or more base interfaces.

```
type Interface1 =
    abstract member Method1 : int -> int

type Interface2 =
    abstract member Method2 : int -> int

type Interface3 =
    inherit Interface1
    inherit Interface2
    abstract member Method3 : int -> int

type MyClass() =
    interface Interface3 with
        member this.Method1(n) = 2 * n
        member this.Method2(n) = n + 100
        member this.Method3(n) = n / 10
```

# Abstract Classes

12/19/2018 • 4 minutes to read • [Edit Online](#)

*Abstract classes* are classes that leave some or all members unimplemented, so that implementations can be provided by derived classes.

## Syntax

```
// Abstract class syntax.  
[<AbstractClass>]  
type [ accessibility-modifier ] abstract-class-name =  
[ inherit base-class-or-interface-name ]  
[ abstract-member-declarations-and-member-definitions ]  
  
// Abstract member syntax.  
abstract member member-name : type-signature
```

## Remarks

In object-oriented programming, an abstract class is used as a base class of a hierarchy, and represents common functionality of a diverse set of object types. As the name "abstract" implies, abstract classes often do not correspond directly onto concrete entities in the problem domain. However, they do represent what many different concrete entities have in common.

Abstract classes must have the `AbstractClass` attribute. They can have implemented and unimplemented members. The use of the term *abstract* when applied to a class is the same as in other .NET languages; however, the use of the term *abstract* when applied to methods (and properties) is a little different in F# from its use in other .NET languages. In F#, when a method is marked with the `abstract` keyword, this indicates that a member has an entry, known as a *virtual dispatch slot*, in the internal table of virtual functions for that type. In other words, the method is virtual, although the `virtual` keyword is not used in the F# language. The keyword `abstract` is used on virtual methods regardless of whether the method is implemented. The declaration of a virtual dispatch slot is separate from the definition of a method for that dispatch slot. Therefore, the F# equivalent of a virtual method declaration and definition in another .NET language is a combination of both an abstract method declaration and a separate definition, with either the `default` keyword or the `override` keyword. For more information and examples, see [Methods](#).

A class is considered abstract only if there are abstract methods that are declared but not defined. Therefore, classes that have abstract methods are not necessarily abstract classes. Unless a class has undefined abstract methods, do not use the **AbstractClass** attribute.

In the previous syntax, *accessibility-modifier* can be `public`, `private` or `internal`. For more information, see [Access Control](#).

As with other types, abstract classes can have a base class and one or more base interfaces. Each base class or interface appears on a separate line together with the `inherit` keyword.

The type definition of an abstract class can contain fully defined members, but it can also contain abstract members. The syntax for abstract members is shown separately in the previous syntax. In this syntax, the *type signature* of a member is a list that contains the parameter types in order and the return types, separated by `->` tokens and/or `*` tokens as appropriate for curried and tupled parameters. The syntax for abstract member type signatures is the same as that used in signature files and that shown by IntelliSense in the Visual Studio Code

Editor.

The following code illustrates an abstract class `Shape`, which has two non-abstract derived classes, `Square` and `Circle`. The example shows how to use abstract classes, methods, and properties. In the example, the abstract class `Shape` represents the common elements of the concrete entities circle and square. The common features of all shapes (in a two-dimensional coordinate system) are abstracted out into the `Shape` class: the position on the grid, an angle of rotation, and the area and perimeter properties. These can be overridden, except for position, the behavior of which individual shapes cannot change.

The rotation method can be overridden, as in the `Circle` class, which is rotation invariant because of its symmetry. So in the `Circle` class, the rotation method is replaced by a method that does nothing.

```
// An abstract class that has some methods and properties defined
// and some left abstract.
[<AbstractClass>]
type Shape2D(x0 : float, y0 : float) =
    let mutable x, y = x0, y0
    let mutable rotAngle = 0.0

    // These properties are not declared abstract. They
    // cannot be overriden.
    member this.CenterX with get() = x and set xval = x <- xval
    member this.CenterY with get() = y and set yval = y <- yval

    // These properties are abstract, and no default implementation
    // is provided. Non-abstract derived classes must implement these.
    abstract Area : float with get
    abstract Perimeter : float with get
    abstract Name : string with get

    // This method is not declared abstract. It cannot be
    // overridden.
    member this.Move dx dy =
        x <- x + dx
        y <- y + dy

    // An abstract method that is given a default implementation
    // is equivalent to a virtual method in other .NET languages.
    // Rotate changes the internal angle of rotation of the square.
    // Angle is assumed to be in degrees.
    abstract member Rotate: float -> unit
    default this.Rotate(angle) = rotAngle <- rotAngle + angle

type Square(x, y, sideLengthIn) =
    inherit Shape2D(x, y)
    member this.SideLength = sideLengthIn
    override this.Area = this.SideLength * this.SideLength
    override this.Perimeter = this.SideLength * 4.
    override this.Name = "Square"

type Circle(x, y, radius) =
    inherit Shape2D(x, y)
    let PI = 3.141592654
    member this.Radius = radius
    override this.Area = PI * this.Radius * this.Radius
    override this.Perimeter = 2. * PI * this.Radius
    // Rotating a circle does nothing, so use the wildcard
    // character to discard the unused argument and
    // evaluate to unit.
    override this.Rotate(_) = ()
    override this.Name = "Circle"

let square1 = new Square(0.0, 0.0, 10.0)
let circle1 = new Circle(0.0, 0.0, 5.0)
circle1.CenterX <- 1.0
circle1.CenterY <- -2.0
```

```
square1.Move -1.0 2.0
square1.Rotate 45.0
circle1.Rotate 45.0
printfn "Perimeter of square with side length %f is %f, %f"
      (square1.SideLength) (square1.Area) (square1.Perimeter)
printfn "Circumference of circle with radius %f is %f, %f"
      (circle1.Radius) (circle1.Area) (circle1.Perimeter)

let shapeList : list<Shape2D> = [ (square1 :> Shape2D);
                                  (circle1 :> Shape2D) ]
List.iter (fun (elem : Shape2D) ->
            printfn "Area of %s: %f" (elem.Name) (elem.Area))
shapeList
```

## Output:

```
Perimeter of square with side length 10.000000 is 40.000000
Circumference of circle with radius 5.000000 is 31.415927
Area of Square: 100.000000
Area of Circle: 78.539816
```

# Members

12/19/2018 • 2 minutes to read • [Edit Online](#)

This section describes members of F# object types.

## Remarks

*Members* are features that are part of a type definition and are declared with the `member` keyword. F# object types such as records, classes, discriminated unions, interfaces, and structures support members. For more information, see [Records](#), [Classes](#), [Discriminated Unions](#), [Interfaces](#), and [Structures](#).

Members typically make up the public interface for a type, which is why they are public unless otherwise specified. Members can also be declared private or internal. For more information, see [Access Control](#). Signatures for types can also be used to expose or not expose certain members of a type. For more information, see [Signatures](#).

Private fields and `do` bindings, which are used only with classes, are not true members, because they are never part of the public interface of a type and are not declared with the `member` keyword, but they are described in this section also.

# let Bindings in Classes

12/19/2018 • 2 minutes to read • [Edit Online](#)

You can define private fields and private functions for F# classes by using `let` bindings in the class definition.

## Syntax

```
// Field.  
[static] let [ mutable ] binding1 [ and ... binding-n ]  
  
// Function.  
[static] let [ rec ] binding1 [ and ... binding-n ]
```

## Remarks

The previous syntax appears after the class heading and inheritance declarations but before any member definitions. The syntax is like that of `let` bindings outside of classes, but the names defined in a class have a scope that is limited to the class. A `let` binding creates a private field or function; to expose data or functions publicly, declare a property or a member method.

A `let` binding that is not static is called an instance `let` binding. Instance `let` bindings execute when objects are created. Static `let` bindings are part of the static initializer for the class, which is guaranteed to execute before the type is first used.

The code within instance `let` bindings can use the primary constructor's parameters.

Attributes and accessibility modifiers are not permitted on `let` bindings in classes.

The following code examples illustrate several types of `let` bindings in classes.

```
type PointWithCounter(a: int, b: int) =  
    // A variable i.  
    let mutable i = 0  
  
    // A let binding that uses a pattern.  
    let (x, y) = (a, b)  
  
    // A private function binding.  
    let privateFunction x y = x * x + 2*y  
  
    // A static let binding.  
    static let mutable count = 0  
  
    // A do binding.  
    do  
        count <- count + 1  
  
        member this.Prop1 = x  
        member this.Prop2 = y  
        member this.CreatedCount = count  
        member this.FunctionValue = privateFunction x y  
  
    let point1 = PointWithCounter(10, 52)  
  
    printfn "%d %d %d %d" (point1.Prop1) (point1.Prop2) (point1.CreatedCount) (point1.FunctionValue)
```

The output is as follows.

```
10 52 1 204
```

## Alternative Ways to Create Fields

You can also use the `val` keyword to create a private field. When using the `val` keyword, the field is not given a value when the object is created, but instead is initialized with a default value. For more information, see [Explicit Fields: The val Keyword](#).

You can also define private fields in a class by using a member definition and adding the keyword `private` to the definition. This can be useful if you expect to change the accessibility of a member without rewriting your code. For more information, see [Access Control](#).

# do Bindings in Classes

12/19/2018 • 2 minutes to read • [Edit Online](#)

A `do` binding in a class definition performs actions when the object is constructed or, for a static `do` binding, when the type is first used.

## Syntax

```
[static] do expression
```

## Remarks

A `do` binding appears together with or after `let` bindings but before member definitions in a class definition. Although the `do` keyword is optional for `do` bindings at the module level, it is not optional for `do` bindings in a class definition.

For the construction of every object of any given type, non-static `do` bindings and non-static `let` bindings are executed in the order in which they appear in the class definition. Multiple `do` bindings can occur in one type. The non-static `let` bindings and the non-static `do` bindings become the body of the primary constructor. The code in the non-static `do` bindings section can reference the primary constructor parameters and any values or functions that are defined in the `let` bindings section.

Non-static `do` bindings can access members of the class as long as the class has a self identifier that is defined by an `as` keyword in the class heading, and as long as all uses of those members are qualified with the self identifier for the class.

Because `let` bindings initialize the private fields of a class, which is often necessary to guarantee that members behave as expected, `do` bindings are usually put after `let` bindings so that code in the `do` binding can execute with a fully initialized object. If your code attempts to use a member before the initialization is complete, an `InvalidOperationException` is raised.

Static `do` bindings can reference static members or fields of the enclosing class but not instance members or fields. Static `do` bindings become part of the static initializer for the class, which is guaranteed to execute before the class is first used.

Attributes are ignored for `do` bindings in types. If an attribute is required for code that executes in a `do` binding, it must be applied to the primary constructor.

In the following code, a class has a static `do` binding and a non-static `do` binding. The object has a constructor that has two parameters, `a` and `b`, and two private fields are defined in the `let` bindings for the class. Two properties are also defined. All of these are in scope in the non-static `do` bindings section, as is illustrated by the line that prints all those values.

```
open System

type MyType(a:int, b:int) as this =
    inherit Object()
    let x = 2*a
    let y = 2*b
    do printfn "Initializing object %d %d %d %d %d"
        a b x y (this.Prop1) (this.Prop2)
    static do printfn "Initializing MyType."
    member this.Prop1 = 4*x
    member this.Prop2 = 4*y
    override this.ToString() = System.String.Format("{0} {1}", this.Prop1, this.Prop2)

let obj1 = new MyType(1, 2)
```

The output is as follows.

```
Initializing MyType.
Initializing object 1 2 2 4 8 16
```

# Properties

12/19/2018 • 7 minutes to read • [Edit Online](#)

*Properties* are members that represent values associated with an object.

## Syntax

```
// Property that has both get and set defined.  
[ attributes ]  
[ static ] member [accessibility-modifier] [self-identifier.]PropertyName  
with [accessibility-modifier] get() =  
    get-function-body  
and [accessibility-modifier] set parameter =  
    set-function-body  
  
// Alternative syntax for a property that has get and set.  
[ attributes-for-get ]  
[ static ] member [accessibility-modifier-for-get] [self-identifier.]PropertyName =  
    get-function-body  
[ attributes-for-set ]  
[ static ] member [accessibility-modifier-for-set] [self-identifier.]PropertyName  
with set parameter =  
    set-function-body  
  
// Property that has get only.  
[ attributes ]  
[ static ] member [accessibility-modifier] [self-identifier.]PropertyName =  
    get-function-body  
  
// Alternative syntax for property that has get only.  
[ attributes ]  
[ static ] member [accessibility-modifier] [self-identifier.]PropertyName  
with get() =  
    get-function-body  
  
// Property that has set only.  
[ attributes ]  
[ static ] member [accessibility-modifier] [self-identifier.]PropertyName  
with set parameter =  
    set-function-body  
  
// Automatically implemented properties.  
[ attributes ]  
[ static ] member val [accessibility-modifier]PropertyName = initialization-expression [ with get, set ]
```

## Remarks

Properties represent the "has a" relationship in object-oriented programming, representing data that is associated with object instances or, for static properties, with the type.

You can declare properties in two ways, depending on whether you want to explicitly specify the underlying value (also called the backing store) for the property, or if you want to allow the compiler to automatically generate the backing store for you. Generally, you should use the more explicit way if the property has a non-trivial implementation and the automatic way when the property is just a simple wrapper for a value or variable. To declare a property explicitly, use the `member` keyword. This declarative syntax is followed by the syntax that specifies the `get` and `set` methods, also named *accessors*. The various forms of the explicit syntax shown in the

syntax section are used for read/write, read-only, and write-only properties. For read-only properties, you define only a `get` method; for write-only properties, define only a `set` method. Note that when a property has both `get` and `set` accessors, the alternative syntax enables you to specify attributes and accessibility modifiers that are different for each accessor, as is shown in the following code.

```
// A read-only property.  
member this.MyReadOnlyProperty = myInternalValue  
// A write-only property.  
member this.MyWriteOnlyProperty with set (value) = myInternalValue <- value  
// A read-write property.  
member this.MyReadWriteProperty  
    with get () = myInternalValue  
        and set (value) = myInternalValue <- value
```

For read/write properties, which have both a `get` and `set` method, the order of `get` and `set` can be reversed. Alternatively, you can provide the syntax shown for `get` only and the syntax shown for `set` only instead of using the combined syntax. Doing this makes it easier to comment out the individual `get` or `set` method, if that is something you might need to do. This alternative to using the combined syntax is shown in the following code.

```
member this.MyReadWriteProperty with get () = myInternalValue  
member this.MyReadWriteProperty with set (value) = myInternalValue <- value
```

Private values that hold the data for properties are called *backing stores*. To have the compiler create the backing store automatically, use the keywords `member val`, omit the self-identifier, then provide an expression to initialize the property. If the property is to be mutable, include `with get, set`. For example, the following class type includes two automatically implemented properties. `Property1` is read-only and is initialized to the argument provided to the primary constructor, and `Property2` is a settable property initialized to an empty string:

```
type MyClass(property1 : int) =  
    member val Property1 = property1  
    member val Property2 = "" with get, set
```

Automatically implemented properties are part of the initialization of a type, so they must be included before any other member definitions, just like `let` bindings and `do` bindings in a type definition. Note that the expression that initializes an automatically implemented property is only evaluated upon initialization, and not every time the property is accessed. This behavior is in contrast to the behavior of an explicitly implemented property. What this effectively means is that the code to initialize these properties is added to the constructor of a class. Consider the following code that shows this difference:

```
type MyClass() =  
    let random = new System.Random()  
    member val AutoProperty = random.Next() with get, set  
    member this.ExplicitProperty = random.Next()  
  
let class1 = new MyClass()  
  
printfn "class1.AutoProperty = %d" class1.AutoProperty  
printfn "class1.AutoProperty = %d" class1.AutoProperty  
printfn "class1.ExplicitProperty = %d" class1.ExplicitProperty  
printfn "class1.ExplicitProperty = %d" class1.ExplicitProperty
```

## Output

```
class1.AutoProperty = 1853799794
class1.AutoProperty = 1853799794
class1.ExplicitProperty = 978922705
class1.ExplicitProperty = 1131210765
```

The output of the preceding code shows that the value of `AutoProperty` is unchanged when called repeatedly, whereas the `ExplicitProperty` changes each time it is called. This demonstrates that the expression for an automatically implemented property is not evaluated each time, as is the getter method for the explicit property.

### WARNING

There are some libraries, such as the Entity Framework (`System.Data.Entity`) that perform custom operations in base class constructors that don't work well with the initialization of automatically implemented properties. In those cases, try using explicit properties.

Properties can be members of classes, structures, discriminated unions, records, interfaces, and type extensions and can also be defined in object expressions.

Attributes can be applied to properties. To apply an attribute to a property, write the attribute on a separate line before the property. For more information, see [Attributes](#).

By default, properties are public. Accessibility modifiers can also be applied to properties. To apply an accessibility modifier, add it immediately before the name of the property if it is meant to apply to both the `get` and `set` methods; add it before the `get` and `set` keywords if different accessibility is required for each accessor. The *accessibility-modifier* can be one of the following: `public`, `private`, `internal`. For more information, see [Access Control](#).

Property implementations are executed each time a property is accessed.

## Static and Instance Properties

Properties can be static or instance properties. Static properties can be invoked without an instance and are used for values associated with the type, not with individual objects. For static properties, omit the self-identifier. The self-identifier is required for instance properties.

The following static property definition is based on a scenario in which you have a static field `myStaticValue` that is the backing store for the property.

```
static member MyStaticProperty
    with get() = myStaticValue
        and set(value) = myStaticValue <- value
```

Properties can also be array-like, in which case they are called *indexed properties*. For more information, see [Indexed Properties](#).

## Type Annotation for Properties

In many cases, the compiler has enough information to infer the type of a property from the type of the backing store, but you can set the type explicitly by adding a type annotation.

```
// To apply a type annotation to a property that does not have an explicit
// get or set, apply the type annotation directly to the property.
member this.MyProperty1 : int = myInternalValue
// If there is a get or set, apply the type annotation to the get or set method.
member this.MyProperty2 with get() : int = myInternalValue
```

## Using Property set Accessors

You can set properties that provide `set` accessors by using the `<-` operator.

```
// Assume that the constructor argument sets the initial value of the
// internal backing store.
let mutable myObject = new MyType(10)
myObject.MyProperty <- 20
printfn "%d" (myObject.MyProperty)
```

The output is **20**.

## Abstract Properties

Properties can be abstract. As with methods, `abstract` just means that there is a virtual dispatch associated with the property. Abstract properties can be truly abstract, that is, without a definition in the same class. The class that contains such a property is therefore an abstract class. Alternatively, abstract can just mean that a property is virtual, and in that case, a definition must be present in the same class. Note that abstract properties must not be private, and if one accessor is abstract, the other must also be abstract. For more information about abstract classes, see [Abstract Classes](#).

```
// Abstract property in abstract class.
// The property is an int type that has a get and
// set method
[<AbstractClass>]
type AbstractBase() =
    abstract Property1 : int with get, set

// Implementation of the abstract property
type Derived1() =
    inherit AbstractBase()
    let mutable value = 10
    override this.Property1 with get() = value and set(v : int) = value <- v

// A type with a "virtual" property.
type Base1() =
    let mutable value = 10
    abstract Property1 : int with get, set
    default this.Property1 with get() = value and set(v : int) = value <- v

// A derived type that overrides the virtual property
type Derived2() =
    inherit Base1()
    let mutable value2 = 11
    override this.Property1 with get() = value2 and set(v) = value2 <- v
```

# Indexed Properties

3/8/2019 • 3 minutes to read • [Edit Online](#)

When defining a class that abstracts over ordered data, it can sometimes be helpful to provide indexed access to that data without exposing the underlying implementation. This is done with the `Index` member.

## Syntax

```
// Indexed property that has both get and set defined.  
member self-identifier.Index  
    with get(index-values) =  
        get-member-body  
    and set index-values values-to-set =  
        set-member-body  
  
// Indexed property with get only  
member self-identifier.Index  
    with get(index-values) =  
        get-member-body  
  
// Indexed property that has set only.  
member self-identifier.Index  
    with set index-values values-to-set =  
        set-member-body
```

## Remarks

The forms of the previous syntax show how to define indexed properties that have both a `get` and a `set` method, have a `get` method only, or have a `set` method only. You can also combine both the syntax shown for get only and the syntax shown for set only, and produce a property that has both get and set. This latter form allows you to put different accessibility modifiers and attributes on the get and set methods.

By using the name `Item`, the compiler treats the property as a default indexed property. A *default indexed property* is a property that you can access by using array-like syntax on the object instance. For example, if `o` is an object of the type that defines this property, the syntax `o.[index]` is used to access the property.

The syntax for accessing a non-default indexed property is to provide the name of the property and the index in parentheses, just like a regular member. For example, if the property on `o` is called `ordinal`, you write `o.Ordinal(index)` to access it.

Regardless of which form you use, you should always use the curried form for the set method on an indexed property. For information about curried functions, see [Functions](#).

## Example

The following code example illustrates the definition and use of default and non-default indexed properties that have get and set methods.

```

type NumberStrings() =
    let mutable ordinals = [| "one"; "two"; "three"; "four"; "five";
                           "six"; "seven"; "eight"; "nine"; "ten" |]
    let mutable cardinals = [| "first"; "second"; "third"; "fourth";
                            "fifth"; "sixth"; "seventh"; "eighth";
                            "ninth"; "tenth" |]
    member this.Item
        with get(index) = ordinals.[index]
        and set index value = ordinals.[index] <- value
    member this.Ordinal
        with get(index) = ordinals.[index]
        and set index value = ordinals.[index] <- value
    member this.Cardinal
        with get(index) = cardinals.[index]
        and set index value = cardinals.[index] <- value

let nstrs = new NumberStrings()
nstrs.[0] <- "ONE"
for i in 0 .. 9 do
    printf "%s " (nstrs.[i])
printfn ""

nstrs.Cardinal(5) <- "6th"

for i in 0 .. 9 do
    printf "%s " (nstrs.Ordinal(i))
    printf "%s " (nstrs.Cardinal(i))
printfn ""

```

## Output

```

ONE two three four five six seven eight nine ten
ONE first two second three third four fourth five fifth six 6th
seven seventh eight eighth nine ninth ten tenth

```

## Indexed Properties with multiple index values

Indexed properties can have more than one index value. In that case, the values are separated by commas when the property is used. The set method in such a property must have two curried arguments, the first of which is a tuple containing the keys, and the second of which is the value to set.

The following code demonstrates the use of an indexed property with multiple index values.

```

open System.Collections.Generic

/// Basic implementation of a sparse matrix based on a dictionary
type SparseMatrix() =
    let table = new Dictionary<(int * int), float>()
    member __.Item
        // Because the key is comprised of two values, 'get' has two index values
        with get(key1, key2) = table.[(key1, key2)]

        // 'set' has two index values and a new value to place in the key's position
        and set (key1, key2) value = table.[(key1, key2)] <- value

    let sm = new SparseMatrix()
    for i in 1..1000 do
        sm.[i, i] <- float i * float i

```

# Methods

12/19/2018 • 7 minutes to read • [Edit Online](#)

A *method* is a function that is associated with a type. In object-oriented programming, methods are used to expose and implement the functionality and behavior of objects and types.

## Syntax

```
// Instance method definition.  
[ attributes ]  
member [inline] self-identifier.method-name parameter-list [ : return-type ] =  
    method-body  
  
// Static method definition.  
[ attributes ]  
static member [inline] method-name parameter-list [ : return-type ] =  
    method-body  
  
// Abstract method declaration or virtual dispatch slot.  
[ attributes ]  
abstract member method-name : type-signature  
  
// Virtual method declaration and default implementation.  
[ attributes ]  
abstract member method-name : type-signature  
[ attributes ]  
default self-identifier.method-name parameter-list [ : return-type ] =  
    method-body  
  
// Override of inherited virtual method.  
[ attributes ]  
override self-identifier.method-name parameter-list [ : return-type ] =  
    method-body  
  
// Optional and DefaultParameterValue attributes on input parameters  
[ attributes ]  
[ modifier ] member [inline] self-identifier.method-name ([<Optional; DefaultParameterValue( default-value  
>)] input) [ : return-type ]
```

## Remarks

In the previous syntax, you can see the various forms of method declarations and definitions. In longer method bodies, a line break follows the equal sign (=), and the whole method body is indented.

Attributes can be applied to any method declaration. They precede the syntax for a method definition and are usually listed on a separate line. For more information, see [Attributes](#).

Methods can be marked `inline`. For information about `inline`, see [Inline Functions](#).

Non-inline methods can be used recursively within the type; there is no need to explicitly use the `rec` keyword.

## Instance Methods

Instance methods are declared with the `member` keyword and a *self-identifier*, followed by a period (.) and the method name and parameters. As is the case for `let` bindings, the *parameter-list* can be a pattern. Typically, you enclose method parameters in parentheses in a tuple form, which is the way methods appear in F# when they are

created in other .NET Framework languages. However, the curried form (parameters separated by spaces) is also common, and other patterns are supported also.

The following example illustrates the definition and use of a non-abstract instance method.

```
type SomeType(factor0: int) =
    let factor = factor0
    member this.SomeMethod(a, b, c) =
        (a + b + c) * factor

    member this.SomeOtherMethod(a, b, c) =
        this.SomeMethod(a, b, c) * factor
```

Within instance methods, do not use the self identifier to access fields defined by using let bindings. Use the self identifier when accessing other members and properties.

## Static Methods

The keyword `static` is used to specify that a method can be called without an instance and is not associated with an object instance. Otherwise, methods are instance methods.

The example in the next section shows fields declared with the `let` keyword, property members declared with the `member` keyword, and a static method declared with the `static` keyword.

The following example illustrates the definition and use of static methods. Assume that these method definitions are in the `SomeType` class in the previous section.

```
static member SomeStaticMethod(a, b, c) =
    (a + b + c)

static member SomeOtherStaticMethod(a, b, c) =
    SomeType.SomeStaticMethod(a, b, c) * 100
```

## Abstract and Virtual Methods

The keyword `abstract` indicates that a method has a virtual dispatch slot and might not have a definition in the class. A *virtual dispatch slot* is an entry in an internally maintained table of functions that is used at run time to look up virtual function calls in an object-oriented type. The virtual dispatch mechanism is the mechanism that implements *polymorphism*, an important feature of object-oriented programming. A class that has at least one abstract method without a definition is an *abstract class*, which means that no instances can be created of that class. For more information about abstract classes, see [Abstract Classes](#).

Abstract method declarations do not include a method body. Instead, the name of the method is followed by a colon (:) and a type signature for the method. The type signature of a method is the same as that shown by IntelliSense when you pause the mouse pointer over a method name in the Visual Studio Code Editor, except without parameter names. Type signatures are also displayed by the interpreter, fsi.exe, when you are working interactively. The type signature of a method is formed by listing out the types of the parameters, followed by the return type, with appropriate separator symbols. Curried parameters are separated by `->` and tuple parameters are separated by `*`. The return value is always separated from the arguments by a `->` symbol. Parentheses can be used to group complex parameters, such as when a function type is a parameter, or to indicate when a tuple is treated as a single parameter rather than as two parameters.

You can also give abstract methods default definitions by adding the definition to the class and using the `default` keyword, as shown in the syntax block in this topic. An abstract method that has a definition in the same class is equivalent to a virtual method in other .NET Framework languages. Whether or not a definition exists, the

`abstract` keyword creates a new dispatch slot in the virtual function table for the class.

Regardless of whether a base class implements its abstract methods, derived classes can provide implementations of abstract methods. To implement an abstract method in a derived class, define a method that has the same name and signature in the derived class, except use the `override` or `default` keyword, and provide the method body. The keywords `override` and `default` mean exactly the same thing. Use `override` if the new method overrides a base class implementation; use `default` when you create an implementation in the same class as the original abstract declaration. Do not use the `abstract` keyword on the method that implements the method that was declared abstract in the base class.

The following example illustrates an abstract method `Rotate` that has a default implementation, the equivalent of a .NET Framework virtual method.

```
type Ellipse(a0 : float, b0 : float, theta0 : float) =
    let mutable axis1 = a0
    let mutable axis2 = b0
    let mutable rotAngle = theta0
    abstract member Rotate: float -> unit
    default this.Rotate(delta : float) = rotAngle <- rotAngle + delta
```

The following example illustrates a derived class that overrides a base class method. In this case, the `override` changes the behavior so that the method does nothing.

```
type Circle(radius : float) =
    inherit Ellipse(radius, radius, 0.0)
    // Circles are invariant to rotation, so do nothing.
    override this.Rotate(_) = ()
```

## Overloaded Methods

Overloaded methods are methods that have identical names in a given type but that have different arguments. In F#, optional arguments are usually used instead of overloaded methods. However, overloaded methods are permitted in the language, provided that the arguments are in tuple form, not curried form.

## Optional Arguments

Starting with F# 4.1, you can also have optional arguments with a default parameter value in methods. This is to help facilitate interoperation with C# code. The following example demonstrates the syntax:

```
// A class with a method M, which takes in an optional integer argument.
type C() =
    __.M([<Optional; DefaultValue(12)>] i) = i + 1
```

Note that the value passed in for `DefaultValue` must match the input type. In the above sample, it is an `int`. Attempting to pass a non-integer value into `DefaultValue` would result in a compile error.

## Example: Properties and Methods

The following example contains a type that has examples of fields, private functions, properties, and a static method.

```

type RectangleXY(x1 : float, y1: float, x2: float, y2: float) =
    // Field definitions.
    let height = y2 - y1
    let width = x2 - x1
    let area = height * width
    // Private functions.
    static let maxFloat (x: float) (y: float) =
        if x >= y then x else y
    static let minFloat (x: float) (y: float) =
        if x <= y then x else y
    // Properties.
    // Here, "this" is used as the self identifier,
    // but it can be any identifier.
    member this.X1 = x1
    member this.Y1 = y1
    member this.X2 = x2
    member this.Y2 = y2
    // A static method.
    static member intersection(rect1 : RectangleXY, rect2 : RectangleXY) =
        let x1 = maxFloat rect1.X1 rect2.X1
        let y1 = maxFloat rect1.Y1 rect2.Y1
        let x2 = minFloat rect1.X2 rect2.X2
        let y2 = minFloat rect1.Y2 rect2.Y2
        let result : RectangleXY option =
            if (x2 > x1 && y2 > y1) then
                Some (RectangleXY(x1, y1, x2, y2))
            else
                None
        result

    // Test code.
let testIntersection =
    let r1 = RectangleXY(10.0, 10.0, 20.0, 20.0)
    let r2 = RectangleXY(15.0, 15.0, 25.0, 25.0)
    let r3 : RectangleXY option = RectangleXY.intersection(r1, r2)
    match r3 with
    | Some(r3) -> printfn "Intersection rectangle: %f %f %f %f" r3.X1 r3.Y1 r3.X2 r3.Y2
    | None -> printfn "No intersection found."

testIntersection

# Constructors

12/19/2018 • 6 minutes to read • [Edit Online](#)

This topic describes how to define and use constructors to create and initialize class and structure objects.

## Construction of Class Objects

Objects of class types have constructors. There are two kinds of constructors. One is the primary constructor, whose parameters appear in parentheses just after the type name. You specify other, optional additional constructors by using the `new` keyword. Any such additional constructors must call the primary constructor.

The primary constructor contains `let` and `do` bindings that appear at the start of the class definition. A `let` binding declares private fields and methods of the class; a `do` binding executes code. For more information about `let` bindings in class constructors, see [let Bindings in Classes](#). For more information about `do` bindings in constructors, see [do Bindings in Classes](#).

Regardless of whether the constructor you want to call is a primary constructor or an additional constructor, you can create objects by using a `new` expression, with or without the optional `new` keyword. You initialize your objects together with constructor arguments, either by listing the arguments in order and separated by commas and enclosed in parentheses, or by using named arguments and values in parentheses. You can also set properties on an object during the construction of the object by using the property names and assigning values just as you use named constructor arguments.

The following code illustrates a class that has a constructor and various ways of creating objects.

```
// This class has a primary constructor that takes three arguments
// and an additional constructor that calls the primary constructor.
type MyClass(x0, y0, z0) =
    let mutable x = x0
    let mutable y = y0
    let mutable z = z0
    do
        printfn "Initialized object that has coordinates (%d, %d, %d)" x y z
        member this.X with get() = x and set(value) = x <- value
        member this.Y with get() = y and set(value) = y <- value
        member this.Z with get() = z and set(value) = z <- value
    new() = MyClass(0, 0, 0)

// Create by using the new keyword.
let myObject1 = new MyClass(1, 2, 3)
// Create without using the new keyword.
let myObject2 = MyClass(4, 5, 6)
// Create by using named arguments.
let myObject3 = MyClass(x0 = 7, y0 = 8, z0 = 9)
// Create by using the additional constructor.
let myObject4 = MyClass()
```

The output is as follows.

```
Initialized object that has coordinates (1, 2, 3)
Initialized object that has coordinates (4, 5, 6)
Initialized object that has coordinates (7, 8, 9)
Initialized object that has coordinates (0, 0, 0)
```

# Construction of Structures

Structures follow all the rules of classes. Therefore, you can have a primary constructor, and you can provide additional constructors by using `new`. However, there is one important difference between structures and classes: structures can have a default constructor (that is, one with no arguments) even if no primary constructor is defined. The default constructor initializes all the fields to the default value for that type, usually zero or its equivalent. Any constructors that you define for structures must have at least one argument so that they do not conflict with the default constructor.

Also, structures often have fields that are created by using the `val` keyword; classes can also have these fields. Structures and classes that have fields defined by using the `val` keyword can also be initialized in additional constructors by using record expressions, as shown in the following code.

```
type MyStruct =
    struct
        val X : int
        val Y : int
        val Z : int
        new(x, y, z) = { X = x; Y = y; Z = z }
    end

let myStructure1 = new MyStruct(1, 2, 3)
```

For more information, see [Explicit Fields: The `val` Keyword](#).

## Executing Side Effects in Constructors

A primary constructor in a class can execute code in a `do` binding. However, what if you have to execute code in an additional constructor, without a `do` binding? To do this, you use the `then` keyword.

```
// Executing side effects in the primary constructor and
// additional constructors.
type Person(nameIn : string, idIn : int) =
    let mutable name = nameIn
    let mutable id = idIn
    do printfn "Created a person object."
    member this.Name with get() = name and set(v) = name <- v
    member this.ID with get() = id and set(v) = id <- v
    new() =
        Person("Invalid Name", -1)
        then
            printfn "Created an invalid person object."

let person1 = new Person("Humberto Acevedo", 123458734)
let person2 = new Person()
```

The side effects of the primary constructor still execute. Therefore, the output is as follows.

```
Created a person object.
Created a person object.
Created an invalid person object.
```

## Self Identifiers in Constructors

In other members, you provide a name for the current object in the definition of each member. You can also put the self identifier on the first line of the class definition by using the `as` keyword immediately following the constructor parameters. The following example illustrates this syntax.

```

type MyClass1(x) as this =
    // This use of the self identifier produces a warning - avoid.
    let x1 = this.X
    // This use of the self identifier is acceptable.
    do printfn "Initializing object with X =%d" this.X
    member this.X = x

```

In additional constructors, you can also define a self identifier by putting the `as` clause right after the constructor parameters. The following example illustrates this syntax.

```

type MyClass2(x : int) =
    member this.X = x
    new() as this = MyClass2(0) then printfn "Initializing with X = %d" this.X

```

Problems can occur when you try to use an object before it is fully defined. Therefore, uses of the self identifier can cause the compiler to emit a warning and insert additional checks to ensure the members of an object are not accessed before the object is initialized. You should only use the self identifier in the `do` bindings of the primary constructor, or after the `then` keyword in additional constructors.

The name of the self identifier does not have to be `this`. It can be any valid identifier.

## Assigning Values to Properties at Initialization

You can assign values to the properties of a class object in the initialization code by appending a list of assignments of the form `property = value` to the argument list for a constructor. This is shown in the following code example.

```

type Account() =
    let mutable balance = 0.0
    let mutable number = 0
    let mutable firstName = ""
    let mutable lastName = ""
    member this.AccountNumber
        with get() = number
        and set(value) = number <- value
    member this.FirstName
        with get() = firstName
        and set(value) = firstName <- value
    member this.LastName
        with get() = lastName
        and set(value) = lastName <- value
    member this.Balance
        with get() = balance
        and set(value) = balance <- value
    member this.Deposit(amount: float) = this.Balance <- this.Balance + amount
    member this.Withdraw(amount: float) = this.Balance <- this.Balance - amount

let account1 = new Account(AccountNumber=8782108,
                           FirstName="Darren", LastName="Parker",
                           Balance=1543.33)

```

The following version of the previous code illustrates the combination of ordinary arguments, optional arguments, and property settings in one constructor call.

```

type Account(accountNumber : int, ?first: string, ?last: string, ?bal : float) =
    let mutable balance = defaultArg bal 0.0
    let mutable number = accountNumber
    let mutable firstName = defaultArg first ""
    let mutable lastName = defaultArg last ""
    member this.AccountNumber
        with get() = number
        and set(value) = number <- value
    member this.FirstName
        with get() = firstName
        and set(value) = firstName <- value
    member this.LastName
        with get() = lastName
        and set(value) = lastName <- value
    member this.Balance
        with get() = balance
        and set(value) = balance <- value
    member this.Deposit(amount: float) = this.Balance <- this.Balance + amount
    member this.Withdraw(amount: float) = this.Balance <- this.Balance - amount

let account1 = new Account(8782108, bal = 543.33,
                           FirstName="Raman", LastName="Iyer")

```

## Constructors in inherited class

When inheriting from a base class that has a constructor, you must specify its arguments in the inherit clause. For more information, see [Constructors and inheritance](#).

## Static Constructors or Type Constructors

In addition to specifying code for creating objects, static `let` and `do` bindings can be authored in class types that execute before the type is first used to perform initialization at the type level. For more information, see [let Bindings in Classes](#) and [do Bindings in Classes](#).

# Events

12/19/2018 • 6 minutes to read • [Edit Online](#)

## NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

Events enable you to associate function calls with user actions and are important in GUI programming. Events can also be triggered by your applications or by the operating system.

## Handling Events

When you use a GUI library like Windows Forms or Windows Presentation Foundation (WPF), much of the code in your application runs in response to events that are predefined by the library. These predefined events are members of GUI classes such as forms and controls. You can add custom behavior to a preexisting event, such as a button click, by referencing the specific named event of interest (for example, the `Click` event of the `Form` class) and invoking the `Add` method, as shown in the following code. If you run this from F# Interactive, omit the call to `System.Windows.Forms.Application.Run(System.Windows.Forms.Form)`.

```
open System.Windows.Forms

let form = new Form(Text="F# Windows Form",
                    Visible = true,
                    TopMost = true)

form.Click.Add(fun evArgs -> System.Console.Beep())
Application.Run(form)
```

The type of the `Add` method is `('a -> unit) -> unit`. Therefore, the event handler method takes one parameter, typically the event arguments, and returns `unit`. The previous example shows the event handler as a lambda expression. The event handler can also be a function value, as in the following code example. The following code example also shows the use of the event handler parameters, which provide information specific to the type of event. For a `MouseMove` event, the system passes a `System.Windows.Forms.MouseEventArgs` object, which contains the `x` and `y` position of the pointer.

```
open System.Windows.Forms

let Beep evArgs =
    System.Console.Beep( )

let form = new Form(Text = "F# Windows Form",
                    Visible = true,
                    TopMost = true)

let MouseMoveEventHandler (evArgs : System.Windows.Forms.MouseEventArgs) =
    form.Text <- System.String.Format("{0},{1}", evArgs.X, evArgs.Y)

form.Click.Add(Beep)
form.MouseMove.Add(MouseMoveEventHandler)
Application.Run(form)
```

## Creating Custom Events

F# events are represented by the F# `Event` class, which implements the `IEvent` interface. `IEvent` is itself an interface that combines the functionality of two other interfaces, `System.IObservable<'T>` and `IDelegateEvent`. Therefore, `Event`s have the equivalent functionality of delegates in other languages, plus the additional functionality from `IObservable`, which means that F# events support event filtering and using F# first-class functions and lambda expressions as event handlers. This functionality is provided in the [Event module](#).

To create an event on a class that acts just like any other .NET Framework event, add to the class a `let` binding that defines an `Event` as a field in a class. You can specify the desired event argument type as the type argument, or leave it blank and have the compiler infer the appropriate type. You also must define an event member that exposes the event as a CLI event. This member should have the `CLIEvent` attribute. It is declared like a property and its implementation is just a call to the `Publish` property of the event. Users of your class can use the `Add` method of the published event to add a handler. The argument for the `Add` method can be a lambda expression. You can use the `Trigger` property of the event to raise the event, passing the arguments to the handler function. The following code example illustrates this. In this example, the inferred type argument for the event is a tuple, which represents the arguments for the lambda expression.

```
open System.Collections.Generic

type MyClassWithCLIEvent() =
    let event1 = new Event<_>()

    [CLIEvent]
    member this.Event1 = event1.Publish

    member this.TestEvent(arg) =
        event1.Trigger(this, arg)

let classWithEvent = new MyClassWithCLIEvent()
classWithEvent.Event1.Add(fun (sender, arg) ->
    printfn "Event1 occurred! Object data: %s" arg)

classWithEvent.TestEvent("Hello World!")

System.Console.ReadLine() |> ignore
```

The output is as follows.

```
Event1 occurred! Object data: Hello World!
```

The additional functionality provided by the `Event` module is illustrated here. The following code example illustrates the basic use of `Event.create` to create an event and a trigger method, add two event handlers in the form of lambda expressions, and then trigger the event to execute both lambda expressions.

```

type MyType() =
    let myEvent = new Event<_>()

    member this.AddHandlers() =
        Event.add (fun string1 -> printfn "%s" string1) myEvent.Publish
        Event.add (fun string1 -> printfn "Given a value: %s" string1) myEvent.Publish

    member this.Trigger(message) =
        myEvent.Trigger(message)

let myMyType = MyType()
myMyType.AddHandlers()
myMyType.Trigger("Event occurred.")

```

The output of the previous code is as follows.

```

Event occurred.
Given a value: Event occurred.

```

## Processing Event Streams

Instead of just adding an event handler for an event by using the `Event.add` function, you can use the functions in the `Event` module to process streams of events in highly customized ways. To do this, you use the forward pipe (`|>`) together with the event as the first value in a series of function calls, and the `Event` module functions as subsequent function calls.

The following code example shows how to set up an event for which the handler is only called under certain conditions.

```

let form = new Form(Text = "F# Windows Form",
                    Visible = true,
                    TopMost = true)
form.MouseMove
|> Event.filter ( fun evArgs -> evArgs.X > 100 && evArgs.Y > 100)
|> Event.add ( fun evArgs ->
    form.BackColor <- System.Drawing.Color.FromArgb(
        evArgs.X, evArgs.Y, evArgs.X ^^^ evArgs.Y) )

```

The [Observable module](#) contains similar functions that operate on observable objects. Observable objects are similar to events but only actively subscribe to events if they themselves are being subscribed to.

## Implementing an Interface Event

As you develop UI components, you often start by creating a new form or a new control that inherits from an existing form or control. Events are frequently defined on an interface, and, in that case, you must implement the interface to implement the event. The `System.ComponentModel.INotifyPropertyChanged` interface defines a single `System.ComponentModel.INotifyPropertyChanged.PropertyChanged` event. The following code illustrates how to implement the event that this inherited interface defined:

```

module CustomForm

open System.Windows.Forms
open System.ComponentModel

type AppForm() as this =
    inherit Form()

    // Define the PropertyChanged event.
    let propertyChanged = Event<PropertyChangedEventHandler, PropertyChangedEventArgs>()
    let mutable underlyingValue = "text0"

    // Set up a click event to change the properties.
    do
        this.Click |> Event.add(fun evArgs -> this.Property1 <- "text2"
                                         this.Property2 <- "text3")

    // This property does not have the property-changed event set.
    member val Property1 : string = "text" with get, set

    // This property has the property-changed event set.
    member this.Property2
        with get() = underlyingValue
        and set(newValue) =
            underlyingValue <- newValue
            propertyChanged.Trigger(this, new PropertyChangedEventArgs("Property2"))

    // Expose the PropertyChanged event as a first class .NET event.
    [<<CLIEvent>]
    member this.PropertyChanged = propertyChanged.Publish

    // Define the add and remove methods to implement this interface.
    interface INotifyPropertyChanged with
        member this.add_PropertyChanged(handler) = propertyChanged.Publish.AddHandler(handler)
        member this.remove_PropertyChanged(handler) = propertyChanged.Publish.RemoveHandler(handler)

    // This is the event-handler method.
    member this.OnPropertyChanged(args : PropertyChangedEventArgs) =
        let newProperty = this.GetType().GetProperty(args.PropertyName)
        let newValue = newProperty.GetValue(this :> obj) :?> string
        printfn "Property %s changed its value to %s" args.PropertyName newValue

    // Create a form, hook up the event handler, and start the application.
    let appForm = new AppForm()
    let inpc = appForm :> INotifyPropertyChanged
    inpc.PropertyChanged.Add(appForm.OnPropertyChanged)
    Application.Run(appForm)

```

If you want to hook up the event in the constructor, the code is a bit more complicated because the event hookup must be in a `then` block in an additional constructor, as in the following example:

```

module CustomForm

open System.Windows.Forms
open System.ComponentModel

// Create a private constructor with a dummy argument so that the public
// constructor can have no arguments.
type AppForm private (dummy) as this =
    inherit Form()

    // Define the PropertyChanged event.
    let propertyChanged = Event<PropertyChangedEventHandler, PropertyChangedEventArgs>()
    let mutable underlyingValue = "text0"

    // Set up a click event to change the properties.
    do
        this.Click |> Event.add(fun evArgs -> this.Property1 <- "text2"
        this.Property2 <- "text3")

    // This property does not have the property changed event set.
    member val Property1 : string = "text" with get, set

    // This property has the property changed event set.
    member this.Property2
        with get() = underlyingValue
        and set(newValue) =
            underlyingValue <- newValue
            propertyChanged.Trigger(this, new PropertyChangedEventArgs("Property2"))

    [<CLIEvent>]
    member this.PropertyChanged = propertyChanged.Publish

    // Define the add and remove methods to implement this interface.
    interface INotifyPropertyChanged with
        member this.add_PropertyChanged(handler) = this.PropertyChanged.AddHandler(handler)
        member this.remove_PropertyChanged(handler) = this.PropertyChanged.RemoveHandler(handler)

    // This is the event handler method.
    member this.OnPropertyChanged(args : PropertyChangedEventArgs) =
        let newProperty = this.GetType().GetProperty(args.PropertyName)
        let newValue = newProperty.GetValue(this :> obj) :? string
        printfn "Property %s changed its value to %s" args.PropertyName newValue

    new() as this =
        new AppForm(0)
        then
            let inpc = this :> INotifyPropertyChanged
            inpc.PropertyChanged.Add(this.OnPropertyChanged)

    // Create a form, hook up the event handler, and start the application.
    let appForm = new AppForm()
    Application.Run(appForm)

```

# Explicit Fields: The `val` Keyword

12/22/2018 • 4 minutes to read • [Edit Online](#)

The `val` keyword is used to declare a location to store a value in a class or structure type, without initializing it. Storage locations declared in this manner are called *explicit fields*. Another use of the `val` keyword is in conjunction with the `member` keyword to declare an auto-implemented property. For more information on auto-implemented properties, see [Properties](#).

## Syntax

```
val [ mutable ] [ access-modifier ] field-name : type-name
```

## Remarks

The usual way to define fields in a class or structure type is to use a `let` binding. However, `let` bindings must be initialized as part of the class constructor, which is not always possible, necessary, or desirable. You can use the `val` keyword when you want a field that is uninitialized.

Explicit fields can be static or non-static. The *access-modifier* can be `public`, `private`, or `internal`. By default, explicit fields are public. This differs from `let` bindings in classes, which are always private.

The [DefaultValue](#) attribute is required on explicit fields in class types that have a primary constructor. This attribute specifies that the field is initialized to zero. The type of the field must support zero-initialization. A type supports zero-initialization if it is one of the following:

- A primitive type that has a zero value.
- A type that supports a null value, either as a normal value, as an abnormal value, or as a representation of a value. This includes classes, tuples, records, functions, interfaces, .NET reference types, the `unit` type, and discriminated union types.
- A .NET value type.
- A structure whose fields all support a default zero value.

For example, an immutable field called `someField` has a backing field in the .NET compiled representation with the name `someField@`, and you access the stored value using a property named `someField`.

For a mutable field, the .NET compiled representation is a .NET field.

### WARNING

**Note** The .NET Framework namespace `System.ComponentModel` contains an attribute that has the same name. For information about this attribute, see [System.ComponentModel.DefaultValueAttribute](#).

The following code shows the use of explicit fields and, for comparison, a `let` binding in a class that has a primary constructor. Note that the `let`-bound field `myInt1` is private. When the `let`-bound field `myInt1` is referenced from a member method, the self identifier `this` is not required. But when you are referencing the explicit fields `myInt2` and `myString`, the self identifier is required.

```

type MyType() =
    let mutable myInt1 = 10
    [] val mutable myInt2 : int
    [] val mutable myString : string
    member this.SetValsAndPrint( i: int, str: string) =
        myInt1 <- i
        this.myInt2 <- i + 1
        this.myString <- str
        printfn "%d %d %s" myInt1 (this.myInt2) (this.myString)

let myObject = new MyType()
myObject.SetValsAndPrint(11, "abc")
// The following line is not allowed because let bindings are private.
// myObject.myInt1 <- 20
myObject.myInt2 <- 30
myObject.myString <- "def"

printfn "%d %s" (myObject.myInt2) (myObject.myString)

```

The output is as follows:

```

11 12 abc
30 def

```

The following code shows the use of explicit fields in a class that does not have a primary constructor. In this case, the `DefaultValue` attribute is not required, but all the fields must be initialized in the constructors that are defined for the type.

```

type MyClass =
    val a : int
    val b : int
    // The following version of the constructor is an error
    // because b is not initialized.
    // new (a0, b0) = { a = a0; }
    // The following version is acceptable because all fields are initialized.
    new(a0, b0) = { a = a0; b = b0; }

let myClassObj = new MyClass(35, 22)
printfn "%d %d" (myClassObj.a) (myClassObj.b)

```

The output is `35 22`.

The following code shows the use of explicit fields in a structure. Because a structure is a value type, it automatically has a default constructor that sets the values of its fields to zero. Therefore, the `DefaultValue` attribute is not required.

```

type MyStruct =
    struct
        val mutable myInt : int
        val mutable myString : string
    end

let mutable myStructObj = new MyStruct()
myStructObj.myInt <- 11
myStructObj.myString <- "xyz"

printfn "%d %s" (myStructObj.myInt) (myStructObj.myString)

```

The output is `11 xyz`.

**Beware**, if you are going to initialize your structure with `mutable` fields without `mutable` keyword, your assignments will work on a copy of the structure which will be discarded right after assignment. Therefore your structure won't change.

```
```fsharp
[<Struct>]
type Foo =
    val mutable bar: string
    member self.ChangeBar bar = self.bar <- bar
    new (bar) = {bar = bar}

let foo = Foo "1"
foo.ChangeBar "2" //make implicit copy of Foo, changes the copy, discards the copy, foo remains unchanged
printfn "%s" foo.bar //prints 1

let mutable foo' = Foo "1"
foo'.ChangeBar "2" //changes foo'
printfn "%s" foo'.bar //prints 2
...```

```

Explicit fields are not intended for routine use. In general, when possible you should use a `let` binding in a class instead of an explicit field. Explicit fields are useful in certain interoperability scenarios, such as when you need to define a structure that will be used in a platform invoke call to a native API, or in COM interop scenarios. For more information, see [External Functions](#). Another situation in which an explicit field might be necessary is when you are working with an F# code generator which emits classes without a primary constructor. Explicit fields are also useful for thread-static variables or similar constructs. For more information, see

[System.ThreadStaticAttribute](#).

When the keywords `member val` appear together in a type definition, it is a definition of an automatically implemented property. For more information, see [Properties](#).

# Type extensions

2/12/2019 • 5 minutes to read • [Edit Online](#)

Type extensions (also called *augmentations*) are a family of features that let you add new members to a previously defined object type. The three features are:

- Intrinsic type extensions
- Optional type extensions
- Extension methods

Each can be used in different scenarios and has different tradeoffs.

## Syntax

```
// Intrinsic and optional extensions
type typename with
    member self-identifier.member-name =
        body
    ...
    
// Extension methods
open System.Runtime.CompilerServices

[<Extension>]
type Extensions() =
    [static] member self-identifier.extension-name (ty: typename, [args]) =
        body
    ...

```

## Intrinsic type extensions

An intrinsic type extension is a type extension that extends a user-defined type.

Intrinsic type extensions must be defined in the same file **and** in the same namespace or module as the type they're extending. Any other definition will result in them being [optional type extensions](#).

Intrinsic type extensions are sometimes a cleaner way to separate functionality from the type declaration. The following example shows how to define an intrinsic type extension:

```
namespace Example

type Variant =
    | Num of int
    | Str of string

module Variant =
    let print v =
        match v with
        | Num n -> printf "Num %d" n
        | Str s -> printf "Str %s" s

// Add a member to Variant as an extension
type Variant with
    member x.Print() = Variant.print x
```

Using a type extension allows you to separate each of the following:

- The declaration of a `Variant` type
- Functionality to print the `Variant` class depending on its "shape"
- A way to access the printing functionality with object-style `.-notation`

This is an alternative to defining everything as a member on `Variant`. Although it is not an inherently better approach, it can be a cleaner representation of functionality in some situations.

Intrinsic type extensions are compiled as members of the type they augment, and appear on the type when the type is examined by reflection.

## Optional type extensions

An optional type extension is an extension that appears outside the original module, namespace, or assembly of the type being extended.

Optional type extensions are useful for extending a type that you have not defined yourself. For example:

```
module Extensions

open System.Collections.Generic

type I Enumerable<'T> with
    /// Repeat each element of the sequence n times
    member xs.RepeatElements(n: int) =
        seq {
            for x in xs do
                for i in 1 .. n do
                    yield x
        }
```

You can now access `RepeatElements` as if it's a member of `IEnumerable<T>` as long as the `Extensions` module is opened in the scope that you are working in.

Optional extensions do not appear on the extended type when examined by reflection. Optional extensions must be in modules, and they're only in scope when the module that contains the extension is open or is otherwise in scope.

Optional extension members are compiled to static members for which the object instance is passed implicitly as the first parameter. However, they act as if they're instance members or static members according to how they're declared.

Optional extension members are also not visible to C# or VB consumers. They can only be consumed in other F# code.

## Generic limitation of intrinsic and optional type extensions

It's possible to declare a type extension on a generic type where the type variable is constrained. The requirement is that the constraint of the extension declaration matches the constraint of the declared type.

However, even when constraints are matched between a declared type and a type extension, it's possible for a constraint to be inferred by the body of an extended member that imposes a different requirement on the type parameter than the declared type. For example:

```

open System.Collections.Generic

// NOT POSSIBLE AND FAILS TO COMPILE!
//
// The member 'Sum' has a different requirement on 'T than the type IEnumerable<'T>
type IEnumerable<'T> with
    member this.Sum() = Seq.sum this

```

There is no way to get this code to work with an optional type extension:

- As is, the `Sum` member has a different constraint on `'T` (`static member get_Zero` and `static member (+)`) than what the type extension defines.
- Modifying the type extension to have the same constraint as `Sum` will no longer match the defined constraint on `IEnumerable<'T>`.
- Changing `member this.Sum` to `member inline this.Sum` will give an error that type constraints are mismatched.

What is desired are static methods that "float in space" and can be presented as if they're extending a type. This is where extension methods become necessary.

## Extension methods

Finally, extension methods (sometimes called "C# style extension members") can be declared in F# as a static member method on a class.

Extension methods are useful for when you wish to define extensions on a generic type that will constrain the type variable. For example:

```

namespace Extensions

open System.Runtime.CompilerServices

[<Extension>]
type IEnumerableExtensions() =
    [<Extension>]
    static member inline Sum(xs: IEnumerable<'T>) = Seq.sum xs

```

When used, this code will make it appear as if `Sum` is defined on `IEnumerable<T>`, so long as `Extensions` has been opened or is in scope.

## Other remarks

Type extensions also have the following attributes:

- Any type that can be accessed can be extended.
- Intrinsic and optional type extensions can define *any* member type, not just methods. So extension properties are also possible, for example.
- The `self-identifier` token in the [syntax](#) represents the instance of the type being invoked, just like ordinary members.
- Extended members can be static or instance members.
- Type variables on a type extension must match the constraints of the declared type.

The following limitations also exist for type extensions:

- Type extensions do not support virtual or abstract methods.
- Type extensions do not support override methods as augmentations.

- Type extensions do not support [Statically Resolved Type Parameters](#).
- Optional Type extensions do not support constructors as augmentations.
- Type extensions cannot be defined on [type abbreviations](#).
- Type extensions are not valid for `byref<'T>` (though they can be declared).
- Type extensions are not valid for attributes (though they can be declared).
- You can define extensions that overload other methods of the same name, but the F# compiler gives preference to non-extension methods if there is an ambiguous call.

Finally, if multiple intrinsic type extensions exist for one type, all members must be unique. For optional type extensions, members in different type extensions to the same type can have the same names. Ambiguity errors occur only if client code opens two different scopes that define the same member names.

# Parameters and Arguments

3/5/2019 • 10 minutes to read • [Edit Online](#)

This topic describes language support for defining parameters and passing arguments to functions, methods, and properties. It includes information about how to pass by reference, and how to define and use methods that can take a variable number of arguments.

## Parameters and Arguments

The term *parameter* is used to describe the names for values that are expected to be supplied. The term *argument* is used for the values provided for each parameter.

Parameters can be specified in tuple or curried form, or in some combination of the two. You can pass arguments by using an explicit parameter name. Parameters of methods can be specified as optional and given a default value.

## Parameter Patterns

Parameters supplied to functions and methods are, in general, patterns separated by spaces. This means that, in principle, any of the patterns described in [Match Expressions](#) can be used in a parameter list for a function or member.

Methods usually use the tuple form of passing arguments. This achieves a clearer result from the perspective of other .NET languages because the tuple form matches the way arguments are passed in .NET methods.

The curried form is most often used with functions created by using `let` bindings.

The following pseudocode shows examples of tuple and curried arguments.

```
// Tuple form.  
member this.SomeMethod(param1, param2) = ...  
// Curried form.  
let function1 param1 param2 = ...
```

Combined forms are possible when some arguments are in tuples and some are not.

```
let function2 param1 (param2a, param2b) param3 = ...
```

Other patterns can also be used in parameter lists, but if the parameter pattern does not match all possible inputs, there might be an incomplete match at run time. The exception `MatchFailureException` is generated when the value of an argument does not match the patterns specified in the parameter list. The compiler issues a warning when a parameter pattern allows for incomplete matches. At least one other pattern is commonly useful for parameter lists, and that is the wildcard pattern. You use the wildcard pattern in a parameter list when you simply want to ignore any arguments that are supplied. The following code illustrates the use of the wildcard pattern in an argument list.

```
let makeList _ = [ for i in 1 .. 100 -> i * i ]  
// The arguments 100 and 200 are ignored.  
let list1 = makeList 100  
let list2 = makeList 200
```

The wildcard pattern can be useful whenever you do not need the arguments passed in, such as in the main entry point to a program, when you are not interested in the command-line arguments that are normally supplied as a string array, as in the following code.

```
[<EntryPoint>]
let main _ =
    printfn "Entry point!"
    0
```

Other patterns that are sometimes used in arguments are the `as` pattern, and identifier patterns associated with discriminated unions and active patterns. You can use the single-case discriminated union pattern as follows.

```
type Slice = Slice of int * int * string

let GetSubstring1 (Slice(p0, p1, text)) =
    printfn "Data begins at %d and ends at %d in string %s" p0 p1 text
    text.[p0..p1]

let substring = GetSubstring1 (Slice(0, 4, "Et tu, Brute?"))
printfn "Substring: %s" substring
```

The output is as follows.

```
Data begins at 0 and ends at 4 in string Et tu, Brute?
Et tu
```

Active patterns can be useful as parameters, for example, when transforming an argument into a desired format, as in the following example:

```
type Point = { x : float; y : float }

let (| Polar |) { x = x; y = y} =
    (sqrt (x*x + y*y), System.Math.Atan (y/ x) )

let radius (Polar(r, _)) = r
let angle (Polar(_, theta)) = theta
```

You can use the `as` pattern to store a matched value as a local value, as is shown in the following line of code.

```
let GetSubstring2 (Slice(p0, p1, text) as s) = s
```

Another pattern that is used occasionally is a function that leaves the last argument unnamed by providing, as the body of the function, a lambda expression that immediately performs a pattern match on the implicit argument. An example of this is the following line of code.

```
let isNil = function [] -> true | _::_ -> false
```

This code defines a function that takes a generic list and returns `true` if the list is empty, and `false` otherwise. The use of such techniques can make code more difficult to read.

Occasionally, patterns that involve incomplete matches are useful, for example, if you know that the lists in your program have only three elements, you might use a pattern like the following in a parameter list.

```
let sum [a; b; c] = a + b + c
```

The use of patterns that have incomplete matches is best reserved for quick prototyping and other temporary uses. The compiler will issue a warning for such code. Such patterns cannot cover the general case of all possible inputs and therefore are not suitable for component APIs.

## Named Arguments

Arguments for methods can be specified by position in a comma-separated argument list, or they can be passed to a method explicitly by providing the name, followed by an equal sign and the value to be passed in. If specified by providing the name, they can appear in a different order from that used in the declaration.

Named arguments can make code more readable and more adaptable to certain types of changes in the API, such as a reordering of method parameters.

Named arguments are allowed only for methods, not for `let`-bound functions, function values, or lambda expressions.

The following code example demonstrates the use of named arguments.

```
type SpeedingTicket() =
    member this.GetMPHOver(speed: int, limit: int) = speed - limit

let CalculateFine (ticket : SpeedingTicket) =
    let delta = ticket.GetMPHOver(limit = 55, speed = 70)
    if delta < 20 then 50.0 else 100.0

let ticket1 : SpeedingTicket = SpeedingTicket()
printfn "%f" (CalculateFine ticket1)
```

In a call to a class constructor, you can set the values of properties of the class by using a syntax similar to that of named arguments. The following example shows this syntax.

```
type Account() =
    let mutable balance = 0.0
    let mutable number = 0
    let mutable firstName = ""
    let mutable lastName = ""
    member this.AccountNumber
        with get() = number
        and set(value) = number <- value
    member this.FirstName
        with get() = firstName
        and set(value) = firstName <- value
    member this.LastName
        with get() = lastName
        and set(value) = lastName <- value
    member this.Balance
        with get() = balance
        and set(value) = balance <- value
    member this.Deposit(amount: float) = this.Balance <- this.Balance + amount
    member this.Withdraw(amount: float) = this.Balance <- this.Balance - amount

let account1 = new Account(AccountNumber=8782108,
                           FirstName="Darren", LastName="Parker",
                           Balance=1543.33)
```

For more information, see [Constructors \(F#\)](#).

# Optional Parameters

You can specify an optional parameter for a method by using a question mark in front of the parameter name. Optional parameters are interpreted as the F# option type, so you can query them in the regular way that option types are queried, by using a `match` expression with `Some` and `None`. Optional parameters are permitted only on members, not on functions created by using `let` bindings.

You can pass existing optional values to method by parameter name, such as `?arg=None` or `?arg=Some(3)` or `?arg=arg`. This can be useful when building a method that passes optional arguments to another method.

You can also use a function `defaultArg`, which sets a default value of an optional argument. The `defaultArg` function takes the optional parameter as the first argument and the default value as the second.

The following example illustrates the use of optional parameters.

```
type DuplexType =
| Full
| Half

type Connection(?rate0 : int, ?duplex0 : DuplexType, ?parity0 : bool) =
    let duplex = defaultArg duplex0 Full
    let parity = defaultArg parity0 false
    let mutable rate = match rate0 with
        | Some rate1 -> rate1
        | None -> match duplex with
            | Full -> 9600
            | Half -> 4800
    do printfn "Baud Rate: %d Duplex: %A Parity: %b" rate duplex parity

let conn1 = Connection(duplex0 = Full)
let conn2 = Connection(duplex0 = Half)
let conn3 = Connection(300, Half, true)
let conn4 = Connection(?duplex0 = None)
let conn5 = Connection(?duplex0 = Some(Full))

let optionalDuplexValue : option<DuplexType> = Some(Half)
let conn6 = Connection(?duplex0 = optionalDuplexValue)
```

The output is as follows.

```
Baud Rate: 9600 Duplex: Full Parity: false
Baud Rate: 4800 Duplex: Half Parity: false
Baud Rate: 300 Duplex: Half Parity: true
Baud Rate: 9600 Duplex: Full Parity: false
Baud Rate: 9600 Duplex: Full Parity: false
Baud Rate: 4800 Duplex: Half Parity: false
```

For the purposes of C# and Visual Basic interop you can use the attributes

`[<Optional; DefaultValue<(...)>]` in F#, so that callers will see an argument as optional. This is equivalent to defining the argument as optional in C# as in `MyMethod(int i = 3)`.

```
open System
open System.Runtime.InteropServices
type C =
    static member Foo([<Optional; DefaultValue("Hello world")>] message) =
        printfn "%s" message
```

You can also specify a new object as a default parameter value. For example, the `Foo` member could have an optional `CancellationToken` as input instead:

```

open System.Threading
open System.Runtime.InteropServices
type C =
    static member Foo([<Optional; DefaultValue(CancellationToken())>] ct: CancellationToken) =
        printfn "%A" ct

```

The value given as argument to `[DefaultValue]` must match the type of the parameter. For example, the following is not allowed:

```

type C =
    static member Wrong([<Optional; DefaultValue("string")>] i:int) = ()

```

In this case, the compiler generates a warning and will ignore both attributes altogether. Note that the default value `null` needs to be type-annotated, as otherwise the compiler infers the wrong type, i.e.

`[<Optional; DefaultValue(null:obj)>] o:obj`.

## Passing by Reference

Passing an F# value by reference involves [byrefs](#), which are managed pointer types. Guidance for which type to use is as follows:

- Use `inref<'T>` if you only need to read the pointer.
- Use `outref<'T>` if you only need to write to the pointer.
- Use `byref<'T>` if you need to both read from and write to the pointer.

```

let example1 (x: inref<int>) = printfn "It's %d" x

let example2 (x: outref<int>) = x <- x + 1

let example3 (x: byref<int>) =
    printfn "It'd %d" x
    x <- x + 1

// No need to make it mutable, since it's read-only
let x = 1
example1 &x

// Needs to be mutable, since we write to it
let mutable y = 2
example2 &y
example3 &y // Now 'y' is 3

```

Because the parameter is a pointer and the value is mutable, any changes to the value are retained after the execution of the function.

You can use a tuple as a return value to store any `out` parameters in .NET library methods. Alternatively, you can treat the `out` parameter as a `byref` parameter. The following code example illustrates both ways.

```
// TryParse has a second parameter that is an out parameter
// of type System.DateTime.
let (b, dt) = System.DateTime.TryParse("12-20-04 12:21:00")

printfn "%b %A" b dt

// The same call, using an address of operator.
let mutable dt2 = System.DateTime.Now
let b2 = System.DateTime.TryParse("12-20-04 12:21:00", &dt2)

printfn "%b %A" b2 dt2
```

## Parameter Arrays

Occasionally it is necessary to define a function that takes an arbitrary number of parameters of heterogeneous type. It would not be practical to create all the possible overloaded methods to account for all the types that could be used. The .NET implementations provide support for such methods through the parameter array feature. A method that takes a parameter array in its signature can be provided with an arbitrary number of parameters. The parameters are put into an array. The type of the array elements determines the parameter types that can be passed to the function. If you define the parameter array with `System.Object` as the element type, then client code can pass values of any type.

In F#, parameter arrays can only be defined in methods. They cannot be used in standalone functions or functions that are defined in modules.

You define a parameter array by using the `[ParamArray]` attribute. The `[ParamArray]` attribute can only be applied to the last parameter.

The following code illustrates both calling a .NET method that takes a parameter array and the definition of a type in F# that has a method that takes a parameter array.

```
open System

type X() =
    member this.F([<ParamArray>] args: Object[]) =
        for arg in args do
            printfn "%A" arg

[<EntryPoint>]
let main _ =
    // call a .NET method that takes a parameter array, passing values of various types
    Console.WriteLine("a {0} {1} {2} {3} {4}", 1, 10.0, "Hello world", 1u, true)

    let xobj = new X()
    // call an F# method that takes a parameter array, passing values of various types
    xobj.F("a", 1, 10.0, "Hello world", 1u, true)
    0
```

When run in a project, the output of the previous code is as follows:

```
a 1 10 Hello world 1 True
"a"
1
10.0
"Hello world"
1u
true
```

# Operator Overloading

12/19/2018 • 7 minutes to read • [Edit Online](#)

This topic describes how to overload arithmetic operators in a class or record type, and at the global level.

## Syntax

```
// Overloading an operator as a class or record member.  
static member (operator-symbols) (parameter-list) =  
    method-body  
// Overloading an operator at the global level  
let [inline] (operator-symbols) parameter-list = function-body
```

## Remarks

In the previous syntax, the *operator-symbol* is one of `+`, `-`, `*`, `/`, `=`, and so on. The *parameter-list* specifies the operands in the order they appear in the usual syntax for that operator. The *method-body* constructs the resulting value.

Operator overloads for operators must be static. Operator overloads for unary operators, such as `+` and `-`, must use a tilde (`~`) in the *operator-symbol* to indicate that the operator is a unary operator and not a binary operator, as shown in the following declaration.

```
static member (~-) (v : Vector)
```

The following code illustrates a vector class that has just two operators, one for unary minus and one for multiplication by a scalar. In the example, two overloads for scalar multiplication are needed because the operator must work regardless of the order in which the vector and scalar appear.

```
type Vector(x: float, y : float) =  
    member this.x = x  
    member this.y = y  
    static member (~-) (v : Vector) =  
        Vector(-1.0 * v.x, -1.0 * v.y)  
    static member (*) (v : Vector, a) =  
        Vector(a * v.x, a * v.y)  
    static member (*) (a, v: Vector) =  
        Vector(a * v.x, a * v.y)  
    override this.ToString() =  
        this.x.ToString() + " " + this.y.ToString()  
  
let v1 = Vector(1.0, 2.0)  
  
let v2 = v1 * 2.0  
let v3 = 2.0 * v1  
  
let v4 = - v2  
  
printfn "%s" (v1.ToString())  
printfn "%s" (v2.ToString())  
printfn "%s" (v3.ToString())  
printfn "%s" (v4.ToString())
```

# Creating New Operators

You can overload all the standard operators, but you can also create new operators out of sequences of certain characters. Allowed operator characters are !, %, &, \*, +, -, ., /, <, =, >, ?, @, ^, |, and ~. The ~ character has the special meaning of making an operator unary, and is not part of the operator character sequence. Not all operators can be made unary.

Depending on the exact character sequence you use, your operator will have a certain precedence and associativity. Associativity can be either left to right or right to left and is used whenever operators of the same level of precedence appear in sequence without parentheses.

The operator character . does not affect precedence, so that, for example, if you want to define your own version of multiplication that has the same precedence and associativity as ordinary multiplication, you could create operators such as .\*.

Only the operators ? and ?<- may start with ?.

A table that shows the precedence of all operators in F# can be found in [Symbol and Operator Reference](#).

## Overloaded Operator Names

When the F# compiler compiles an operator expression, it generates a method that has a compiler-generated name for that operator. This is the name that appears in the Microsoft intermediate language (MSIL) for the method, and also in reflection and IntelliSense. You do not normally need to use these names in F# code.

The following table shows the standard operators and their corresponding generated names.

OPERATOR	GENERATED NAME
[]	op_Nil
::	op_Cons
+	op_Addition
-	op_Subtraction
*	op_Multiply
/	op_Division
@	op_Append
^	op_Concatenate
%	op_Modulus
&&	op_BitwiseAnd
	op_BitwiseOr
^^^	op_ExclusiveOr

OPERATOR	GENERATED NAME
<<<	op_LeftShift
~~~	op_LogicalNot
>>>	op_RightShift
~+	op_UnaryPlus
~-	op_UnaryNegation
=	op_Equality
<=	op_LessThanOrEqual
>=	op_GreaterThanOrEqual
<	op_LessThan
>	op_GreaterThan
?	op_Dynamic
?<-	op_DynamicAssignment
>	op_PipeRight
<	op_PipeLeft
!	op_Dereference
>>	op_ComposeRight
<<	op_ComposeLeft
<@ @>	op_Quotation
<@@ @@>	op_QuotationUntyped
+=	op_AdditionAssignment
-=	op_SubtractionAssignment
*=	op_MultiplyAssignment
/=	op_DivisionAssignment
..	op_Range

OPERATOR	GENERATED NAME
...	op_RangeStep

Other combinations of operator characters that are not listed here can be used as operators and have names that are made up by concatenating names for the individual characters from the following table. For example, `+` becomes `op_PlusBang`.

OPERATOR CHARACTER	NAME
>	Greater
<	Less
+	Plus
-	Minus
*	Multiply
/	Divide
=	Equals
~	Twiddle
%	Percent
.	Dot
&	Amp
	Bar
@	At
^	Hat
!	Bang
?	Qmark
(LParen
,	Comma
)	RParen
[LBrack

OPERATOR CHARACTER	NAME
]	RBrack

Prefix and Infix Operators

Prefix operators are expected to be placed in front of an operand or operands, much like a function. *Infix* operators are expected to be placed between the two operands.

Only certain operators can be used as prefix operators. Some operators are always prefix operators, others can be infix or prefix, and the rest are always infix operators. Operators that begin with `!`, except `!=`, and the operator `~`, or repeated sequences of `~`, are always prefix operators. The operators `+, -, +., -., &, &&, %`, and `%%` can be prefix operators or infix operators. You distinguish the prefix version of these operators from the infix version by adding a `~` at the beginning of a prefix operator when it is defined. The `~` is not used when you use the operator, only when it is defined.

Example

The following code illustrates the use of operator overloading to implement a fraction type. A fraction is represented by a numerator and a denominator. The function `hcf` is used to determine the highest common factor, which is used to reduce fractions.

```
// Determine the highest common factor between
// two positive integers, a helper for reducing
// fractions.
let rec hcf a b =
  if a = 0u then b
  elif a < b then hcf a (b - a)
  else hcf (a - b) b

// type Fraction: represents a positive fraction
// (positive rational number).
type Fraction =
{
  // n: Numerator of fraction.
  n : uint32
  // d: Denominator of fraction.
  d : uint32
}

// Produce a string representation. If the
// denominator is "1", do not display it.
override this.ToString() =
  if (this.d = 1u)
    then this.n.ToString()
    else this.n.ToString() + "/" + this.d.ToString()

// Add two fractions.
static member (+) (f1 : Fraction, f2 : Fraction) =
  let nTemp = f1.n * f2.d + f2.n * f1.d
  let dTemp = f1.d * f2.d
  let hcftemp = hcf nTemp dTemp
  { n = nTemp / hcftemp; d = dTemp / hcftemp }

// Adds a fraction and a positive integer.
static member (+) (f1: Fraction, i : uint32) =
  let nTemp = f1.n + i * f1.d
  let dTemp = f1.d
  let hcftemp = hcf nTemp dTemp
  { n = nTemp / hcftemp; d = dTemp / hcftemp }
```

```

// Adds a positive integer and a fraction.
static member (+) (i : uint32, f2: Fraction) =
    let nTemp = f2.n + i * f2.d
    let dTemp = f2.d
    let hcfTemp = hcf nTemp dTemp
    { n = nTemp / hcfTemp; d = dTemp / hcfTemp }

// Subtract one fraction from another.
static member (-) (f1 : Fraction, f2 : Fraction) =
    if (f2.n * f1.d > f1.n * f2.d)
        then failwith "This operation results in a negative number, which is not supported."
    let nTemp = f1.n * f2.d - f2.n * f1.d
    let dTemp = f1.d * f2.d
    let hcfTemp = hcf nTemp dTemp
    { n = nTemp / hcfTemp; d = dTemp / hcfTemp }

// Multiply two fractions.
static member (*) (f1 : Fraction, f2 : Fraction) =
    let nTemp = f1.n * f2.n
    let dTemp = f1.d * f2.d
    let hcfTemp = hcf nTemp dTemp
    { n = nTemp / hcfTemp; d = dTemp / hcfTemp }

// Divide two fractions.
static member (/) (f1 : Fraction, f2 : Fraction) =
    let nTemp = f1.n * f2.d
    let dTemp = f2.n * f1.d
    let hcfTemp = hcf nTemp dTemp
    { n = nTemp / hcfTemp; d = dTemp / hcfTemp }

// A full set of operators can be quite lengthy. For example,
// consider operators that support other integral data types,
// with fractions, on the left side and the right side for each.
// Also consider implementing unary operators.

let fraction1 = { n = 3u; d = 4u }
let fraction2 = { n = 1u; d = 2u }
let result1 = fraction1 + fraction2
let result2 = fraction1 - fraction2
let result3 = fraction1 * fraction2
let result4 = fraction1 / fraction2
let result5 = fraction1 + 1u
printfn "%s + %s = %s" (fraction1.ToString()) (fraction2.ToString()) (result1.ToString())
printfn "%s - %s = %s" (fraction1.ToString()) (fraction2.ToString()) (result2.ToString())
printfn "%s * %s = %s" (fraction1.ToString()) (fraction2.ToString()) (result3.ToString())
printfn "%s / %s = %s" (fraction1.ToString()) (fraction2.ToString()) (result4.ToString())
printfn "%s + 1 = %s" (fraction1.ToString()) (result5.ToString())

```

Output:

```

3/4 + 1/2 = 5/4
3/4 - 1/2 = 1/4
3/4 * 1/2 = 3/8
3/4 / 1/2 = 3/2
3/4 + 1 = 7/4

```

Operators at the Global Level

You can also define operators at the global level. The following code defines an operator `+?`.

```

let inline (+?) (x: int) (y: int) = x + 2*y
printf "%d" (10 +? 1)

```

The output of the above code is `12`.

You can redefine the regular arithmetic operators in this manner because the scoping rules for F# dictate that newly defined operators take precedence over the built-in operators.

The keyword `inline` is often used with global operators, which are often small functions that are best integrated into the calling code. Making operator functions inline also enables them to work with statically resolved type parameters to produce statically resolved generic code. For more information, see [Inline Functions](#) and [Statically Resolved Type Parameters](#).

Flexible Types

12/19/2018 • 2 minutes to read • [Edit Online](#)

A *flexible type annotation* indicates that a parameter, variable, or value has a type that is compatible with a specified type, where compatibility is determined by position in an object-oriented hierarchy of classes or interfaces. Flexible types are useful specifically when the automatic conversion to types higher in the type hierarchy does not occur but you still want to enable your functionality to work with any type in the hierarchy or any type that implements an interface.

Syntax

```
#type
```

Remarks

In the previous syntax, *type* represents a base type or an interface.

A flexible type is equivalent to a generic type that has a constraint that limits the allowed types to types that are compatible with the base or interface type. That is, the following two lines of code are equivalent.

```
#SomeType  
'T when 'T :> SomeType
```

Flexible types are useful in several types of situations. For example, when you have a higher order function (a function that takes a function as an argument), it is often useful to have the function return a flexible type. In the following example, the use of a flexible type with a sequence argument in `iterate2` enables the higher order function to work with functions that generate sequences, arrays, lists, and any other enumerable type.

Consider the following two functions, one of which returns a sequence, the other of which returns a flexible type.

```
let iterate1 (f : unit -> seq<int>) =  
    for e in f() do printfn "%d" e  
let iterate2 (f : unit -> #seq<int>) =  
    for e in f() do printfn "%d" e  
  
// Passing a function that takes a list requires a cast.  
iterate1 (fun () -> [1] :> seq<int>)  
  
// Passing a function that takes a list to the version that specifies a  
// flexible type as the return value is OK as is.  
iterate2 (fun () -> [1])
```

As another example, consider the `Seq.concat` library function:

```
val concat: sequences:seq<#seq<'T>> -> seq<'T>
```

You can pass any of the following enumerable sequences to this function:

- A list of lists

- A list of arrays
- An array of lists
- An array of sequences
- Any other combination of enumerable sequences

The following code uses `Seq.concat` to demonstrate the scenarios that you can support by using flexible types.

```
let list1 = [1;2;3]
let list2 = [4;5;6]
let list3 = [7;8;9]

let concat1 = Seq.concat [ list1; list2; list3]
printfn "%A" concat1

let array1 = [|1;2;3|]
let array2 = [|4;5;6|]
let array3 = [|7;8;9|]

let concat2 = Seq.concat [ array1; array2; array3 ]
printfn "%A" concat2

let concat3 = Seq.concat [| list1; list2; list3 |]
printfn "%A" concat3

let concat4 = Seq.concat [| array1; array2; array3 |]
printfn "%A" concat4

let seq1 = { 1 .. 3 }
let seq2 = { 4 .. 6 }
let seq3 = { 7 .. 9 }

let concat5 = Seq.concat [| seq1; seq2; seq3 |]

printfn "%A" concat5
```

The output is as follows.

```
seq [1; 2; 3; 4; ...]
```

In F#, as in other object-oriented languages, there are contexts in which derived types or types that implement interfaces are automatically converted to a base type or interface type. These automatic conversions occur in direct arguments, but not when the type is in a subordinate position, as part of a more complex type such as a return type of a function type, or as a type argument. Thus, the flexible type notation is primarily useful when the type you are applying it to is part of a more complex type.

Delegates

12/19/2018 • 3 minutes to read • [Edit Online](#)

A delegate represents a function call as an object. In F#, you ordinarily should use function values to represent functions as first-class values; however, delegates are used in the .NET Framework and so are needed when you interoperate with APIs that expect them. They may also be used when authoring libraries designed for use from other .NET Framework languages.

Syntax

```
type delegate-typename = delegate of type1 -> type2
```

Remarks

In the previous syntax, `type1` represents the argument type or types and `type2` represents the return type. The argument types that are represented by `type1` are automatically curried. This suggests that for this type you use a tuple form if the arguments of the target function are curried, and a parenthesized tuple for arguments that are already in the tuple form. The automatic currying removes a set of parentheses, leaving a tuple argument that matches the target method. Refer to the code example for the syntax you should use in each case.

Delegates can be attached to F# function values, and static or instance methods. F# function values can be passed directly as arguments to delegate constructors. For a static method, you construct the delegate by using the name of the class and the method. For an instance method, you provide the object instance and method in one argument. In both cases, the member access operator (`.`) is used.

The `Invoke` method on the delegate type calls the encapsulated function. Also, delegates can be passed as function values by referencing the `Invoke` method name without the parentheses.

The following code shows the syntax for creating delegates that represent various methods in a class. Depending on whether the method is a static method or an instance method, and whether it has arguments in the tuple form or the curried form, the syntax for declaring and assigning the delegate is a little different.

```

type Test1() =
    static member add(a : int, b : int) =
        a + b
    static member add2 (a : int) (b : int) =
        a + b

    member x.Add(a : int, b : int) =
        a + b
    member x.Add2 (a : int) (b : int) =
        a + b

// Delegate1 works with tuple arguments.
type Delegate1 = delegate of (int * int) -> int
// Delegate2 works with curried arguments.
type Delegate2 = delegate of int * int -> int

let InvokeDelegate1 (dlg : Delegate1) (a : int) (b: int) =
    dlg.Invoke(a, b)
let InvokeDelegate2 (dlg : Delegate2) (a : int) (b: int) =
    dlg.Invoke(a, b)

// For static methods, use the class name, the dot operator, and the
// name of the static method.
let del1 : Delegate1 = new Delegate1( Test1.add )
let del2 : Delegate2 = new Delegate2( Test1.add2 )

let testObject = Test1()

// For instance methods, use the instance value name, the dot operator, and the instance method name.
let del3 : Delegate1 = new Delegate1( testObject.Add )
let del4 : Delegate2 = new Delegate2( testObject.Add2 )

for (a, b) in [ (100, 200); (10, 20) ] do
    printfn "%d + %d = %d" a b (InvokeDelegate1 del1 a b)
    printfn "%d + %d = %d" a b (InvokeDelegate2 del2 a b)
    printfn "%d + %d = %d" a b (InvokeDelegate1 del3 a b)
    printfn "%d + %d = %d" a b (InvokeDelegate2 del4 a b)

```

The following code shows some of the different ways you can work with delegates.

```

type Delegate1 = delegate of int * char -> string

let replicate n c = String.replicate n (string c)

// An F# function value constructed from an unapplied let-bound function
let function1 = replicate

// A delegate object constructed from an F# function value
let delObject = new Delegate1(function1)

// An F# function value constructed from an unapplied .NET member
let functionValue = delObject.Invoke

List.map (fun c -> functionValue(5,c)) ['a'; 'b'; 'c']
|> List.iter (printfn "%s")

// Or if you want to get back the same curried signature
let replicate' n c = delObject.Invoke(n,c)

// You can pass a lambda expression as an argument to a function expecting a compatible delegate type
// System.Array.ConvertAll takes an array and a converter delegate that transforms an element from
// one type to another according to a specified function.
let stringArray = System.Array.ConvertAll(['a';'b'], fun c -> replicate' 3 c)
printfn "%A" stringArray

```

The output of the previous code example is as follows.

```

aaaaa
bbbbb
ccccc
[|"aaa"; "bbb"|]

```

Object Expressions

2/12/2019 • 2 minutes to read • [Edit Online](#)

An *object expression* is an expression that creates a new instance of a dynamically created, anonymous object type that is based on an existing base type, interface, or set of interfaces.

Syntax

```
// When typename is a class:  
{ new typename [type-params]arguments with  
    member-definitions  
    [ additional-interface-definitions ]  
}  
// When typename is not a class:  
{ new typename [generic-type-args] with  
    member-definitions  
    [ additional-interface-definitions ]  
}
```

Remarks

In the previous syntax, the *typename* represents an existing class type or interface type. *type-params* describes the optional generic type parameters. The *arguments* are used only for class types, which require constructor parameters. The *member-definitions* are overrides of base class methods, or implementations of abstract methods from either a base class or an interface.

The following example illustrates several different types of object expressions.

```

// This object expression specifies a System.Object but overrides the
// ToString method.
let obj1 = { new System.Object() with member x.ToString() = "F#" }
printfn "%A" obj1

// This object expression implements the IFormattable interface.
let delimiter(delim1: string, delim2: string, value: string) =
    { new System.IFormattable with
        member x.ToString(format: string, provider: System.IFormatProvider) =
            if format = "D" then
                delim1 + value + delim2
            else
                value }

let obj2 = delimiter("{", "}", "Bananas!");

printfn "%A" (System.String.Format("{0:D}", obj2))

// This object expression implements multiple interfaces.
type IFirst =
    abstract F : unit -> unit
    abstract G : unit -> unit

type ISecond =
    inherit IFirst
    abstract H : unit -> unit
    abstract J : unit -> unit

// This object expression implements an interface chain.
let implementer() =
    { new ISecond with
        member this.H() = ()
        member this.J() = ()
        interface IFirst with
            member this.F() = ()
            member this.G() = () }

```

Using Object Expressions

You use object expressions when you want to avoid the extra code and overhead that is required to create a new, named type. If you use object expressions to minimize the number of types created in a program, you can reduce the number of lines of code and prevent the unnecessary proliferation of types. Instead of creating many types just to handle specific situations, you can use an object expression that customizes an existing type or provides an appropriate implementation of an interface for the specific case at hand.

Copy and Update Record Expressions

12/19/2018 • 2 minutes to read • [Edit Online](#)

A *copy and update record expression* is an expression that copies an existing record, updates specified fields, and returns the updated record.

Syntax

```
{ record-name with  
    updated-member-definitions }
```

Remarks

Records are immutable by default, so that there is no update to an existing record possible. To create an updated record all the fields of a record would have to be specified again. To simplify this task a *copy and update record expression* can be used. This expression takes an existing record, creates a new one of the same type by using specified fields from the expression and the missing field specified by the expression. This can be useful when you have to copy an existing record, and possibly change some of the field values.

Take for instance a newly created record.

```
let myRecord2 = { MyRecord.X = 1; MyRecord.Y = 2; MyRecord.Z = 3 }
```

If you were to update only one field of that record you could use the *copy and update record expression* like the following:

```
let myRecord3 = { myRecord2 with Y = 100; Z = 2 }
```

Casting and Conversions (F#)

12/20/2018 • 6 minutes to read • [Edit Online](#)

This topic describes support for type conversions in F#.

Arithmetic Types

F# provides conversion operators for arithmetic conversions between various primitive types, such as between integer and floating point types. The integral and char conversion operators have checked and unchecked forms; the floating point operators and the `enum` conversion operator do not. The unchecked forms are defined in `Microsoft.FSharp.Core.Operators` and the checked forms are defined in `Microsoft.FSharp.Core.Operators.Checked`. The checked forms check for overflow and generate a runtime exception if the resulting value exceeds the limits of the target type.

Each of these operators has the same name as the name of the destination type. For example, in the following code, in which the types are explicitly annotated, `byte` appears with two different meanings. The first occurrence is the type and the second is the conversion operator.

```
let x : int = 5  
  
let b : byte = byte x
```

The following table shows conversion operators defined in F#.

OPERATOR	DESCRIPTION
<code>byte</code>	Convert to byte, an 8-bit unsigned type.
<code>sbyte</code>	Convert to signed byte.
<code>int16</code>	Convert to a 16-bit signed integer.
<code>uint16</code>	Convert to a 16-bit unsigned integer.
<code>int32, int</code>	Convert to a 32-bit signed integer.
<code>uint32</code>	Convert to a 32-bit unsigned integer.
<code>int64</code>	Convert to a 64-bit signed integer.
<code>uint64</code>	Convert to a 64-bit unsigned integer.
<code>nativeint</code>	Convert to a native integer.
<code>unativeint</code>	Convert to an unsigned native integer.
<code>float, double</code>	Convert to a 64-bit double-precision IEEE floating point number.

OPERATOR	DESCRIPTION
<code>float32, single</code>	Convert to a 32-bit single-precision IEEE floating point number.
<code>decimal</code>	Convert to <code>System.Decimal</code> .
<code>char</code>	Convert to <code>System.Char</code> , a Unicode character.
<code>enum</code>	Convert to an enumerated type.

In addition to built-in primitive types, you can use these operators with types that implement `op_Explicit` or `op_Implicit` methods with appropriate signatures. For example, the `int` conversion operator works with any type that provides a static method `op_Explicit` that takes the type as a parameter and returns `int`. As a special exception to the general rule that methods cannot be overloaded by return type, you can do this for `op_Explicit` and `op_Implicit`.

Enumerated Types

The `enum` operator is a generic operator that takes one type parameter that represents the type of the `enum` to convert to. When it converts to an enumerated type, type inference attempts to determine the type of the `enum` that you want to convert to. In the following example, the variable `col1` is not explicitly annotated, but its type is inferred from the later equality test. Therefore, the compiler can deduce that you are converting to a `Color` enumeration. Alternatively, you can supply a type annotation, as with `col2` in the following example.

```
type Color =
| Red = 1
| Green = 2
| Blue = 3

// The target type of the conversion is determined by type inference.
let col1 = enum 1
// The target type is supplied by a type annotation.
let col2 : Color = enum 2
do
    if (col1 = Color.Red) then
        printfn "Red"
```

You can also specify the target enumeration type explicitly as a type parameter, as in the following code:

```
let col3 = enum<Color> 3
```

Note that the enumeration casts work only if the underlying type of the enumeration is compatible with the type being converted. In the following code, the conversion fails to compile because of the mismatch between `int32` and `uint32`.

```
// Error: types are incompatible
let col4 : Color = enum 2u
```

For more information, see [Enumerations](#).

Casting Object Types

Conversion between types in an object hierarchy is fundamental to object-oriented programming. There are two basic types of conversions: casting up (upcasting) and casting down (downcasting). Casting up a hierarchy means casting from a derived object reference to a base object reference. Such a cast is guaranteed to work as long as the base class is in the inheritance hierarchy of the derived class. Casting down a hierarchy, from a base object reference to a derived object reference, succeeds only if the object actually is an instance of the correct destination (derived) type or a type derived from the destination type.

F# provides operators for these types of conversions. The `:>` operator casts up the hierarchy, and the `:?>` operator casts down the hierarchy.

Upcasting

In many object-oriented languages, upcasting is implicit; in F#, the rules are slightly different. Upcasting is applied automatically when you pass arguments to methods on an object type. However, for let-bound functions in a module, upcasting is not automatic, unless the parameter type is declared as a flexible type. For more information, see [Flexible Types](#).

The `:>` operator performs a static cast, which means that the success of the cast is determined at compile time. If a cast that uses `:>` compiles successfully, it is a valid cast and has no chance of failure at run time.

You can also use the `upcast` operator to perform such a conversion. The following expression specifies a conversion up the hierarchy:

```
upcast expression
```

When you use the `upcast` operator, the compiler attempts to infer the type you are converting to from the context. If the compiler is unable to determine the target type, the compiler reports an error.

Downcasting

The `:?>` operator performs a dynamic cast, which means that the success of the cast is determined at run time. A cast that uses the `:?>` operator is not checked at compile time; but at run time, an attempt is made to cast to the specified type. If the object is compatible with the target type, the cast succeeds. If the object is not compatible with the target type, the runtime raises an `InvalidOperationException`.

You can also use the `downcast` operator to perform a dynamic type conversion. The following expression specifies a conversion down the hierarchy to a type that is inferred from program context:

```
downcast expression
```

As for the `upcast` operator, if the compiler cannot infer a specific target type from the context, it reports an error.

The following code illustrates the use of the `:>` and `:?>` operators. The code illustrates that the `:?>` operator is best used when you know that conversion will succeed, because it throws `InvalidOperationException` if the conversion fails. If you do not know that a conversion will succeed, a type test that uses a `match` expression is better because it avoids the overhead of generating an exception.

```

type Base1() =
    abstract member F : unit -> unit
    default u.F() =
        printfn "F Base1"

type Derived1() =
    inherit Base1()
    override u.F() =
        printfn "F Derived1"

let d1 : Derived1 = Derived1()

// Upcast to Base1.
let base1 = d1 :> Base1

// This might throw an exception, unless
// you are sure that base1 is really a Derived1 object, as
// is the case here.
let derived1 = base1 :?> Derived1

// If you cannot be sure that b1 is a Derived1 object,
// use a type test, as follows:
let downcastBase1 (b1 : Base1) =
    match b1 with
    | :? Derived1 as derived1 -> derived1.F()
    | _ -> ()

downcastBase1 base1

```

Because generic operators `downcast` and `upcast` rely on type inference to determine the argument and return type, in the above code, you can replace

```
let base1 = d1 :> Base1
```

with

```
let base1 = upcast d1
```

In the previous code, the argument type and return types are `Derived1` and `Base1`, respectively.

For more information about type tests, see [Match Expressions](#).

Access Control

12/19/2018 • 3 minutes to read • [Edit Online](#)

Access control refers to declaring which clients can use certain program elements, such as types, methods, and functions.

Basics of Access Control

In F#, the access control specifiers `public`, `internal`, and `private` can be applied to modules, types, methods, value definitions, functions, properties, and explicit fields.

- `public` indicates that the entity can be accessed by all callers.
- `internal` indicates that the entity can be accessed only from the same assembly.
- `private` indicates that the entity can be accessed only from the enclosing type or module.

NOTE

The access specifier `protected` is not used in F#, although it is acceptable if you are using types authored in languages that do support `protected` access. Therefore, if you override a protected method, your method remains accessible only within the class and its descendants.

In general, the specifier is put in front of the name of the entity, except when a `mutable` or `inline` specifier is used, which appear after the access control specifier.

If no access specifier is used, the default is `public`, except for `let` bindings in a type, which are always `private` to the type.

Signatures in F# provide another mechanism for controlling access to F# program elements. Signatures are not required for access control. For more information, see [Signatures](#).

Rules for Access Control

Access control is subject to the following rules:

- Inheritance declarations (that is, the use of `inherit` to specify a base class for a class), interface declarations (that is, specifying that a class implements an interface), and abstract members always have the same accessibility as the enclosing type. Therefore, an access control specifier cannot be used on these constructs.
- Accessibility for individual cases in a discriminated union is determined by the accessibility of the discriminated union itself. That is, a particular union case is no less accessible than the union itself.
- Accessibility for individual fields of a record type cannot be determined by the accessibility of the record itself. That is, a particular record label is no less accessible than the record itself.

Example

The following code illustrates the use of access control specifiers. There are two files in the project, `Module1.fs` and `Module2.fs`. Each file is implicitly a module. Therefore, there are two modules, `Module1` and `Module2`. A private type and an internal type are defined in `Module1`. The private type cannot be accessed from `Module2`,

but the internal type can.

```
// Module1.fs

module Module1

// This type is not usable outside of this file
type private MyPrivateType() =
    // x is private since this is an internal let binding
    let x = 5
    // X is private and does not appear in the QuickInfo window
    // when viewing this type in the Visual Studio editor
    member private this.X() = 10
    member this.Z() = x * 100

type internal MyInternalType() =
    let x = 5
    member private this.X() = 10
    member this.Z() = x * 100

// Top-level let bindings are public by default,
// so "private" and "internal" are needed here since a
// value cannot be more accessible than its type.
let private myPrivateObj = new MyPrivateType()
let internal myInternalObj = new MyInternalType()

// let bindings at the top level are public by default,
// so result1 and result2 are public.
let result1 = myPrivateObj.Z
let result2 = myInternalObj.Z
```

The following code tests the accessibility of the types created in `Module1.fs`.

```
// Module2.fs
module Module2

open Module1

// The following line is an error because private means
// that it cannot be accessed from another file or module
// let private myPrivateObj = new MyPrivateType()
let internal myInternalObj = new MyInternalType()

let result = myInternalObj.Z
```

Conditional Expressions: if...then...else

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `if...then...else` expression runs different branches of code and also evaluates to a different value depending on the Boolean expression given.

Syntax

```
if boolean-expression then expression1 [ else expression2 ]
```

Remarks

In the previous syntax, *expression1* runs when the Boolean expression evaluates to `true`; otherwise, *expression2* runs.

Unlike in other languages, the `if...then...else` construct is an expression, not a statement. That means that it produces a value, which is the value of the last expression in the branch that executes. The types of the values produced in each branch must match. If there is no explicit `else` branch, its type is `unit`. Therefore, if the type of the `then` branch is any type other than `unit`, there must be an `else` branch with the same return type. When chaining `if...then...else` expressions together, you can use the keyword `elif` instead of `else if`; they are equivalent.

Example

The following example illustrates how to use the `if...then...else` expression.

```
let test x y =
    if x = y then "equals"
    elif x < y then "is less than"
    else "is greater than"

printfn "%d %s %d." 10 (test 10 20) 20

printfn "What is your name? "
let nameString = System.Console.ReadLine()

printfn "What is your age? "
let ageString = System.Console.ReadLine()
let age = System.Int32.Parse(ageString)

if age < 10
then printfn "You are only %d years old and already learning F#? Wow!" age
```

```
10 is less than 20
What is your name? John
How old are you? 9
You are only 9 years old and already learning F#? Wow!
```

Match expressions

12/19/2018 • 3 minutes to read • [Edit Online](#)

The `match` expression provides branching control that is based on the comparison of an expression with a set of patterns.

Syntax

```
// Match expression.  
match test-expression with  
| pattern1 [ when condition ] -> result-expression1  
| pattern2 [ when condition ] -> result-expression2  
| ...  
  
// Pattern matching function.  
function  
| pattern1 [ when condition ] -> result-expression1  
| pattern2 [ when condition ] -> result-expression2  
| ...
```

Remarks

The pattern matching expressions allow for complex branching based on the comparison of a test expression with a set of patterns. In the `match` expression, the *test-expression* is compared with each pattern in turn, and when a match is found, the corresponding *result-expression* is evaluated and the resulting value is returned as the value of the match expression.

The pattern matching function shown in the previous syntax is a lambda expression in which pattern matching is performed immediately on the argument. The pattern matching function shown in the previous syntax is equivalent to the following.

```
fun arg ->  
  match arg with  
  | pattern1 [ when condition ] -> result-expression1  
  | pattern2 [ when condition ] -> result-expression2  
  | ...
```

For more information about lambda expressions, see [Lambda Expressions: The `fun` Keyword](#).

The whole set of patterns should cover all the possible matches of the input variable. Frequently, you use the wildcard pattern (`_`) as the last pattern to match any previously unmatched input values.

The following code illustrates some of the ways in which the `match` expression is used. For a reference and examples of all the possible patterns that can be used, see [Pattern Matching](#).

```

let list1 = [ 1; 5; 100; 450; 788 ]

// Pattern matching by using the cons pattern and a list
// pattern that tests for an empty list.
let rec printList listx =
    match listx with
    | head :: tail -> printf "%d " head; printList tail
    | [] -> printfn ""

printList list1

// Pattern matching with multiple alternatives on the same line.
let filter123 x =
    match x with
    | 1 | 2 | 3 -> printfn "Found 1, 2, or 3!"
    | a -> printfn "%d" a

// The same function written with the pattern matching
// function syntax.
let filterNumbers =
    function | 1 | 2 | 3 -> printfn "Found 1, 2, or 3!"
             | a -> printfn "%d" a

```

Guards on patterns

You can use a `when` clause to specify an additional condition that the variable must satisfy to match a pattern. Such a clause is referred to as a *guard*. The expression following the `when` keyword is not evaluated unless a match is made to the pattern associated with that guard.

The following example illustrates the use of a guard to specify a numeric range for a variable pattern. Note that multiple conditions are combined by using Boolean operators.

```

let rangeTest testValue mid size =
    match testValue with
    | var1 when var1 >= mid - size/2 && var1 <= mid + size/2 -> printfn "The test value is in range."
    | _ -> printfn "The test value is out of range."

rangeTest 10 20 5
rangeTest 10 20 10
rangeTest 10 20 40

```

Note that because values other than literals cannot be used in the pattern, you must use a `when` clause if you have to compare some part of the input against a value. This is shown in the following code:

```

// This example uses patterns that have when guards.
let detectValue point target =
    match point with
    | (a, b) when a = target && b = target -> printfn "Both values match target %d." target
    | (a, b) when a = target -> printfn "First value matched target in (%d, %d)" target b
    | (a, b) when b = target -> printfn "Second value matched target in (%d, %d)" a target
    | _ -> printfn "Neither value matches target."
detectValue (0, 0) 0
detectValue (1, 0) 0
detectValue (0, 10) 0
detectValue (10, 15) 0

```

Note that when a union pattern is covered by a guard, the guard applies to **all** of the patterns, not just the last one. For example, given the following code, the guard `when a > 12` applies to both `A a` and `B a`:

```
type Union =
| A of int
| B of int

let foo() =
    let test = A 42
    match test with
    | A a
    | B a when a > 41 -> a // the guard applies to both patterns
    | _ -> 1

foo() // returns 42
```

Pattern Matching

12/19/2018 • 12 minutes to read • [Edit Online](#)

Patterns are rules for transforming input data. They are used throughout the F# language to compare data with a logical structure or structures, decompose data into constituent parts, or extract information from data in various ways.

Remarks

Patterns are used in many language constructs, such as the `match` expression. They are used when you are processing arguments for functions in `let` bindings, lambda expressions, and in the exception handlers associated with the `try...with` expression. For more information, see [Match Expressions](#), [let Bindings](#), [Lambda Expressions: The `fun` Keyword](#), and [Exceptions: The `try...with` Expression](#).

For example, in the `match` expression, the *pattern* is what follows the pipe symbol.

```
match expression with
| pattern [ when condition ] -> result-expression
...
```

Each pattern acts as a rule for transforming input in some way. In the `match` expression, each pattern is examined in turn to see if the input data is compatible with the pattern. If a match is found, the result expression is executed. If a match is not found, the next pattern rule is tested. The optional *when condition* part is explained in [Match Expressions](#).

Supported patterns are shown in the following table. At run time, the input is tested against each of the following patterns in the order listed in the table, and patterns are applied recursively, from first to last as they appear in your code, and from left to right for the patterns on each line.

NAME	DESCRIPTION	EXAMPLE
Constant pattern	Any numeric, character, or string literal, an enumeration constant, or a defined literal identifier	<code>1.0</code> , <code>"test"</code> , <code>30</code> , <code>Color.Red</code>
Identifier pattern	A case value of a discriminated union, an exception label, or an active pattern case	<code>Some(x)</code> <code>Failure(msg)</code>
Variable pattern	<i>identifier</i>	<code>a</code>
<code>as</code> pattern	<i>pattern as identifier</i>	<code>(a, b) as tuple1</code>
OR pattern	<i>pattern1 pattern2</i>	<code>([h] [h; _])</code>
AND pattern	<i>pattern1 & pattern2</i>	<code>(a, b) & (_, "test")</code>
Cons pattern	<i>identifier :: list-identifier</i>	<code>h :: t</code>

NAME	DESCRIPTION	EXAMPLE
List pattern	<code>[pattern_1; ... ; pattern_n]</code>	<code>[a; b; c]</code>
Array pattern	<code>[pattern_1; ..; pattern_n]</code>	<code>[a; b; c]</code>
Parenthesized pattern	<code>(pattern)</code>	<code>(a)</code>
Tuple pattern	<code>(pattern_1, ..., pattern_n)</code>	<code>(a, b)</code>
Record pattern	<code>{ identifier1 = pattern_1; ... ; identifier_n = pattern_n }</code>	<code>{ Name = name; }</code>
Wildcard pattern	<code>_</code>	<code>_</code>
Pattern together with type annotation	<code>pattern : type</code>	<code>a : int</code>
Type test pattern	<code>:? type [as identifier]</code>	<code>:? System.DateTime as dt</code>
Null pattern	<code>null</code>	<code>null</code>

Constant Patterns

Constant patterns are numeric, character, and string literals, enumeration constants (with the enumeration type name included). A `match` expression that has only constant patterns can be compared to a case statement in other languages. The input is compared with the literal value and the pattern matches if the values are equal. The type of the literal must be compatible with the type of the input.

The following example demonstrates the use of literal patterns, and also uses a variable pattern and an OR pattern.

```
[<Literal>]
let Three = 3

let filter123 x =
    match x with
    // The following line contains literal patterns combined with an OR pattern.
    | 1 | 2 | Three -> printfn "Found 1, 2, or 3!"
    // The following line contains a variable pattern.
    | var1 -> printfn "%d" var1

for x in 1..10 do filter123 x
```

Another example of a literal pattern is a pattern based on enumeration constants. You must specify the enumeration type name when you use enumeration constants.

```

type Color =
| Red = 0
| Green = 1
| Blue = 2

let printColorName (color:Color) =
    match color with
    | Color.Red -> printfn "Red"
    | Color.Green -> printfn "Green"
    | Color.Blue -> printfn "Blue"
    | _ -> ()

printColorName Color.Red
printColorName Color.Green
printColorName Color.Blue

```

Identifier Patterns

If the pattern is a string of characters that forms a valid identifier, the form of the identifier determines how the pattern is matched. If the identifier is longer than a single character and starts with an uppercase character, the compiler tries to make a match to the identifier pattern. The identifier for this pattern could be a value marked with the `Literal` attribute, a discriminated union case, an exception identifier, or an active pattern case. If no matching identifier is found, the match fails and the next pattern rule, the variable pattern, is compared to the input.

Discriminated union patterns can be simple named cases or they can have a value, or a tuple containing multiple values. If there is a value, you must specify an identifier for the value. In the case of a tuple, you must supply a tuple pattern with an identifier for each element of the tuple or an identifier with a field name for one or more named union fields. See the code examples in this section for examples.

The `option` type is a discriminated union that has two cases, `Some` and `None`. One case (`Some`) has a value, but the other (`None`) is just a named case. Therefore, `Some` needs to have a variable for the value associated with the `Some` case, but `None` must appear by itself. In the following code, the variable `var1` is given the value that is obtained by matching to the `Some` case.

```

let printOption (data : int option) =
    match data with
    | Some var1 -> printfn "%d" var1
    | None -> ()

```

In the following example, the `PersonName` discriminated union contains a mixture of strings and characters that represent possible forms of names. The cases of the discriminated union are `FirstOnly`, `LastOnly`, and `FirstLast`.

```

type PersonName =
| FirstOnly of string
| LastOnly of string
| FirstLast of string * string

let constructQuery personName =
    match personName with
    | FirstOnly(firstName) -> printf "May I call you %s?" firstName
    | LastOnly(lastName) -> printf "Are you Mr. or Ms. %s?" lastName
    | FirstLast(firstName, lastName) -> printf "Are you %s %s?" firstName lastName

```

For discriminated unions that have named fields, you use the equals sign (=) to extract the value of a named field. For example, consider a discriminated union with a declaration like the following.

```
type Shape =
| Rectangle of height : float * width : float
| Circle of radius : float
```

You can use the named fields in a pattern matching expression as follows.

```
let matchShape shape =
match shape with
| Rectangle(height = h) -> printfn "Rectangle with length %f" h
| Circle(r) -> printfn "Circle with radius %f" r
```

The use of the named field is optional, so in the previous example, both `Circle(r)` and `Circle(radius = r)` have the same effect.

When you specify multiple fields, use the semicolon (;) as a separator.

```
match shape with
| Rectangle(height = h; width = w) -> printfn "Rectangle with height %f and width %f" h w
| _ -> ()
```

Active patterns enable you to define more complex custom pattern matching. For more information about active patterns, see [Active Patterns](#).

The case in which the identifier is an exception is used in pattern matching in the context of exception handlers. For information about pattern matching in exception handling, see [Exceptions: The `try...with` Expression](#).

Variable Patterns

The variable pattern assigns the value being matched to a variable name, which is then available for use in the execution expression to the right of the `->` symbol. A variable pattern alone matches any input, but variable patterns often appear within other patterns, therefore enabling more complex structures such as tuples and arrays to be decomposed into variables.

The following example demonstrates a variable pattern within a tuple pattern.

```
let function1 x =
match x with
| (var1, var2) when var1 > var2 -> printfn "%d is greater than %d" var1 var2
| (var1, var2) when var1 < var2 -> printfn "%d is less than %d" var1 var2
| (var1, var2) -> printfn "%d equals %d" var1 var2

function1 (1,2)
function1 (2, 1)
function1 (0, 0)
```

as Pattern

The `as` pattern is a pattern that has an `as` clause appended to it. The `as` clause binds the matched value to a name that can be used in the execution expression of a `match` expression, or, in the case where this pattern is used in a `let` binding, the name is added as a binding to the local scope.

The following example uses an `as` pattern.

```
let (var1, var2) as tuple1 = (1, 2)
printfn "%d %d %A" var1 var2 tuple1
```

OR Pattern

The OR pattern is used when input data can match multiple patterns, and you want to execute the same code as a result. The types of both sides of the OR pattern must be compatible.

The following example demonstrates the OR pattern.

```
let detectZeroOR point =
    match point with
    | (0, 0) | (0, _) | (_, 0) -> printfn "Zero found."
    | _ -> printfn "Both nonzero."
detectZeroOR (0, 0)
detectZeroOR (1, 0)
detectZeroOR (0, 10)
detectZeroOR (10, 15)
```

AND Pattern

The AND pattern requires that the input match two patterns. The types of both sides of the AND pattern must be compatible.

The following example is like `detectZeroTuple` shown in the [Tuple Pattern](#) section later in this topic, but here both `var1` and `var2` are obtained as values by using the AND pattern.

```
let detectZeroAND point =
    match point with
    | (0, 0) -> printfn "Both values zero."
    | (var1, var2) & (0, _) -> printfn "First value is 0 in (%d, %d)" var1 var2
    | (var1, var2) & (_, 0) -> printfn "Second value is 0 in (%d, %d)" var1 var2
    | _ -> printfn "Both nonzero."
detectZeroAND (0, 0)
detectZeroAND (1, 0)
detectZeroAND (0, 10)
detectZeroAND (10, 15)
```

Cons Pattern

The cons pattern is used to decompose a list into the first element, the *head*, and a list that contains the remaining elements, the *tail*.

```
let list1 = [ 1; 2; 3; 4 ]

// This example uses a cons pattern and a list pattern.
let rec printList l =
    match l with
    | head :: tail -> printf "%d " head; printList tail
    | [] -> printfn ""

printList list1
```

List Pattern

The list pattern enables lists to be decomposed into a number of elements. The list pattern itself can match only lists of a specific number of elements.

```
// This example uses a list pattern.
let listLength list =
    match list with
    | [] -> 0
    | [ _ ] -> 1
    | [ _; _ ] -> 2
    | [ _; _; _ ] -> 3
    | _ -> List.length list

printfn "%d" (listLength [ 1 ])
printfn "%d" (listLength [ 1; 1 ])
printfn "%d" (listLength [ 1; 1; 1; ])
printfn "%d" (listLength [ ] )
```

Array Pattern

The array pattern resembles the list pattern and can be used to decompose arrays of a specific length.

```
// This example uses array patterns.
let vectorLength vec =
    match vec with
    | [| var1 |] -> var1
    | [| var1; var2 |] -> sqrt (var1*var1 + var2*var2)
    | [| var1; var2; var3 |] -> sqrt (var1*var1 + var2*var2 + var3*var3)
    | _ -> failwith "vectorLength called with an unsupported array size of %d." (vec.Length)

printfn "%f" (vectorLength [| 1. |])
printfn "%f" (vectorLength [| 1.; 1. |])
printfn "%f" (vectorLength [| 1.; 1.; 1.; |])
printfn "%f" (vectorLength [| |] )
```

Parenthesized Pattern

Parentheses can be grouped around patterns to achieve the desired associativity. In the following example, parentheses are used to control associativity between an AND pattern and a cons pattern.

```
let countValues list value =
    let rec checkList list acc =
        match list with
        | (elem1 & head) :: tail when elem1 = value -> checkList tail (acc + 1)
        | head :: tail -> checkList tail acc
        | [] -> acc
    checkList list 0

let result = countValues [ for x in -10..10 -> x*x - 4 ] 0
printfn "%d" result
```

Tuple Pattern

The tuple pattern matches input in tuple form and enables the tuple to be decomposed into its constituent elements by using pattern matching variables for each position in the tuple.

The following example demonstrates the tuple pattern and also uses literal patterns, variable patterns, and the wildcard pattern.

```

let detectZeroTuple point =
    match point with
    | (0, 0) -> printfn "Both values zero."
    | (0, var2) -> printfn "First value is 0 in (0, %d)" var2
    | (var1, 0) -> printfn "Second value is 0 in (%d, 0)" var1
    | _ -> printfn "Both nonzero."
detectZeroTuple (0, 0)
detectZeroTuple (1, 0)
detectZeroTuple (0, 10)
detectZeroTuple (10, 15)

```

Record Pattern

The record pattern is used to decompose records to extract the values of fields. The pattern does not have to reference all fields of the record; any omitted fields just do not participate in matching and are not extracted.

```

// This example uses a record pattern.

type MyRecord = { Name: string; ID: int }

let IsMatchByName record1 (name: string) =
    match record1 with
    | { MyRecord.Name = nameFound; MyRecord.ID = _ } when nameFound = name -> true
    | _ -> false

let recordX = { Name = "Parker"; ID = 10 }
let isMatched1 = IsMatchByName recordX "Parker"
let isMatched2 = IsMatchByName recordX "Hartono"

```

Wildcard Pattern

The wildcard pattern is represented by the underscore (`_`) character and matches any input, just like the variable pattern, except that the input is discarded instead of assigned to a variable. The wildcard pattern is often used within other patterns as a placeholder for values that are not needed in the expression to the right of the `->` symbol. The wildcard pattern is also frequently used at the end of a list of patterns to match any unmatched input. The wildcard pattern is demonstrated in many code examples in this topic. See the preceding code for one example.

Patterns That Have Type Annotations

Patterns can have type annotations. These behave like other type annotations and guide inference like other type annotations. Parentheses are required around type annotations in patterns. The following code shows a pattern that has a type annotation.

```

let detect1 x =
    match x with
    | 1 -> printfn "Found a 1!"
    | (var1 : int) -> printfn "%d" var1
detect1 0
detect1 1

```

Type Test Pattern

The type test pattern is used to match the input against a type. If the input type is a match to (or a derived type of) the type specified in the pattern, the match succeeds.

The following example demonstrates the type test pattern.

```
open System.Windows.Forms

let RegisterControl(control:Control) =
    match control with
    | :? Button as button -> button.Text <- "Registered."
    | :? CheckBox as checkbox -> checkbox.Text <- "Registered."
    | _ -> ()
```

Null Pattern

The null pattern matches the null value that can appear when you are working with types that allow a null value. Null patterns are frequently used when interoperating with .NET Framework code. For example, the return value of a .NET API might be the input to a `match` expression. You can control program flow based on whether the return value is null, and also on other characteristics of the returned value. You can use the null pattern to prevent null values from propagating to the rest of your program.

The following example uses the null pattern and the variable pattern.

```
let ReadFromFile (reader : System.IO.StreamReader) =
    match reader.ReadLine() with
    | null -> printfn "\n"; false
    | line -> printfn "%s" line; true

let fs = System.IO.File.Open("../..\Program.fs", System.IO.FileMode.Open)
let sr = new System.IO.StreamReader(fs)
while ReadFromFile(sr) = true do ()
sr.Close()
```

Active Patterns

3/25/2019 • 7 minutes to read • [Edit Online](#)

Active patterns enable you to define named partitions that subdivide input data, so that you can use these names in a pattern matching expression just as you would for a discriminated union. You can use active patterns to decompose data in a customized manner for each partition.

Syntax

```
// Complete active pattern definition.  
let (|identifier1|identifier2|...|) [ arguments ] = expression  
// Partial active pattern definition.  
let (|identifier|_|) [ arguments ] = expression
```

Remarks

In the previous syntax, the identifiers are names for partitions of the input data that is represented by *arguments*, or, in other words, names for subsets of the set of all values of the arguments. There can be up to seven partitions in an active pattern definition. The *expression* describes the form into which to decompose the data. You can use an active pattern definition to define the rules for determining which of the named partitions the values given as arguments belong to. The (| and |) symbols are referred to as *banana clips* and the function created by this type of let binding is called an *active recognizer*.

As an example, consider the following active pattern with an argument.

```
let (|Even|Odd|) input = if input % 2 = 0 then Even else Odd
```

You can use the active pattern in a pattern matching expression, as in the following example.

```
let TestNumber input =  
    match input with  
    | Even -> printfn "%d is even" input  
    | Odd -> printfn "%d is odd" input  
  
TestNumber 7  
TestNumber 11  
TestNumber 32
```

The output of this program is as follows:

```
7 is odd  
11 is odd  
32 is even
```

Another use of active patterns is to decompose data types in multiple ways, such as when the same underlying data has various possible representations. For example, a `Color` object could be decomposed into an RGB representation or an HSB representation.

```

open System.Drawing

let (|RGB|) (col : System.Drawing.Color) =
    ( col.R, col.G, col.B )

let (|HSB|) (col : System.Drawing.Color) =
    ( col.GetHue(), col.GetSaturation(), col.GetBrightness() )

let printRGB (col: System.Drawing.Color) =
    match col with
    | RGB(r, g, b) -> printfn " Red: %d Green: %d Blue: %d" r g b

let printHSB (col: System.Drawing.Color) =
    match col with
    | HSB(h, s, b) -> printfn " Hue: %f Saturation: %f Brightness: %f" h s b

let printAll col colorString =
    printfn "%s" colorString
    printRGB col
    printHSB col

printAll Color.Red "Red"
printAll Color.Black "Black"
printAll Color.White "White"
printAll Color.Gray "Gray"
printAll Color.BlanchedAlmond "BlanchedAlmond"

```

The output of the above program is as follows:

```

Red
Red: 255 Green: 0 Blue: 0
Hue: 360.000000 Saturation: 1.000000 Brightness: 0.500000
Black
Red: 0 Green: 0 Blue: 0
Hue: 0.000000 Saturation: 0.000000 Brightness: 0.000000
White
Red: 255 Green: 255 Blue: 255
Hue: 0.000000 Saturation: 0.000000 Brightness: 1.000000
Gray
Red: 128 Green: 128 Blue: 128
Hue: 0.000000 Saturation: 0.000000 Brightness: 0.501961
BlanchedAlmond
Red: 255 Green: 235 Blue: 205
Hue: 36.000000 Saturation: 1.000000 Brightness: 0.901961

```

In combination, these two ways of using active patterns enable you to partition and decompose data into just the appropriate form and perform the appropriate computations on the appropriate data in the form most convenient for the computation.

The resulting pattern matching expressions enable data to be written in a convenient way that is very readable, greatly simplifying potentially complex branching and data analysis code.

Partial Active Patterns

Sometimes, you need to partition only part of the input space. In that case, you write a set of partial patterns each of which match some inputs but fail to match other inputs. Active patterns that do not always produce a value are called *partial active patterns*; they have a return value that is an option type. To define a partial active pattern, you use a wildcard character (`_`) at the end of the list of patterns inside the banana clips. The following code illustrates the use of a partial active pattern.

```

let (|Integer|_|) (str: string) =
    let mutable intvalue = 0
    if System.Int32.TryParse(str, &intvalue) then Some(intvalue)
    else None

let (|Float|_|) (str: string) =
    let mutable floatvalue = 0.0
    if System.Double.TryParse(str, &floatvalue) then Some(floatvalue)
    else None

let parseNumeric str =
    match str with
    | Integer i -> printfn "%d : Integer" i
    | Float f -> printfn "%f : Floating point" f
    | _ -> printfn "%s : Not matched." str

parseNumeric "1.1"
parseNumeric "0"
parseNumeric "0.0"
parseNumeric "10"
parseNumeric "Something else"

```

The output of the previous example is as follows:

```

1.100000 : Floating point
0 : Integer
0.000000 : Floating point
10 : Integer
Something else : Not matched.

```

When using partial active patterns, sometimes the individual choices can be disjoint or mutually exclusive, but they need not be. In the following example, the pattern Square and the pattern Cube are not disjoint, because some numbers are both squares and cubes, such as 64. The following program uses the AND pattern to combine the Square and Cube patterns. It print out all integers up to 1000 that are both squares and cubes, as well as those which are only cubes.

```

let err = 1.e-10

let isNearlyIntegral (x:float) = abs (x - round(x)) < err

let (|Square|_|) (x : int) =
    if isNearlyIntegral (sqrt (float x)) then Some(x)
    else None

let (|Cube|_|) (x : int) =
    if isNearlyIntegral ((float x) ** ( 1.0 / 3.0)) then Some(x)
    else None

let examineNumber x =
    match x with
    | Cube x -> printfn "%d is a cube" x
    | _ -> ()
    match x with
    | Square x -> printfn "%d is a square" x
    | _ -> ()

let findSquareCubes x =
    match x with
    | Cube x & Square _ -> printfn "%d is a cube and a square" x
    | Cube x -> printfn "%d is a cube" x
    | _ -> ()

[ 1 .. 1000 ] |> List.iter (fun elem -> findSquareCubes elem)

```

The output is as follows:

```

1 is a cube and a square
8 is a cube
27 is a cube
64 is a cube and a square
125 is a cube
216 is a cube
343 is a cube
512 is a cube
729 is a cube and a square
1000 is a cube

```

Parameterized Active Patterns

Active patterns always take at least one argument for the item being matched, but they may take additional arguments as well, in which case the name *parameterized active pattern* applies. Additional arguments allow a general pattern to be specialized. For example, active patterns that use regular expressions to parse strings often include the regular expression as an extra parameter, as in the following code, which also uses the partial active pattern `Integer` defined in the previous code example. In this example, strings that use regular expressions for various date formats are given to customize the general `ParseRegex` active pattern. The `Integer` active pattern is used to convert the matched strings into integers that can be passed to the `DateTime` constructor.

```

open System.Text.RegularExpressions

// ParseRegex parses a regular expression and returns a list of the strings that match each group in
// the regular expression.
// List.tail is called to eliminate the first element in the list, which is the full matched expression,
// since only the matches for each group are wanted.
let (|ParseRegex|_|) regex str =
    let m = Regex(regex).Match(str)
    if m.Success
    then Some (List.tail [ for x in m.Groups -> x.Value ])
    else None

// Three different date formats are demonstrated here. The first matches two-
// digit dates and the second matches full dates. This code assumes that if a two-digit
// date is provided, it is an abbreviation, not a year in the first century.
let parseDate str =
    match str with
    | ParseRegex "(\d{1,2})/(\d{1,2})/(\d{1,2})$" [Integer m; Integer d; Integer y]
        -> new System.DateTime(y + 2000, m, d)
    | ParseRegex "(\d{1,2})/(\d{1,2})/(\d{3,4})" [Integer m; Integer d; Integer y]
        -> new System.DateTime(y, m, d)
    | ParseRegex "(\d{1,4})-(\d{1,2})-(\d{1,2})" [Integer y; Integer m; Integer d]
        -> new System.DateTime(y, m, d)
    | _ -> new System.DateTime()

let dt1 = parseDate "12/22/08"
let dt2 = parseDate "1/1/2009"
let dt3 = parseDate "2008-1-15"
let dt4 = parseDate "1995-12-28"

printfn "%s %s %s %s" (dt1.ToString()) (dt2.ToString()) (dt3.ToString()) (dt4.ToString())

```

The output of the previous code is as follows:

```
12/22/2008 12:00:00 AM 1/1/2009 12:00:00 AM 1/15/2008 12:00:00 AM 12/28/1995 12:00:00 AM
```

Active patterns are not restricted only to pattern matching expressions, you can also use them on let-bindings.

```

let (|Default|) onNone value =
    match value with
    | None -> onNone
    | Some e -> e

let greet (Default "random citizen" name) =
    printfn "Hello, %s!" name

greet None
greet (Some "George")

```

The output of the previous code is as follows:

```
Hello, random citizen!
Hello, George!
```

Loops: for...to Expression

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `for...to` expression is used to iterate in a loop over a range of values of a loop variable.

Syntax

```
for identifier = start [ to | downto ] finish do  
    body-expression
```

Remarks

The type of the identifier is inferred from the type of the *start* and *finish* expressions. Types for these expressions must be 32-bit integers.

Although technically an expression, `for...to` is more like a traditional statement in an imperative programming language. The return type for the *body-expression* must be `unit`. The following examples show various uses of the `for...to` expression.

```
// A simple for...to loop.  
let function1() =  
    for i = 1 to 10 do  
        printf "%d " i  
    printfn ""  
  
// A for...to loop that counts in reverse.  
let function2() =  
    for i = 10 downto 1 do  
        printf "%d " i  
    printfn ""  
  
function1()  
function2()  
  
// A for...to loop that uses functions as the start and finish expressions.  
let beginning x y = x - 2*y  
let ending x y = x + 2*y  
  
let function3 x y =  
    for i = (beginning x y) to (ending x y) do  
        printf "%d " i  
    printfn ""  
  
function3 10 4
```

The output of the previous code is as follows.

```
1 2 3 4 5 6 7 8 9 10  
10 9 8 7 6 5 4 3 2 1  
2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18
```

- F# Language Reference
- Loops: `for...in` Expression
- Loops: `while...do` Expression

Loops: for...in Expression

12/19/2018 • 3 minutes to read • [Edit Online](#)

This looping construct is used to iterate over the matches of a pattern in an enumerable collection such as a range expression, sequence, list, array, or other construct that supports enumeration.

Syntax

```
for pattern in enumerable-expression do  
    body-expression
```

Remarks

The `for...in` expression can be compared to the `for each` statement in other .NET languages because it is used to loop over the values in an enumerable collection. However, `for...in` also supports pattern matching over the collection instead of just iteration over the whole collection.

The enumerable expression can be specified as an enumerable collection or, by using the `..` operator, as a range on an integral type. Enumerable collections include lists, sequences, arrays, sets, maps, and so on. Any type that implements `System.Collections.IEnumerable` can be used.

When you express a range by using the `..` operator, you can use the following syntax.

start .. finish

You can also use a version that includes an increment called the *skip*, as in the following code.

start .. skip .. finish

When you use integral ranges and a simple counter variable as a pattern, the typical behavior is to increment the counter variable by 1 on each iteration, but if the range includes a skip value, the counter is incremented by the skip value instead.

Values matched in the pattern can also be used in the body expression.

The following code examples illustrate the use of the `for...in` expression.

```
// Looping over a list.  
let list1 = [ 1; 5; 100; 450; 788 ]  
for i in list1 do  
    printfn "%d" i
```

The output is as follows.

```
1  
5  
100  
450  
788
```

The following example shows how to loop over a sequence, and how to use a tuple pattern instead of a simple variable.

```
let seq1 = seq { for i in 1 .. 10 -> (i, i*i) }
for (a, asqr) in seq1 do
    printfn "%d squared is %d" a asqr
```

The output is as follows.

```
1 squared is 1
2 squared is 4
3 squared is 9
4 squared is 16
5 squared is 25
6 squared is 36
7 squared is 49
8 squared is 64
9 squared is 81
10 squared is 100
```

The following example shows how to loop over a simple integer range.

```
let function1() =
    for i in 1 .. 10 do
        printf "%d " i
    printfn ""
function1()
```

The output of `function1` is as follows.

```
1 2 3 4 5 6 7 8 9 10
```

The following example shows how to loop over a range with a skip of 2, which includes every other element of the range.

```
let function2() =
    for i in 1 .. 2 .. 10 do
        printf "%d " i
    printfn ""
function2()
```

The output of `function2` is as follows.

```
1 3 5 7 9
```

The following example shows how to use a character range.

```
let function3() =
    for c in 'a' .. 'z' do
        printf "%c " c
    printfn ""
function3()
```

The output of `function3` is as follows.

```
a b c d e f g h i j k l m n o p q r s t u v w x y z
```

The following example shows how to use a negative skip value for a reverse iteration.

```
let function4() =
    for i in 10 .. -1 .. 1 do
        printf "%d " i
    printfn "... Lift off!"
function4()
```

The output of `function4` is as follows.

```
10 9 8 7 6 5 4 3 2 1 ... Lift off!
```

The beginning and ending of the range can also be expressions, such as functions, as in the following code.

```
let beginning x y = x - 2*y
let ending x y = x + 2*y

let function5 x y =
    for i in (beginning x y) .. (ending x y) do
        printf "%d " i
    printfn ""

function5 10 4
```

The output of `function5` with this input is as follows.

```
2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18
```

The next example shows the use of a wildcard character (`_`) when the element is not needed in the loop.

```
let mutable count = 0
for _ in list1 do
    count <- count + 1
printfn "Number of elements in list1: %d" count
```

The output is as follows.

```
Number of elements in list1: 5
```

Note You can use `for...in` in sequence expressions and other computation expressions, in which case a customized version of the `for...in` expression is used. For more information, see [Sequences, Asynchronous Workflows](#), and [Computation Expressions](#).

Loops: while...do Expression

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `while...do` expression is used to perform iterative execution (looping) while a specified test condition is true.

Syntax

```
while test-expression do  
    body-expression
```

Remarks

The *test-expression* is evaluated; if it is `true`, the *body-expression* is executed and the test expression is evaluated again. The *body-expression* must have type `unit`. If the test expression is `false`, the iteration ends.

The following example illustrates the use of the `while...do` expression.

```
open System  
  
let lookForValue value maxValue =  
    let mutable continueLooping = true  
    let randomNumberGenerator = new Random()  
    while continueLooping do  
        // Generate a random number between 1 and maxValue.  
        let rand = randomNumberGenerator.Next(maxValue)  
        printf "%d" rand  
        if rand = value then  
            printfn "\nFound a %d!" value  
            continueLooping <- false  
  
lookForValue 10 20
```

The output of the previous code is a stream of random numbers between 1 and 20, the last of which is 10.

```
13 19 8 18 16 2 10  
Found a 10!
```

NOTE

You can use `while...do` in sequence expressions and other computation expressions, in which case a customized version of the `while...do` expression is used. For more information, see [Sequences](#), [Asynchronous Workflows](#), and [Computation Expressions](#).

Assertions

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `assert` expression is a debugging feature that you can use to test an expression. Upon failure in Debug mode, an assertion generates a system error dialog box.

Syntax

```
assert condition
```

Remarks

The `assert` expression has type `bool -> unit`.

In the previous syntax, *condition* represents a Boolean expression that is to be tested. If the expression evaluates to `true`, execution continues unaffected. If it evaluates to `false`, a system error dialog box is generated. The error dialog box has a caption that contains the string **Assertion Failed**. The dialog box contains a stack trace that indicates where the assertion failure occurred.

Assertion checking is enabled only when you compile in Debug mode; that is, if the constant `DEBUG` is defined. In the project system, by default, the `DEBUG` constant is defined in the Debug configuration but not in the Release configuration.

The assertion failure error cannot be caught by using F# exception handling.

NOTE

The `assert` function resolves to [Debug.Assert](#).

Example

The following code example illustrates the use of the `assert` expression.

```
let subtractUnsigned (x : uint32) (y : uint32) =
    assert (x > y)
    let z = x - y
    z
// This code does not generate an assertion failure.
let result1 = subtractUnsigned 2u 1u
// This code generates an assertion failure.
let result2 = subtractUnsigned 1u 2u
```

Exception Handling

12/19/2018 • 2 minutes to read • [Edit Online](#)

This section contains information about exception handling support in the F# language.

Exception Handling Basics

Exception handling is the standard way of handling error conditions in the .NET Framework. Thus, any .NET language must support this mechanism, including F#. An *exception* is an object that encapsulates information about an error. When errors occur, exceptions are raised and regular execution stops. Instead, the runtime searches for an appropriate handler for the exception. The search starts in the current function, and proceeds up the stack through the layers of callers until a matching handler is found. Then the handler is executed.

In addition, as the stack is unwound, the runtime executes any code in `finally` blocks, to guarantee that objects are cleaned up correctly during the unwinding process.

Related Topics

TITLE	DESCRIPTION
Exception Types	Describes how to declare an exception type.
Exceptions: The <code>try...with</code> Expression	Describes the language construct that supports exception handling.
Exceptions: The <code>try...finally</code> Expression	Describes the language construct that enables you to execute clean-up code as the stack unwinds when an exception is thrown.
Exceptions: the <code>raise</code> Function	Describes how to throw an exception object.
Exceptions: The <code>failwith</code> Function	Describes how to generate a general F# exception.
Exceptions: The <code>invalidArg</code> Function	Describes how to generate an invalid argument exception.

Exception Types

12/19/2018 • 2 minutes to read • [Edit Online](#)

There are two categories of exceptions in F#: .NET exception types and F# exception types. This topic describes how to define and use F# exception types.

Syntax

```
exception exception-type of argument-type
```

Remarks

In the previous syntax, *exception-type* is the name of a new F# exception type, and *argument-type* represents the type of an argument that can be supplied when you raise an exception of this type. You can specify multiple arguments by using a tuple type for *argument-type*.

A typical definition for an F# exception resembles the following.

```
exception MyError of string
```

You can generate an exception of this type by using the `raise` function, as follows.

```
raise (MyError("Error message"))
```

You can use an F# exception type directly in the filters in a `try...with` expression, as shown in the following example.

```
exception Error1 of string
// Using a tuple type as the argument type.
exception Error2 of string * int

let function1 x y =
    try
        if x = y then raise (Error1("x"))
        else raise (Error2("x", 10))
    with
        | Error1(str) -> printfn "Error1 %s" str
        | Error2(str, i) -> printfn "Error2 %s %d" str i

function1 10 10
function1 9 2
```

The exception type that you define with the `exception` keyword in F# is a new type that inherits from `System.Exception`.

Exceptions: The try...with Expression

12/19/2018 • 3 minutes to read • [Edit Online](#)

This topic describes the `try...with` expression, the expression that is used for exception handling in the F# language.

Syntax

```
try
    expression1
with
| pattern1 -> expression2
| pattern2 -> expression3
...
...
```

Remarks

The `try...with` expression is used to handle exceptions in F#. It is similar to the `try...catch` statement in C#. In the preceding syntax, the code in *expression1* might generate an exception. The `try...with` expression returns a value. If no exception is thrown, the whole expression returns the value of *expression1*. If an exception is thrown, each *pattern* is compared in turn with the exception, and for the first matching pattern, the corresponding *expression*, known as the *exception handler*, for that branch is executed, and the overall expression returns the value of the expression in that exception handler. If no pattern matches, the exception propagates up the call stack until a matching handler is found. The types of the values returned from each expression in the exception handlers must match the type returned from the expression in the `try` block.

Frequently, the fact that an error occurred also means that there is no valid value that can be returned from the expressions in each exception handler. A frequent pattern is to have the type of the expression be an option type. The following code example illustrates this pattern.

```
let divide1 x y =
    try
        Some (x / y)
    with
    | :? System.DivideByZeroException -> printfn "Division by zero!"; None

let result1 = divide1 100 0
```

Exceptions can be .NET exceptions, or they can be F# exceptions. You can define F# exceptions by using the `exception` keyword.

You can use a variety of patterns to filter on the exception type and other conditions; the options are summarized in the following table.

PATTERN	DESCRIPTION
<code>:? exception-type</code>	Matches the specified .NET exception type.
<code>:? exception-type as identifier</code>	Matches the specified .NET exception type, but gives the exception a named value.

PATTERN	DESCRIPTION
<code>exception-name(arguments)</code>	Matches an F# exception type and binds the arguments.
<code>identifier</code>	Matches any exception and binds the name to the exception object. Equivalent to <code>:? System.Exception as identifier</code>
<code>identifier when condition</code>	Matches any exception if the condition is true.

Examples

The following code examples illustrate the use of the various exception handler patterns.

```
// This example shows the use of the as keyword to assign a name to a
// .NET exception.
let divide2 x y =
    try
        Some( x / y )
    with
        | :? System.DivideByZeroException as ex -> printfn "Exception! %s" (ex.Message); None

// This version shows the use of a condition to branch to multiple paths
// with the same exception.
let divide3 x y flag =
    try
        x / y
    with
        | ex when flag -> printfn "TRUE: %s" (ex.ToString()); 0
        | ex when not flag -> printfn "FALSE: %s" (ex.ToString()); 1

let result2 = divide3 100 0 true

// This version shows the use of F# exceptions.
exception Error1 of string
exception Error2 of string * int

let function1 x y =
    try
        if x = y then raise (Error1("x"))
        else raise (Error2("x", 10))
    with
        | Error1(str) -> printfn "Error1 %s" str
        | Error2(str, i) -> printfn "Error2 %s %d" str i

function1 10 10
function1 9 2
```

NOTE

The `try...with` construct is a separate expression from the `try...finally` expression. Therefore, if your code requires both a `with` block and a `finally` block, you will have to nest the two expressions.

NOTE

You can use `try...with` in asynchronous workflows and other computation expressions, in which case a customized version of the `try...with` expression is used. For more information, see [Asynchronous Workflows](#), and [Computation Expressions](#).

See also

- [Exception Handling](#)
- [Exception Types](#)
- [Exceptions: The `try...finally` Expression](#)

Exceptions: The try...finally Expression

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `try...finally` expression enables you to execute clean-up code even if a block of code throws an exception.

Syntax

```
try
    expression1
finally
    expression2
```

Remarks

The `try...finally` expression can be used to execute the code in *expression2* in the preceding syntax regardless of whether an exception is generated during the execution of *expression1*.

The type of *expression2* does not contribute to the value of the whole expression; the type returned when an exception does not occur is the last value in *expression1*. When an exception does occur, no value is returned and the flow of control transfers to the next matching exception handler up the call stack. If no exception handler is found, the program terminates. Before the code in a matching handler is executed or the program terminates, the code in the `finally` branch is executed.

The following code demonstrates the use of the `try...finally` expression.

```
let divide x y =
    let stream : System.IO.FileStream = System.IO.File.Create("test.txt")
    let writer : System.IO.StreamWriter = new System.IO.StreamWriter(stream)
    try
        writer.WriteLine("test1");
        Some( x / y )
    finally
        writer.Flush()
        printfn "Closing stream"
        stream.Close()

let result =
    try
        divide 100 0
    with
        | :? System.DivideByZeroException -> printfn "Exception handled."; None
```

The output to the console is as follows.

```
Closing stream
Exception handled.
```

As you can see from the output, the stream was closed before the outer exception was handled, and the file `test.txt` contains the text `test1`, which indicates that the buffers were flushed and written to disk even though the exception transferred control to the outer exception handler.

Note that the `try...with` construct is a separate construct from the `try...finally` construct. Therefore, if your

code requires both a `with` block and a `finally` block, you have to nest the two constructs, as in the following code example.

```
exception InnerError of string
exception OuterError of string

let function1 x y =
    try
        try
            if x = y then raise (InnerError("inner"))
            else raise (OuterError("outer"))
        with
            | InnerError(str) -> printfn "Error1 %s" str
        finally
            printfn "Always print this."

let function2 x y =
    try
        function1 x y
    with
        | OuterError(str) -> printfn "Error2 %s" str

function2 100 100
function2 100 10
```

In the context of computation expressions, including sequence expressions and asynchronous workflows, **try...finally** expressions can have a custom implementation. For more information, see [Computation Expressions](#).

See also

- [Exception Handling](#)
- [Exceptions: The `try...with` Expression](#)

Exceptions: the raise Function

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `raise` function is used to indicate that an error or exceptional condition has occurred. Information about the error is captured in an exception object.

Syntax

```
raise (expression)
```

Remarks

The `raise` function generates an exception object and initiates a stack unwinding process. The stack unwinding process is managed by the common language runtime (CLR), so the behavior of this process is the same as it is in any other .NET language. The stack unwinding process is a search for an exception handler that matches the generated exception. The search starts in the current `try...with` expression, if there is one. Each pattern in the `with` block is checked, in order. When a matching exception handler is found, the exception is considered handled; otherwise, the stack is unwound and `with` blocks up the call chain are checked until a matching handler is found. Any `finally` blocks that are encountered in the call chain are also executed in sequence as the stack unwinds.

The `raise` function is the equivalent of `throw` in C# or C++. Use `reraise` in a catch handler to propagate the same exception up the call chain.

The following code examples illustrate the use of the `raise` function to generate an exception.

```
exception InnerError of string
exception OuterError of string

let function1 x y =
    try
        try
            if x = y then raise (InnerError("inner"))
            else raise (OuterError("outer"))
        with
            | InnerError(str) -> printfn "Error1 %s" str
        finally
            printfn "Always print this."

let function2 x y =
    try
        function1 x y
    with
        | OuterError(str) -> printfn "Error2 %s" str

function2 100 100
function2 100 10
```

The `raise` function can also be used to raise .NET exceptions, as shown in the following example.

```
let divide x y =
  if (y = 0) then raise (System.ArgumentException("Divisor cannot be zero!"))
  else
    x / y
```

Exceptions: The failwith Function

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `failwith` function generates an F# exception.

Syntax

```
failwith error-message-string
```

Remarks

The *error-message-string* in the previous syntax is a literal string or a value of type `string`. It becomes the `Message` property of the exception.

The exception that is generated by `failwith` is a `System.Exception` exception, which is a reference that has the name `Failure` in F# code. The following code illustrates the use of `failwith` to throw an exception.

```
let divideFailwith x y =
    if (y = 0) then failwith "Divisor cannot be zero."
    else
        x / y

let testDivideFailwith x y =
    try
        divideFailwith x y
    with
        | Failure(msg) -> printfn "%s" msg; 0

let result1 = testDivideFailwith 100 0
```

Exceptions: The invalidArg Function

12/19/2018 • 2 minutes to read • [Edit Online](#)

The `invalidArg` function generates an argument exception.

Syntax

```
invalidArg parameter-name error-message-string
```

Remarks

The `parameter-name` in the previous syntax is a string with the name of the parameter whose argument was invalid. The `error-message-string` is a literal string or a value of type `string`. It becomes the `Message` property of the exception object.

The exception generated by `invalidArg` is a `System.ArgumentException` exception. The following code illustrates the use of `invalidArg` to throw an exception.

```
let months = [| "January"; "February"; "March"; "April";
              "May"; "June"; "July"; "August"; "September";
              "October"; "November"; "December" |]

let lookupMonth month =
    if (month > 12 || month < 1)
        then invalidArg "month" (sprintf "Value passed in was %d." month)
    months.[month - 1]

printfn "%s" (lookupMonth 12)
printfn "%s" (lookupMonth 1)
printfn "%s" (lookupMonth 13)
```

The output is the following, followed by a stack trace (not shown).

```
December
January
System.ArgumentException: Month parameter out of range.
```

Attributes

3/26/2019 • 3 minutes to read • [Edit Online](#)

Attributes enable metadata to be applied to a programming construct.

Syntax

```
[<target:attribute-name(arguments)>]
```

Remarks

In the previous syntax, the *target* is optional and, if present, specifies the kind of program entity that the attribute applies to. Valid values for *target* are shown in the table that appears later in this document.

The *attribute-name* refers to the name (possibly qualified with namespaces) of a valid attribute type, with or without the suffix `Attribute` that is usually used in attribute type names. For example, the type `ObsoleteAttribute` can be shortened to just `obsolete` in this context.

The *arguments* are the arguments to the constructor for the attribute type. If an attribute has a default constructor, the argument list and parentheses can be omitted. Attributes support both positional arguments and named arguments. *Positional arguments* are arguments that are used in the order in which they appear. Named arguments can be used if the attribute has public properties. You can set these by using the following syntax in the argument list.

```
*property-name* = *property-value*
```

Such property initializations can be in any order, but they must follow any positional arguments. Following is an example of an attribute that uses positional arguments and property initializations.

```
open System.Runtime.InteropServices

[<DllImport("kernel32", SetLastError=true)>]
extern bool CloseHandle(nativeint handle)
```

In this example, the attribute is `DllImportAttribute`, here used in shortened form. The first argument is a positional parameter and the second is a property.

Attributes are a .NET programming construct that enables an object known as an *attribute* to be associated with a type or other program element. The program element to which an attribute is applied is known as the *attribute target*. The attribute usually contains metadata about its target. In this context, metadata could be any data about the type other than its fields and members.

Attributes in F# can be applied to the following programming constructs: functions, methods, assemblies, modules, types (classes, records, structures, interfaces, delegates, enumerations, unions, and so on), constructors, properties, fields, parameters, type parameters, and return values. Attributes are not allowed on `let` bindings inside classes, expressions, or workflow expressions.

Typically, the attribute declaration appears directly before the declaration of the attribute target. Multiple attribute declarations can be used together, as follows.

```
[<Owner("Jason Carlson")>]
[<Company("Microsoft")>]
type SomeType1 =
```

You can query attributes at run time by using .NET reflection.

You can declare multiple attributes individually, as in the previous code example, or you can declare them in one set of brackets if you use a semicolon to separate the individual attributes and constructors, as shown here.

```
[<Owner("Darren Parker"); Company("Microsoft")>]
type SomeType2 =
```

Typically encountered attributes include the `obsolete` attribute, attributes for security considerations, attributes for COM support, attributes that relate to ownership of code, and attributes indicating whether a type can be serialized. The following example demonstrates the use of the `Obsolete` attribute.

```
open System

[<Obsolete("Do not use. Use newFunction instead.")>]
let obsoleteFunction x y =
    x + y

let newFunction x y =
    x + 2 * y

// The use of the obsolete function produces a warning.
let result1 = obsoleteFunction 10 100
let result2 = newFunction 10 100
```

For the attribute targets `assembly` and `module`, you apply the attributes to a top-level `do` binding in your assembly. You can include the word `assembly` or `module` in the attribute declaration, as follows.

```
open System.Reflection
[<assembly:AssemblyVersionAttribute("1.0.0.0")>]
do
    printfn "Executing..."
```

If you omit the attribute target for an attribute applied to a `do` binding, the F# compiler attempts to determine the attribute target that makes sense for that attribute. Many attribute classes have an attribute of type `System.AttributeUsageAttribute` that includes information about the possible targets supported for that attribute. If the `System.AttributeUsageAttribute` indicates that the attribute supports functions as targets, the attribute is taken to apply to the main entry point of the program. If the `System.AttributeUsageAttribute` indicates that the attribute supports assemblies as targets, the compiler takes the attribute to apply to the assembly. Most attributes do not apply to both functions and assemblies, but in cases where they do, the attribute is taken to apply to the program's main function. If the attribute target is specified explicitly, the attribute is applied to the specified target.

Although you do not usually need to specify the attribute target explicitly, valid values for `target` in an attribute are shown in the following table, along with examples of usage.

ATTRIBUTE TARGET	EXAMPLE
------------------	---------

assembly

```
[<assembly:  
AssemblyVersionAttribute("1.0.0.0")>]
```

return

```
let function1 x : [<return: Obsolete>] int = x +  
1
```

field

```
[<field: DefaultValue>] val mutable x: int
```

property

```
[<property: Obsolete>] this.MyProperty = x
```

param

```
member this.MyMethod([<param: Out>] x :  
ref<int>) = x := 10
```

type

```
[<type: StructLayout(Sequential)>]  
type MyStruct =  
struct  
x : byte  
y : int  
end
```

Resource Management: The use Keyword

12/19/2018 • 3 minutes to read • [Edit Online](#)

This topic describes the keyword `use` and the `using` function, which can control the initialization and release of resources.

Resources

The term *resource* is used in more than one way. Yes, resources can be data that an application uses, such as strings, graphics, and the like, but in this context, *resources* refers to software or operating system resources, such as graphics device contexts, file handles, network and database connections, concurrency objects such as wait handles, and so on. The use of these resources by applications involves the acquisition of the resource from the operating system or other resource provider, followed by the later release of the resource to the pool so that it can be provided to another application. Problems occur when applications do not release resources back to the common pool.

Managing Resources

To efficiently and responsibly manage resources in an application, you must release resources promptly and in a predictable manner. The .NET Framework helps you do this by providing the `System.IDisposable` interface. A type that implements `System.IDisposable` has the `System.IDisposable.Dispose` method, which correctly frees resources. Well-written applications guarantee that `System.IDisposable.Dispose` is called promptly when any object that holds a limited resource is no longer needed. Fortunately, most .NET languages provide support to make this easier, and F# is no exception. There are two useful language constructs that support the dispose pattern: the `use` binding and the `using` function.

use Binding

The `use` keyword has a form that resembles that of the `let` binding:

`use value = expression`

It provides the same functionality as a `let` binding but adds a call to `Dispose` on the value when the value goes out of scope. Note that the compiler inserts a null check on the value, so that if the value is `null`, the call to `Dispose` is not attempted.

The following example shows how to close a file automatically by using the `use` keyword.

```
open System.IO

let writetofile filename obj =
    use file1 = File.CreateText(filename)
    file1.WriteLine("{0}", obj.ToString() )
    // file1.Dispose() is called implicitly here.

writetofile "abc.txt" "Humpty Dumpty sat on a wall."
```

NOTE

You can use `use` in computation expressions, in which case a customized version of the `use` expression is used. For more information, see [Sequences](#), [Asynchronous Workflows](#), and [Computation Expressions](#).

using Function

The `using` function has the following form:

```
using (expression1) function-or-lambda
```

In a `using` expression, *expression1* creates the object that must be disposed. The result of *expression1* (the object that must be disposed) becomes an argument, *value*, to *function-or-lambda*, which is either a function that expects a single remaining argument of a type that matches the value produced by *expression1*, or a lambda expression that expects an argument of that type. At the end of the execution of the function, the runtime calls `Dispose` and frees the resources (unless the value is `null`, in which case the call to `Dispose` is not attempted).

The following example demonstrates the `using` expression with a lambda expression.

```
open System.IO

let writetofile2 filename obj =
    using (System.IO.File.CreateText(filename)) ( fun file1 ->
        file1.WriteLine("{0}", obj.ToString() )
    )

writetofile2 "abc2.txt" "The quick sly fox jumps over the lazy brown dog."
```

The next example shows the `using` expression with a function.

```
let printToFile (file1 : System.IO.StreamWriter) =
    file1.WriteLine("Test output");

using (System.IO.File.CreateText("test.txt")) printToFile
```

Note that the function could be a function that has some arguments applied already. The following code example demonstrates this. It creates a file that contains the string `xyz`.

```
let printToFile2 obj (file1 : System.IO.StreamWriter) =
    file1.WriteLine(obj.ToString())

using (System.IO.File.CreateText("test.txt")) (printToFile2 "XYZ")
```

The `using` function and the `use` binding are nearly equivalent ways to accomplish the same thing. The `using` keyword provides more control over when `Dispose` is called. When you use `using`, `Dispose` is called at the end of the function or lambda expression; when you use the `use` keyword, `Dispose` is called at the end of the containing code block. In general, you should prefer to use `use` instead of the `using` function.

Namespaces

12/19/2018 • 4 minutes to read • [Edit Online](#)

A namespace lets you organize code into areas of related functionality by enabling you to attach a name to a grouping of F# program elements. Namespaces are typically top-level elements in F# files.

Syntax

```
namespace [rec] [parent-namespaces.]identifier
```

Remarks

If you want to put code in a namespace, the first declaration in the file must declare the namespace. The contents of the entire file then become part of the namespace, provided no other namespaces declaration exists further in the file. If that is the case, then all code up until the next namespace declaration is considered to be within the first namespace.

Namespaces cannot directly contain values and functions. Instead, values and functions must be included in modules, and modules are included in namespaces. Namespaces can contain types, modules.

XML doc comments can be declared above a namespace, but they're ignored. Compiler directives can also be declared above a namespace.

Namespaces can be declared explicitly with the `namespace` keyword, or implicitly when declaring a module. To declare a namespace explicitly, use the `namespace` keyword followed by the namespace name. The following example shows a code file that declares a namespace `Widgets` with a type and a module included in that namespace.

```
namespace Widgets

type MyWidget1 =
    member this.WidgetName = "Widget1"

module WidgetsModule =
    let widgetName = "Widget2"
```

If the entire contents of the file are in one module, you can also declare namespaces implicitly by using the `module` keyword and providing the new namespace name in the fully qualified module name. The following example shows a code file that declares a namespace `Widgets` and a module `WidgetsModule`, which contains a function.

```
module Widgets.WidgetModule

let widgetFunction x y =
    printfn "%A %A" x y
```

The following code is equivalent to the preceding code, but the module is a local module declaration. In that case, the namespace must appear on its own line.

```
namespace Widgets

module WidgetModule =
    let widgetFunction x y =
        printfn "%A %A" x y
```

If more than one module is required in the same file in one or more namespaces, you must use local module declarations. When you use local module declarations, you cannot use the qualified namespace in the module declarations. The following code shows a file that has a namespace declaration and two local module declarations. In this case, the modules are contained directly in the namespace; there is no implicitly created module that has the same name as the file. Any other code in the file, such as a `do` binding, is in the namespace but not in the inner modules, so you need to qualify the module member `widgetFunction` by using the module name.

```
namespace Widgets

module WidgetModule1 =
    let widgetFunction x y =
        printfn "Module1 %A %A" x y
module WidgetModule2 =
    let widgetFunction x y =
        printfn "Module2 %A %A" x y

module useWidgets =
    do
        WidgetModule1.widgetFunction 10 20
        WidgetModule2.widgetFunction 5 6
```

The output of this example is as follows.

```
Module1 10 20
Module2 5 6
```

For more information, see [Modules](#).

Nested Namespaces

When you create a nested namespace, you must fully qualify it. Otherwise, you create a new top-level namespace. Indentation is ignored in namespace declarations.

The following example shows how to declare a nested namespace.

```
namespace Outer

    // Full name: Outer.MyClass
    type MyClass() =
        member this.X(x) = x + 1

    // Fully qualify any nested namespaces.
    namespace Outer.Inner

        // Full name: Outer.Inner.MyClass
        type MyClass() =
            member this.Prop1 = "X"
```

Namespaces in Files and Assemblies

Namespaces can span multiple files in a single project or compilation. The term *namespace fragment* describes the part of a namespace that is included in one file. Namespaces can also span multiple assemblies. For example, the `System` namespace includes the whole .NET Framework, which spans many assemblies and contains many nested namespaces.

Global Namespace

You use the predefined namespace `global` to put names in the .NET top-level namespace.

```
namespace global

type SomeType() =
    member this.SomeMember = 0
```

You can also use `global` to reference the top-level .NET namespace, for example, to resolve name conflicts with other namespaces.

```
global.System.Console.WriteLine("Hello World!")
```

Recursive namespaces

Namespaces can also be declared as recursive to allow for all contained code to be mutually recursive. This is done via `namespace rec`. Use of `namespace rec` can alleviate some pains in not being able to write mutually referential code between types and modules. The following is an example of this:

```

namespace rec MutualReferences

type Orientation = Up | Down
type PeelState = Peeled | Unpeeled

// This exception depends on the type below.
exception DontSqueezeTheBananaException of Banana

type BananaPeel() = class end

type Banana(orientation : Orientation) =
    member val IsPeeled = false with get, set
    member val Orientation = orientation with get, set
    member val Sides: PeelState list = [ Unpeeled; Unpeeled; Unpeeled; Unpeeled] with get, set

    member self.Peel() = BananaHelpers.peel self // Note the dependency on the BananaHelpers module.
    member self.SqueezeJuiceOut() = raise (DontSqueezeTheBananaException self) // This member depends on the
exception above.

module BananaHelpers =
    let peel (b: Banana) =
        let flip (banana: Banana) =
            match banana.Orientation with
            | Up ->
                banana.Orientation <- Down
                banana
            | Down -> banana

        let peelSides (banana: Banana) =
            banana.Sides
            |> List.map (function
                | Unpeeled -> Peeled
                | Peeled -> Peeled)

        match b.Orientation with
        | Up -> b |> flip |> peelSides
        | Down -> b |> peelSides

```

Note that the exception `DontSqueezeTheBananaException` and the class `Banana` both refer to each other. Additionally, the module `BananaHelpers` and the class `Banana` also refer to each other. This wouldn't be possible to express in F# if you removed the `rec` keyword from the `MutualReferences` namespace.

This feature is also available for top-level [Modules](#).

See also

- [F# Language Reference](#)
- [Modules](#)
- [F# RFC FS-1009 - Allow mutually referential types and modules over larger scopes within files](#)

Modules

12/19/2018 • 6 minutes to read • [Edit Online](#)

In the context of the F# language, a *module* is a grouping of F# code, such as values, types, and function values, in an F# program. Grouping code in modules helps keep related code together and helps avoid name conflicts in your program.

Syntax

```
// Top-level module declaration.  
module [accessibility-modifier] [qualified-namespace.]module-name  
declarations  
// Local module declaration.  
module [accessibility-modifier] module-name =  
    declarations
```

Remarks

An F# module is a grouping of F# code constructs such as types, values, function values, and code in `do` bindings. It is implemented as a common language runtime (CLR) class that has only static members. There are two types of module declarations, depending on whether the whole file is included in the module: a top-level module declaration and a local module declaration. A top-level module declaration includes the whole file in the module. A top-level module declaration can appear only as the first declaration in a file.

In the syntax for the top-level module declaration, the optional *qualified-namespace* is the sequence of nested namespace names that contains the module. The qualified namespace does not have to be previously declared.

You do not have to indent declarations in a top-level module. You do have to indent all declarations in local modules. In a local module declaration, only the declarations that are indented under that module declaration are part of the module.

If a code file does not begin with a top-level module declaration or a namespace declaration, the whole contents of the file, including any local modules, becomes part of an implicitly created top-level module that has the same name as the file, without the extension, with the first letter converted to uppercase. For example, consider the following file.

```
// In the file program.fs.  
let x = 40
```

This file would be compiled as if it were written in this manner:

```
module Program  
let x = 40
```

If you have multiple modules in a file, you must use a local module declaration for each module. If an enclosing namespace is declared, these modules are part of the enclosing namespace. If an enclosing namespace is not declared, the modules become part of the implicitly created top-level module. The following code example shows a code file that contains multiple modules. The compiler implicitly creates a top-level module named `Multiplemodules`, and `MyModule1` and `MyModule2` are nested in that top-level module.

```
// In the file multiplemodules.fs.
// MyModule1
module MyModule1 =
    // Indent all program elements within modules that are declared with an equal sign.
    let module1Value = 100

    let module1Function x =
        x + 10

// MyModule2
module MyModule2 =

    let module2Value = 121

    // Use a qualified name to access the function.
    // from MyModule1.
    let module2Function x =
        x * (MyModule1.module1Function module2Value)
```

If you have multiple files in a project or in a single compilation, or if you are building a library, you must include a namespace declaration or module declaration at the top of the file. The F# compiler only determines a module name implicitly when there is only one file in a project or compilation command line, and you are creating an application.

The *accessibility-modifier* can be one of the following: `public`, `private`, `internal`. For more information, see [Access Control](#). The default is public.

Referencing Code in Modules

When you reference functions, types, and values from another module, you must either use a qualified name or open the module. If you use a qualified name, you must specify the namespaces, the module, and the identifier for the program element you want. You separate each part of the qualified path with a dot (.), as follows.

```
Namespace1.Namespace2.ModuleName.Identifier
```

You can open the module or one or more of the namespaces to simplify the code. For more information about opening namespaces and modules, see [Import Declarations: The `open` Keyword](#).

The following code example shows a top-level module that contains all the code up to the end of the file.

```
module Arithmetic

let add x y =
    x + y

let sub x y =
    x - y
```

To use this code from another file in the same project, you either use qualified names or you open the module before you use the functions, as shown in the following examples.

```
// Fully qualify the function name.
let result1 = Arithmetic.add 5 9
// Open the module.
open Arithmetic
let result2 = add 5 9
```

Nested Modules

Modules can be nested. Inner modules must be indented as far as outer module declarations to indicate that they are inner modules, not new modules. For example, compare the following two examples. Module `Z` is an inner module in the following code.

```
module Y =
    let x = 1

    module Z =
        let z = 5
```

But module `Z` is a sibling to module `Y` in the following code.

```
module Y =
    let x = 1

    module Z =
        let z = 5
```

Module `Z` is also a sibling module in the following code, because it is not indented as far as other declarations in module `Y`.

```
module Y =
    let x = 1

    module Z =
        let z = 5
```

Finally, if the outer module has no declarations and is followed immediately by another module declaration, the new module declaration is assumed to be an inner module, but the compiler will warn you if the second module definition is not indented farther than the first.

```
// This code produces a warning, but treats Z as a inner module.
module Y =
    module Z =
        let z = 5
```

To eliminate the warning, indent the inner module.

```
module Y =
    module Z =
        let z = 5
```

If you want all the code in a file to be in a single outer module and you want inner modules, the outer module does not require the equal sign, and the declarations, including any inner module declarations, that will go in the outer module do not have to be indented. Declarations inside the inner module declarations do have to be indented. The following code shows this case.

```
// The top-level module declaration can be omitted if the file is named
// TopLevel.fs or topLevel.fs, and the file is the only file in an
// application.
module TopLevel

let topLevelX = 5

module Inner1 =
    let inner1X = 1
module Inner2 =
    let inner2X = 5
```

Recursive modules

F# 4.1 introduces the notion of modules which allow for all contained code to be mutually recursive. This is done via `module rec`. Use of `module rec` can alleviate some pains in not being able to write mutually referential code between types and modules. The following is an example of this:

```
module rec RecursiveModule =
    type Orientation = Up | Down
    type PeelState = Peeled | Unpeeled

    // This exception depends on the type below.
    exception DontSqueezeTheBananaException of Banana

    type BananaPeel() = class end

    type Banana(orientation : Orientation) =
        member val IsPeeled = false with get, set
        member val Orientation = orientation with get, set
        member val Sides: PeelState list = [ Unpeeled; Unpeeled; Unpeeled; Unpeeled] with get, set

        member self.Peel() = BananaHelpers.peel self // Note the dependency on the BananaHelpers module.
        member self.SqueezeJuiceOut() = raise (DontSqueezeTheBananaException self) // This member depends on
        the exception above.

    module BananaHelpers =
        let peel (b: Banana) =
            let flip (banana: Banana) =
                match banana.Orientation with
                | Up ->
                    banana.Orientation <- Down
                    banana
                | Down -> banana

            let peelSides (banana: Banana) =
                banana.Sides
                |> List.map (function
                    | Unpeeled -> Peeled
                    | Peeled -> Peeled)

            match b.Orientation with
            | Up -> b |> flip |> peelSides
            | Down -> b |> peelSides
```

Note that the exception `DontSqueezeTheBananaException` and the class `Banana` both refer to each other. Additionally, the module `BananaHelpers` and the class `Banana` also refer to each other. This would not be possible to express in F# if you removed the `rec` keyword from the `RecursiveModule` module.

This capability is also possible in [Namespaces](#) with F# 4.1.

- [F# RFC FS-1009 - Allow mutually referential types and modules over larger scopes within files](#)

Import Declarations: The `open` Keyword

12/19/2018 • 3 minutes to read • [Edit Online](#)

NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

An *import declaration* specifies a module or namespace whose elements you can reference without using a fully qualified name.

Syntax

```
open module-or-namespace-name
```

Remarks

Referencing code by using the fully qualified namespace or module path every time can create code that is hard to write, read, and maintain. Instead, you can use the `open` keyword for frequently used modules and namespaces so that when you reference a member of that module or namespace, you can use the short form of the name instead of the fully qualified name. This keyword is similar to the `using` keyword in C#, `using namespace` in Visual C++, and `Imports` in Visual Basic.

The module or namespace provided must be in the same project or in a referenced project or assembly. If it is not, you can add a reference to the project, or use the `-reference` command-line option (or its abbreviation, `-r`). For more information, see [Compiler Options](#).

The import declaration makes the names available in the code that follows the declaration, up to the end of the enclosing namespace, module, or file.

When you use multiple import declarations, they should appear on separate lines.

The following code shows the use of the `open` keyword to simplify code.

```
// Without the import declaration, you must include the full
// path to .NET Framework namespaces such as System.IO.
let writeToFile1 filename (text: string) =
    let stream1 = new System.IO.FileStream(filename, System.IO FileMode.Create)
    let writer = new System.IO.StreamWriter(stream1)
    writer.WriteLine(text)

// Open a .NET Framework namespace.
open System.IO

// Now you do not have to include the full paths.
let writeToFile2 filename (text: string) =
    let stream1 = new FileStream(filename, FileMode.Create)
    let writer = new StreamWriter(stream1)
    writer.WriteLine(text)

writeToFile2 "file1.txt" "Testing..."
```

The F# compiler does not emit an error or warning when ambiguities occur when the same name occurs in more

than one open module or namespace. When ambiguities occur, F# gives preference to the more recently opened module or namespace. For example, in the following code, `empty` means `Seq.empty`, even though `empty` is located in both the `List` and `Seq` modules.

```
open List
open Seq
printfn "%A" empty
```

Therefore, be careful when you open modules or namespaces such as `List` or `Seq` that contain members that have identical names; instead, consider using the qualified names. You should avoid any situation in which the code is dependent upon the order of the import declarations.

Namespaces That Are Open by Default

Some namespaces are so frequently used in F# code that they are opened implicitly without the need of an explicit import declaration. The following table shows the namespaces that are open by default.

NAMESPACE	DESCRIPTION
<code>Microsoft.FSharp.Core</code>	Contains basic F# type definitions for built-in types such as <code>int</code> and <code>float</code> .
<code>Microsoft.FSharp.Core.Operators</code>	Contains basic arithmetic operations such as <code>+</code> and <code>*</code> .
<code>Microsoft.FSharp.Collections</code>	Contains immutable collection classes such as <code>List</code> and <code>Array</code> .
<code>Microsoft.FSharp.Control</code>	Contains types for control constructs such as lazy evaluation and asynchronous workflows.
<code>Microsoft.FSharp.Text</code>	Contains functions for formatted IO, such as the <code>printf</code> function.

AutoOpen Attribute

You can apply the `AutoOpen` attribute to an assembly if you want to automatically open a namespace or module when the assembly is referenced. You can also apply the `AutoOpen` attribute to a module to automatically open that module when the parent module or namespace is opened. For more information, see [Core.AutoOpenAttribute Class](#).

RequireQualifiedAccess Attribute

Some modules, records, or union types may specify the `RequireQualifiedAccess` attribute. When you reference elements of those modules, records, or unions, you must use a qualified name regardless of whether you include an import declaration. If you use this attribute strategically on types that define commonly used names, you help avoid name collisions and thereby make code more resilient to changes in libraries. For more information, see [Core.RequireQualifiedAccessAttribute Class](#).

Signatures

12/19/2018 • 4 minutes to read • [Edit Online](#)

A signature file contains information about the public signatures of a set of F# program elements, such as types, namespaces, and modules. It can be used to specify the accessibility of these program elements.

Remarks

For each F# code file, you can have a *signature file*, which is a file that has the same name as the code file but with the extension .fsi instead of .fs. Signature files can also be added to the compilation command-line if you are using the command line directly. To distinguish between code files and signature files, code files are sometimes referred to as *implementation files*. In a project, the signature file should precede the associated code file.

A signature file describes the namespaces, modules, types, and members in the corresponding implementation file. You use the information in a signature file to specify what parts of the code in the corresponding implementation file can be accessed from code outside the implementation file, and what parts are internal to the implementation file. The namespaces, modules, and types that are included in the signature file must be a subset of the namespaces, modules, and types that are included in the implementation file. With some exceptions noted later in this topic, those language elements that are not listed in the signature file are considered private to the implementation file. If no signature file is found in the project or command line, the default accessibility is used.

For more information about the default accessibility, see [Access Control](#).

In a signature file, you do not repeat the definition of the types and the implementations of each method or function. Instead, you use the signature for each method and function, which acts as a complete specification of the functionality that is implemented by a module or namespace fragment. The syntax for a type signature is the same as that used in abstract method declarations in interfaces and abstract classes, and is also shown by IntelliSense and by the F# interpreter fsi.exe when it displays correctly compiled input.

If there is not enough information in the type signature to indicate whether a type is sealed, or whether it is an interface type, you must add an attribute that indicates the nature of the type to the compiler. Attributes that you use for this purpose are described in the following table.

ATTRIBUTE	DESCRIPTION
[<Sealed>]	For a type that has no abstract members, or that should not be extended.
[<Interface>]	For a type that is an interface.

The compiler produces an error if the attributes are not consistent between the signature and the declaration in the implementation file.

Use the keyword `val` to create a signature for a value or function value. The keyword `type` introduces a type signature.

You can generate a signature file by using the `--sig` compiler option. Generally, you do not write .fsi files manually. Instead, you generate .fsi files by using the compiler, add them to your project, if you have one, and edit them by removing methods and functions that you do not want to be accessible.

There are several rules for type signatures:

- Type abbreviations in an implementation file must not match a type without an abbreviation in a signature file.
- Records and discriminated unions must expose either all or none of their fields and constructors, and the order in the signature must match the order in the implementation file. Classes can reveal some, all, or none of their fields and methods in the signature.
- Classes and structures that have constructors must expose the declarations of their base classes (the `inherits` declaration). Also, classes and structures that have constructors must expose all of their abstract methods and interface declarations.
- Interface types must reveal all their methods and interfaces.

The rules for value signatures are as follows:

- Modifiers for accessibility (`public`, `internal`, and so on) and the `inline` and `mutable` modifiers in the signature must match those in the implementation.
- The number of generic type parameters (either implicitly inferred or explicitly declared) must match, and the types and type constraints in generic type parameters must match.
- If the `Literal` attribute is used, it must appear in both the signature and the implementation, and the same literal value must be used for both.
- The pattern of parameters (also known as the *arity*) of signatures and implementations must be consistent.
- If parameter names in a signature file differ from the corresponding implementation file, the name in the signature file will be used instead, which may cause issues when debugging or profiling. If you wish to be notified of such mismatches, enable warning 3218 in your project file or when invoking the compiler (see `--warnon` under [Compiler Options](#)).

The following code example shows an example of a signature file that has namespace, module, function value, and type signatures together with the appropriate attributes. It also shows the corresponding implementation file.

```
// Module1.fsi

namespace Library1
module Module1 =
    val function1 : int -> int
    type Type1 =
        new : unit -> Type1
        member method1 : unit -> unit
        member method2 : unit -> unit

    [<Sealed>]
    type Type2 =
        new : unit -> Type2
        member method1 : unit -> unit
        member method2 : unit -> unit

    [<Interface>]
    type InterfaceType1 =
        abstract member method1 : int -> int
        abstract member method2 : string -> unit
```

The following code shows the implementation file.

```
namespace Library1

module Module1 =

    let function1 x = x + 1

    type Type1() =
        member type1.method1() =
            printfn "type1.method1"
        member type1.method2() =
            printfn "type1.method2"

    [<>Sealed>]
    type Type2() =
        member type2.method1() =
            printfn "type2.method1"
        member type2.method2() =
            printfn "type2.method2"

    [<>Interface>]
    type InterfaceType1 =
        abstract member method1 : int -> int
        abstract member method2 : string -> unit
```

Units of Measure

12/19/2018 • 7 minutes to read • [Edit Online](#)

Floating point and signed integer values in F# can have associated units of measure, which are typically used to indicate length, volume, mass, and so on. By using quantities with units, you enable the compiler to verify that arithmetic relationships have the correct units, which helps prevent programming errors.

Syntax

```
[<Measure>] type unit-name [ = measure ]
```

Remarks

The previous syntax defines *unit-name* as a unit of measure. The optional part is used to define a new measure in terms of previously defined units. For example, the following line defines the measure `cm` (centimeter).

```
[<Measure>] type cm
```

The following line defines the measure `m1` (milliliter) as a cubic centimeter (`cm^3`).

```
[<Measure>] type m1 = cm^3
```

In the previous syntax, *measure* is a formula that involves units. In formulas that involve units, integral powers are supported (positive and negative), spaces between units indicate a product of the two units, `*` also indicates a product of units, and `/` indicates a quotient of units. For a reciprocal unit, you can either use a negative integer power or a `/` that indicates a separation between the numerator and denominator of a unit formula. Multiple units in the denominator should be surrounded by parentheses. Units separated by spaces after a `/` are interpreted as being part of the denominator, but any units following a `*` are interpreted as being part of the numerator.

You can use 1 in unit expressions, either alone to indicate a dimensionless quantity, or together with other units, such as in the numerator. For example, the units for a rate would be written as `1/s`, where `s` indicates seconds. Parentheses are not used in unit formulas. You do not specify numeric conversion constants in the unit formulas; however, you can define conversion constants with units separately and use them in unit-checked computations.

Unit formulas that mean the same thing can be written in various equivalent ways. Therefore, the compiler converts unit formulas into a consistent form, which converts negative powers to reciprocals, groups units into a single numerator and a denominator, and alphabetizes the units in the numerator and denominator.

For example, the unit formulas `kg m s^-2` and `m /s s * kg` are both converted to `kg m/s^2`.

You use units of measure in floating point expressions. Using floating point numbers together with associated units of measure adds another level of type safety and helps avoid the unit mismatch errors that can occur in formulas when you use weakly typed floating point numbers. If you write a floating point expression that uses units, the units in the expression must match.

You can annotate literals with a unit formula in angle brackets, as shown in the following examples.

```
1.0<cm>
55.0<miles/hour>
```

You do not put a space between the number and the angle bracket; however, you can include a literal suffix such as `f`, as in the following example.

```
// The f indicates single-precision floating point.
55.0f<miles/hour>
```

Such an annotation changes the type of the literal from its primitive type (such as `float`) to a dimensioned type, such as `float<cm>` or, in this case, `float<miles/hour>`. A unit annotation of `<1>` indicates a dimensionless quantity, and its type is equivalent to the primitive type without a unit parameter.

The type of a unit of measure is a floating point or signed integral type together with an extra unit annotation, indicated in brackets. Thus, when you write the type of a conversion from `g` (grams) to `kg` (kilograms), you describe the types as follows.

```
let convertg2kg (x : float<g>) = x / 1000.0<g/kg>
```

Units of measure are used for compile-time unit checking but are not persisted in the run-time environment. Therefore, they do not affect performance.

Units of measure can be applied to any type, not just floating point types; however, only floating point types, signed integral types, and decimal types support dimensioned quantities. Therefore, it only makes sense to use units of measure on the primitive types and on aggregates that contain these primitive types.

The following example illustrates the use of units of measure.

```

// Mass, grams.
[<Measure>] type g
// Mass, kilograms.
[<Measure>] type kg
// Weight, pounds.
[<Measure>] type lb

// Distance, meters.
[<Measure>] type m
// Distance, cm
[<Measure>] type cm

// Distance, inches.
[<Measure>] type inch
// Distance, feet
[<Measure>] type ft

// Time, seconds.
[<Measure>] type s

// Force, Newtons.
[<Measure>] type N = kg m / s

// Pressure, bar.
[<Measure>] type bar
// Pressure, Pascals
[<Measure>] type Pa = N / m^2

// Volume, milliliters.
[<Measure>] type ml
// Volume, liters.
[<Measure>] type L

// Define conversion constants.
let gramsPerKilogram : float<g kg^-1> = 1000.0<g/kg>
let cmPerMeter : float<cm/m> = 100.0<cm/m>
let cmPerInch : float<cm/inch> = 2.54<cm/inch>

let mlPerCubicCentimeter : float<ml/cm^3> = 1.0<ml/cm^3>
let mlPerLiter : float<ml/L> = 1000.0<ml/L>

// Define conversion functions.
let convertGramsToKilograms (x : float<g>) = x / gramsPerKilogram
let convertCentimetersToInches (x : float<cm>) = x / cmPerInch

```

The following code example illustrates how to convert from a dimensionless floating point number to a dimensioned floating point value. You just multiply by 1.0, applying the dimensions to the 1.0. You can abstract this into a function like `degreesFahrenheit`.

Also, when you pass dimensioned values to functions that expect dimensionless floating point numbers, you must cancel out the units or cast to `float` by using the `float` operator. In this example, you divide by `1.0<degC>` for the arguments to `printf` because `printf` expects dimensionless quantities.

```

[<Measure>] type degC // temperature, Celsius/Centigrade
[<Measure>] type degF // temperature, Fahrenheit

let convertCtoF ( temp : float<degC> ) = 9.0<degF> / 5.0<degC> * temp + 32.0<degF>
let convertFtoC ( temp: float<degF> ) = 5.0<degC> / 9.0<degF> * ( temp - 32.0<degF> )

// Define conversion functions from dimensionless floating point values.
let degreesFahrenheit temp = temp * 1.0<degF>
let degreesCelsius temp = temp * 1.0<degC>

printfn "Enter a temperature in degrees Fahrenheit."
let input = System.Console.ReadLine()
let parsedOk, floatValue = System.Double.TryParse(input)
if parsedOk
    then
        printfn "That temperature in Celsius is %8.2f degrees C." ((convertFtoC (degreesFahrenheit
floatValue))/(1.0<degC>))
    else
        printfn "Error parsing input."

```

The following example session shows the outputs from and inputs to this code.

```

Enter a temperature in degrees Fahrenheit.
90
That temperature in degrees Celsius is      32.22.

```

Using Generic Units

You can write generic functions that operate on data that has an associated unit of measure. You do this by specifying a type together with a generic unit as a type parameter, as shown in the following code example.

```

// Distance, meters.
[<Measure>] type m
// Time, seconds.
[<Measure>] type s

let genericSumUnits ( x : float<'u> ) (y: float<'u>) = x + y

let v1 = 3.1<m/s>
let v2 = 2.7<m/s>
let x1 = 1.2<m>
let t1 = 1.0<s>

// OK: a function that has unit consistency checking.
let result1 = genericSumUnits v1 v2
// Error reported: mismatched units.
// Uncomment to see error.
// let result2 = genericSumUnits v1 x1

```

Creating Aggregate Types with Generic Units

The following code shows how to create an aggregate type that consists of individual floating point values that have units that are generic. This enables a single type to be created that works with a variety of units. Also, generic units preserve type safety by ensuring that a generic type that has one set of units is a different type than the same generic type with a different set of units. The basis of this technique is that the `Measure` attribute can be applied to the type parameter.

```

// Distance, meters.
[<Measure>] type m
// Time, seconds.
[<Measure>] type s

// Define a vector together with a measure type parameter.
// Note the attribute applied to the type parameter.
type vector3D<[<Measure>] 'u> = { x : float<'u>; y : float<'u>; z : float<'u> }

// Create instances that have two different measures.
// Create a position vector.
let xvec : vector3D<m> = { x = 0.0<m>; y = 0.0<m>; z = 0.0<m> }
// Create a velocity vector.
let v1vec : vector3D<m/s> = { x = 1.0<m/s>; y = -1.0<m/s>; z = 0.0<m/s> }

```

Units at Runtime

Units of measure are used for static type checking. When floating point values are compiled, the units of measure are eliminated, so the units are lost at run time. Therefore, any attempt to implement functionality that depends on checking the units at run time is not possible. For example, implementing a `ToString` function to print out the units is not possible.

Conversions

To convert a type that has units (for example, `float<'u>`) to a type that does not have units, you can use the standard conversion function. For example, you can use `float` to convert to a `float` value that does not have units, as shown in the following code.

```

[<Measure>]
type cm
let length = 12.0<cm>
let x = float length

```

To convert a unitless value to a value that has units, you can multiply by a 1 or 1.0 value that is annotated with the appropriate units. However, for writing interoperability layers, there are also some explicit functions that you can use to convert unitless values to values with units. These are in the [Microsoft.FSharp.Core.LanguagePrimitives](#) module. For example, to convert from a unitless `float` to a `float<cm>`, use `FloatWithMeasure`, as shown in the following code.

```

open Microsoft.FSharp.Core
let height:float<cm> = LanguagePrimitives.FloatWithMeasure x

```

Units of Measure in the F# Core library

A unit library is available in the `FSharp.Data.UnitSystems.SI` namespace. It includes SI units in both their symbol form (like `m` for meter) in the `UnitSymbols` sub-namespace, and their full name (like `meter` for meter) in the `UnitNames` sub-namespace.

XML Documentation

1/29/2019 • 3 minutes to read • [Edit Online](#)

You can produce documentation from triple-slash (///) code comments in F#. XML comments can precede declarations in code files (.fs) or signature (.fsi) files.

Generating Documentation from Comments

The support in F# for generating documentation from comments is the same as that in other .NET Framework languages. As in other .NET Framework languages, the [-doc compiler option](#) enables you to produce an XML file that contains information that you can convert into documentation by using a tool such as [DocFX](#) or [Sandcastle](#). The documentation generated by using tools that are designed for use with assemblies that are written in other .NET Framework languages generally produce a view of the APIs that is based on the compiled form of F# constructs. Unless tools specifically support F#, documentation generated by these tools does not match the F# view of an API.

For more information about how to generate documentation from XML, see [XML Documentation Comments \(C# Programming Guide\)](#).

Recommended Tags

There are two ways to write XML documentation comments. One is to just write the documentation directly in a triple-slash comment, without using XML tags. If you do this, the entire comment text is taken as the summary documentation for the code construct that immediately follows. Use this method when you want to write only a brief summary for each construct. The other method is to use XML tags to provide more structured documentation. The second method enables you to specify separate notes for a short summary, additional remarks, documentation for each parameter and type parameter and exceptions thrown, and a description of the return value. The following table describes XML tags that are recognized in F# XML code comments.

TAG SYNTAX	DESCRIPTION
<code><c>text</c></code>	Specifies that <i>text</i> is code. This tag can be used by documentation generators to display text in a font that is appropriate for code.
<code><summary>text</summary></code>	Specifies that <i>text</i> is a brief description of the program element. The description is usually one or two sentences.
<code><remarks>text</remarks></code>	Specifies that <i>text</i> contains supplementary information about the program element.
<code><param name="name">description</param></code>	Specifies the name and description for a function or method parameter.
<code><typeparam name="name">description</typeparam></code>	Specifies the name and description for a type parameter.
<code><returns>text</returns></code>	Specifies that <i>text</i> describes the return value of a function or method.
<code><exception cref="type">description</exception></code>	Specifies the type of exception that can be generated and the circumstances under which it is thrown.

TAG SYNTAX	DESCRIPTION
<see cref="reference">text</see>	Specifies an inline link to another program element. The <i>reference</i> is the name as it appears in the XML documentation file. The <i>text</i> is the text shown in the link.
<seealso cref="reference"/>	Specifies a See Also link to the documentation for another type. The <i>reference</i> is the name as it appears in the XML documentation file. See Also links usually appear at the bottom of a documentation page.
<para>text</para>	Specifies a paragraph of text. This is used to separate text inside the remarks tag.

Example

Description

The following is a typical XML documentation comment in a signature file.

Code

```
/// <summary>Builds a new string whose characters are the results of applying the function <c>mapping</c>
/// to each of the characters of the input string and concatenating the resulting
/// strings.</summary>
/// <param name="mapping">The function to produce a string from each character of the input string.</param>
/// <param name="str">The input string.</param>
/// <returns>The concatenated string.</returns>
/// <exception cref="System.ArgumentNullException">Thrown when the input string is null.</exception>
val collect : (char -> string) -> string -> string
```

Example

Description

The following example shows the alternative method, without XML tags. In this example, the entire text in the comment is considered a summary. Note that if you do not specify a summary tag explicitly, you should not specify other tags, such as **param** or **returns** tags.

Code

```
/// Creates a new string whose characters are the result of applying
/// the function mapping to each of the characters of the input string
/// and concatenating the resulting strings.
val collect : (char -> string) -> string -> string
```

Lazy Expressions

3/14/2019 • 2 minutes to read • [Edit Online](#)

Lazy expressions are expressions that are not evaluated immediately, but are instead evaluated when the result is needed. This can help to improve the performance of your code.

Syntax

```
let identifier = lazy ( expression )
```

Remarks

In the previous syntax, *expression* is code that is evaluated only when a result is required, and *identifier* is a value that stores the result. The value is of type `Lazy<'T>`, where the actual type that is used for `'T` is determined from the result of the expression.

Lazy expressions enable you to improve performance by restricting the execution of an expressions to only those situations in which a result is needed.

To force the expressions to be performed, you call the method `Force`. `Force` causes the execution to be performed only one time. Subsequent calls to `Force` return the same result, but do not execute any code.

The following code illustrates the use of lazy expressions and the use of `Force`. In this code, the type of `result` is `Lazy<int>`, and the `Force` method returns an `int`.

```
let x = 10
let result = lazy (x + 10)
printfn "%d" (result.Force())
```

Lazy evaluation, but not the `Lazy` type, is also used for sequences. For more information, see [Sequences](#).

Computation Expressions

3/16/2019 • 14 minutes to read • [Edit Online](#)

Computation expressions in F# provide a convenient syntax for writing computations that can be sequenced and combined using control flow constructs and bindings. Depending on the kind of computation expression, they can be thought of as a way to express monads, monoids, monad transformers, and applicative functors. However, unlike other languages (such as *do-notation* in Haskell), they are not tied to a single abstraction, and do not rely on macros or other forms of metaprogramming to accomplish a convenient and context-sensitive syntax.

Overview

Computations can take many forms. The most common form of computation is single-threaded execution, which is easy to understand and modify. However, not all forms of computation are as straightforward as single-threaded execution. Some examples include:

- Non-deterministic computations
- Asynchronous computations
- Effectful computations
- Generative computations

More generally, there are *context-sensitive* computations that you must perform in certain parts of an application. Writing context-sensitive code can be challenging, as it is easy to "leak" computations outside of a given context without abstractions to prevent you from doing so. These abstractions are often challenging to write by yourself, which is why F# has a generalized way to do so called **computation expressions**.

Computation expressions offer a uniform syntax and abstraction model for encoding context-sensitive computations.

Every computation expression is backed by a *builder* type. The builder type defines the operations that are available for the computation expression. See [Creating a New Type of Computation Expression](#), which shows how to create a custom computation expression.

Syntax overview

All computation expressions have the following form:

```
builder-expr { cexpr }
```

where `builder-expr` is the name of a builder type that defines the computation expression, and `cexpr` is the expression body of the computation expression. For example, `async` computation expression code can look like this:

```
let fetchAndDownload url =
    async {
        let! data = downloadData url

        let processedData = processData data

        return processedData
    }
```

There is a special, additional syntax available within a computation expression, as shown in the previous example. The following expression forms are possible with computation expressions:

```
expr { let! ... }
expr { do! ... }
expr { yield ... }
expr { yield! ... }
expr { return ... }
expr { return! ... }
expr { match! ... }
```

Each of these keywords, and other standard F# keywords are only available in a computation expression if they have been defined in the backing builder type. The only exception to this is `match!`, which is itself syntactic sugar for the use of `let!` followed by a pattern match on the result.

The builder type is an object that defines special methods that govern the way the fragments of the computation expression are combined; that is, its methods control how the computation expression behaves. Another way to describe a builder class is to say that it enables you to customize the operation of many F# constructs, such as loops and bindings.

`let!`

The `let!` keyword binds the result of a call to another computation expression to a name:

```
let doThingsAsync url =
    async {
        let! data = getDataAsync url
        ...
    }
```

If you bind the call to a computation expression with `let`, you will not get the result of the computation expression. Instead, you will have bound the value of the *unrealized* call to that computation expression. Use `let!` to bind to the result.

`let!` is defined by the `Bind(x, f)` member on the builder type.

`do!`

The `do!` keyword is for calling a computation expression that returns a `unit`-like type (defined by the `zero` member on the builder):

```
let doThingsAsync data url =
    async {
        do! submitData data url
        ...
    }
```

For the [async workflow](#), this type is `Async<unit>`. For other computation expressions, the type is likely to be `CExpType<unit>`.

`do!` is defined by the `Bind(x, f)` member on the builder type, where `f` produces a `unit`.

`yield`

The `yield` keyword is for returning a value from the computation expression so that it can be consumed as an `IEnumerable<T>`:

```

let squares =
    seq {
        for i in 1..10 do
            yield i * i
    }

for sq in squares do
    printfn "%d" sq

```

As with the [yield keyword in C#](#), each element in the computation expression is yielded back as it is iterated.

`yield` is defined by the `Yield(x)` member on the builder type, where `x` is the item to yield back.

`yield!`

The `yield!` keyword is for flattening a collection of values from a computation expression:

```

let squares =
    seq {
        for i in 1..3 -> i * i
    }

let cubes =
    seq {
        for i in 1..3 -> i * i * i
    }

let squaresAndCubes =
    seq {
        yield! squares
        yield! cubes
    }

printfn "%A" squaresAndCubes // Prints - 1; 4; 9; 1; 8; 27

```

When evaluated, the computation expression called by `yield!` will have its items yielded back one-by-one, flattening the result.

`yield!` is defined by the `YieldFrom(x)` member on the builder type, where `x` is a collection of values.

`return`

The `return` keyword wraps a value in the type corresponding to the computation expression. Aside from computation expressions using `yield`, it is used to "complete" a computation expression:

```

let req = // 'req' is of type is 'Async<data>'
    async {
        let! data = fetch url
        return data
    }

// 'result' is of type 'data'
let result = Async.RunSynchronously req

```

`return` is defined by the `Return(x)` member on the builder type, where `x` is the item to wrap.

`return!`

The `return!` keyword realizes the value of a computation expression and wraps that result in the type corresponding to the computation expression:

```

let req = // 'req' is of type 'Async<data>'
    async {
        return! fetch url
    }

// 'result' is of type 'data'
let result = Async.RunSynchronously req

```

`return!` is defined by the `ReturnFrom(x)` member on the builder type, where `x` is another computation expression.

`match!`

Starting with F# 4.5, the `match!` keyword allows you to inline a call to another computation expression and pattern match on its result:

```

let doThingsAsync url =
    async {
        match! callService url with
        | Some data -> ...
        | None -> ...
    }

```

When calling a computation expression with `match!`, it will realize the result of the call like `let!`. This is often used when calling a computation expression where the result is an [optional](#).

Built-in computation expressions

The F# core library defines three built-in computation expressions: [Sequence Expressions](#), [Asynchronous Workflows](#), and [Query Expressions](#).

Creating a New Type of Computation Expression

You can define the characteristics of your own computation expressions by creating a builder class and defining certain special methods on the class. The builder class can optionally define the methods as listed in the following table.

The following table describes methods that can be used in a workflow builder class.

METHOD	TYPICAL SIGNATURE(S)	DESCRIPTION
<code>Bind</code>	<code>M<'T> * ('T -> M<'U>) -> M<'U></code>	Called for <code>let!</code> and <code>do!</code> in computation expressions.
<code>Delay</code>	<code>(unit -> M<'T>) -> M<'T></code>	Wraps a computation expression as a function.
<code>Return</code>	<code>'T -> M<'T></code>	Called for <code>return</code> in computation expressions.
<code>ReturnFrom</code>	<code>M<'T> -> M<'T></code>	Called for <code>return!</code> in computation expressions.
<code>Run</code>	<code>M<'T> -> M<'T></code> or <code>M<'T> -> 'T</code>	Executes a computation expression.

METHOD	TYPICAL SIGNATURE(S)	DESCRIPTION
Combine	$M< 'T > * M< 'T > \rightarrow M< 'T >$ or $M< unit > * M< 'T > \rightarrow M< 'T >$	Called for sequencing in computation expressions.
For	$seq< 'T > * ('T \rightarrow M< 'U >) \rightarrow M< 'U >$ or $seq< 'T > * ('T \rightarrow M< 'U >) \rightarrow seq< M< 'U > >$	Called for <code>for...do</code> expressions in computation expressions.
TryFinally	$M< 'T > * (unit \rightarrow unit) \rightarrow M< 'T >$	Called for <code>try...finally</code> expressions in computation expressions.
TryWith	$M< 'T > * (exn \rightarrow M< 'T >) \rightarrow M< 'T >$	Called for <code>try...with</code> expressions in computation expressions.
Using	$'T * ('T \rightarrow M< 'U >) \rightarrow M< 'U > \text{ when } 'U :> IDisposable$	Called for <code>use</code> bindings in computation expressions.
While	$(unit \rightarrow bool) * M< 'T > \rightarrow M< 'T >$	Called for <code>while...do</code> expressions in computation expressions.
Yield	$'T \rightarrow M< 'T >$	Called for <code>yield</code> expressions in computation expressions.
YieldFrom	$M< 'T > \rightarrow M< 'T >$	Called for <code>yield!</code> expressions in computation expressions.
Zero	$unit \rightarrow M< 'T >$	Called for empty <code>else</code> branches of <code>if...then</code> expressions in computation expressions.
Quote	$Quotations.Expr< 'T > \rightarrow Quotations.Expr< 'T >$	Indicates that the computation expression is passed to the <code>Run</code> member as a quotation. It translates all instances of a computation into a quotation.

Many of the methods in a builder class use and return an `M< 'T >` construct, which is typically a separately defined type that characterizes the kind of computations being combined, for example, `Async< 'T >` for asynchronous workflows and `Seq< 'T >` for sequence workflows. The signatures of these methods enable them to be combined and nested with each other, so that the workflow object returned from one construct can be passed to the next. The compiler, when it parses a computation expression, converts the expression into a series of nested function calls by using the methods in the preceding table and the code in the computation expression.

The nested expression is of the following form:

```
builder.Run(builder.Delay(fun () -> {| cexpr |}))
```

In the above code, the calls to `Run` and `Delay` are omitted if they are not defined in the computation expression builder class. The body of the computation expression, here denoted as `{| cexpr |}`, is translated

into calls involving the methods of the builder class by the translations described in the following table. The computation expression `{| cexpr |}` is defined recursively according to these translations where `expr` is an F# expression and `cexpr` is a computation expression.

EXPRESSION	TRANSLATION
<code>{ let binding in cexpr }</code>	<code>let binding in { cexpr }</code>
<code>{ let! pattern = expr in cexpr }</code>	<code>builder.Bind(expr, (fun pattern -> { cexpr }))</code>
<code>{ do! expr in cexpr }</code>	<code>builder.Bind(expr, (fun () -> { cexpr }))</code>
<code>{ yield expr }</code>	<code>builder.Yield(expr)</code>
<code>{ yield! expr }</code>	<code>builder.YieldFrom(expr)</code>
<code>{ return expr }</code>	<code>builder.Return(expr)</code>
<code>{ return! expr }</code>	<code>builder.ReturnFrom(expr)</code>
<code>{ use pattern = expr in cexpr }</code>	<code>builder.Using(expr, (fun pattern -> { cexpr }))</code>
<code>{ use! value = expr in cexpr }</code>	<code>builder.Bind(expr, (fun value -> builder.Using(value, (fun value -> { cexpr }))))</code>
<code>{ if expr then cexpr0 }</code>	<code>if expr then { cexpr0 } else binder.Zero()</code>
<code>{ if expr then cexpr0 else cexpr1 }</code>	<code>if expr then { cexpr0 } else { cexpr1 }</code>
<code>{ match expr with pattern_i -> cexpr_i }</code>	<code>match expr with pattern_i -> { cexpr_i }</code>
<code>{ for pattern in expr do cexpr }</code>	<code>builder.For(enumeration, (fun pattern -> { cexpr }))</code>
<code>{ for identifier = expr1 to expr2 do cexpr }</code>	<code>builder.For(enumeration, (fun identifier -> { cexpr }))</code>
<code>{ while expr do cexpr }</code>	<code>builder.While(fun () -> expr, builder.Delay({ cexpr }))</code>
<code>{ try cexpr with pattern_i -> expr_i }</code>	<code>builder.TryWith(builder.Delay({ cexpr }), (fun value -> match value with pattern_i -> expr_i exn -> reraise exn)))</code>
<code>{ try cexpr finally expr }</code>	<code>builder.TryFinally(builder.Delay({ cexpr }), (fun () -> expr))</code>
<code>{ cexpr1; cexpr2 }</code>	<code>builder.Combine({ cexpr1 }, { cexpr2 })</code>
<code>{ other-expr; cexpr }</code>	<code>expr; { cexpr }</code>
<code>{ other-expr }</code>	<code>expr; builder.Zero()</code>

In the previous table, `other-expr` describes an expression that is not otherwise listed in the table. A builder

class does not need to implement all of the methods and support all of the translations listed in the previous table. Those constructs that are not implemented are not available in computation expressions of that type. For example, if you do not want to support the `use` keyword in your computation expressions, you can omit the definition of `use` in your builder class.

The following code example shows a computation expression that encapsulates a computation as a series of steps that can be evaluated one step at a time. A discriminated union type, `OkOrException`, encodes the error state of the expression as evaluated so far. This code demonstrates several typical patterns that you can use in your computation expressions, such as boilerplate implementations of some of the builder methods.

```
// Computations that can be run step by step
type Eventually<'T> =
| Done of 'T
| NotYetDone of (unit -> Eventually<'T>)

module Eventually =
// The bind for the computations. Append 'func' to the
// computation.
let rec bind func expr =
    match expr with
    | Done value -> func value
    | NotYetDone work -> NotYetDone (fun () -> bind func (work()))

// Return the final value wrapped in the Eventually type.
let result value = Done value

type OkOrException<'T> =
| Ok of 'T
| Exception of System.Exception

// The catch for the computations. Stitch try/with throughout
// the computation, and return the overall result as an OkOrException.
let rec catch expr =
    match expr with
    | Done value -> result (Ok value)
    | NotYetDone work ->
        NotYetDone (fun () ->
            let res = try Ok(work()) with | exn -> Exception exn
            match res with
            | Ok cont -> catch cont // note, a tailcall
            | Exception exn -> result (Exception exn))

// The delay operator.
let delay func = NotYetDone (fun () -> func())

// The stepping action for the computations.
let step expr =
    match expr with
    | Done _ -> expr
    | NotYetDone func -> func ()

// The rest of the operations are boilerplate.

// The tryFinally operator.
// This is boilerplate in terms of "result", "catch", and "bind".
let tryFinally expr compensation =
    catch (expr)
    |> bind (fun res ->
        compensation();
        match res with
        | Ok value -> result value
        | Exception exn -> raise exn)

// The tryWith operator.
// This is boilerplate in terms of "result", "catch", and "bind".
let tryWith exn handler =
    catch exn
```

```

|> bind (function Ok value -> result value | Exception exn -> handler exn)

// The whileLoop operator.
// This is boilerplate in terms of "result" and "bind".
let rec whileLoop pred body =
    if pred() then body |> bind (fun _ -> whileLoop pred body)
    else result ()

// The sequential composition operator.
// This is boilerplate in terms of "result" and "bind".
let combine expr1 expr2 =
    expr1 |> bind (fun () -> expr2)

// The using operator.
let using (resource: #System.IDisposable) func =
    tryFinally (func resource) (fun () -> resource.Dispose())

// The forLoop operator.
// This is boilerplate in terms of "catch", "result", and "bind".
let forLoop (collection:seq<_>) func =
    let ie = collection.GetEnumerator()
    tryFinally
        (whileLoop
            (fun () -> ie.MoveNext())
            (delay (fun () -> let value = ie.Current in func value)))
        (fun () -> ie.Dispose())

// The builder class.
type EventuallyBuilder() =
    member x.Bind(comp, func) = Eventually.bind func comp
    member x.Return(value) = Eventually.result value
    member x.ReturnFrom(value) = value
    member x.Combine(expr1, expr2) = Eventually.combine expr1 expr2
    member x.Delay(func) = Eventually.delay func
    member x.Zero() = Eventually.result ()
    member x.TryWith(expr, handler) = Eventually.tryWith expr handler
    member x.TryFinally(expr, compensation) = Eventually.tryFinally expr compensation
    member x.For(coll:seq<_>, func) = Eventually.forLoop coll func
    member x.Using(resource, expr) = Eventually.using resource expr

let eventually = new EventuallyBuilder()

let comp = eventually {
    for x in 1..2 do
        printfn " x = %d" x
    return 3 + 4 }

// Try the remaining lines in F# interactive to see how this
// computation expression works in practice.
let step x = Eventually.step x

// returns "NotYetDone <closure>"
comp |> step

// prints "x = 1"
// returns "NotYetDone <closure>"
comp |> step |> step

// prints "x = 1"
// prints "x = 2"
// returns "Done 7"
comp |> step |> step |> step |> step

```

A computation expression has an underlying type, which the expression returns. The underlying type may represent a computed result or a delayed computation that can be performed, or it may provide a way to iterate through some type of collection. In the previous example, the underlying type was **Eventually**. For a sequence

expression, the underlying type is `System.Collections.Generic.IEnumerable<T>`. For a query expression, the underlying type is `System.Linq.IQueryable`. For an asynchronous workflow, the underlying type is `Async`. The `Async` object represents the work to be performed to compute the result. For example, you call `Async.RunSynchronously` to execute a computation and return the result.

Custom Operations

You can define a custom operation on a computation expression and use a custom operation as an operator in a computation expression. For example, you can include a query operator in a query expression. When you define a custom operation, you must define the `Yield` and `For` methods in the computation expression. To define a custom operation, put it in a builder class for the computation expression, and then apply the `CustomOperationAttribute`. This attribute takes a string as an argument, which is the name to be used in a custom operation. This name comes into scope at the start of the opening curly brace of the computation expression. Therefore, you shouldn't use identifiers that have the same name as a custom operation in this block. For example, avoid the use of identifiers such as `all` or `last` in query expressions.

Extending existing Builders with new Custom Operations

If you already have a builder class, its custom operations can be extended from outside of this builder class. Extensions must be declared in modules. Namespaces cannot contain extension members except in the same file and the same namespace declaration group where the type is defined.

The following example shows the extension of the existing `Microsoft.FSharp.Linq.QueryBuilder` class.

```
type Microsoft.FSharp.Linq.QueryBuilder with
    [<CustomOperation("existsNot")>]
    member __.ExistsNot (source: QuerySource<'T, 'Q>, predicate) =
        Enumerable.Any (source.Source, Func<_,_>(predicate)) |> not
```

Asynchronous Workflows

12/19/2018 • 4 minutes to read • [Edit Online](#)

NOTE

The API reference link will take you to MSDN. The docs.microsoft.com API reference is not complete.

This topic describes support in F# for performing computations asynchronously, that is, without blocking execution of other work. For example, asynchronous computations can be used to write applications that have UIs that remain responsive to users as the application performs other work.

Syntax

```
async { expression }
```

Remarks

In the previous syntax, the computation represented by `expression` is set up to run asynchronously, that is, without blocking the current computation thread when asynchronous sleep operations, I/O, and other asynchronous operations are performed. Asynchronous computations are often started on a background thread while execution continues on the current thread. The type of the expression is `Async<'T>`, where `'T` is the type returned by the expression when the `return` keyword is used. The code in such an expression is referred to as an *asynchronous block*, or *async block*.

There are a variety of ways of programming asynchronously, and the `Async` class provides methods that support several scenarios. The general approach is to create `Async` objects that represent the computation or computations that you want to run asynchronously, and then start these computations by using one of the triggering functions. The various triggering functions provide different ways of running asynchronous computations, and which one you use depends on whether you want to use the current thread, a background thread, or a .NET Framework task object, and whether there are continuation functions that should run when the computation finishes. For example, to start an asynchronous computation on the current thread, you can use `Async.StartImmediate`. When you start an asynchronous computation from the UI thread, you do not block the main event loop that processes user actions such as keystrokes and mouse activity, so your application remains responsive.

Asynchronous Binding by Using `let!`

In an asynchronous workflow, some expressions and operations are synchronous, and some are longer computations that are designed to return a result asynchronously. When you call a method asynchronously, instead of an ordinary `let` binding, you use `let!`. The effect of `let!` is to enable execution to continue on other computations or threads as the computation is being performed. After the right side of the `let!` binding returns, the rest of the asynchronous workflow resumes execution.

The following code shows the difference between `let` and `let!`. The line of code that uses `let` just creates an asynchronous computation as an object that you can run later by using, for example, `Async.StartImmediate` or `Async.RunSynchronously`. The line of code that uses `let!` starts the computation, and then the thread is suspended until the result is available, at which point execution continues.

```
// let just stores the result as an asynchronous operation.  
let (result1 : Async<byte[]>) = stream.AsyncRead(bufferSize)  
// let! completes the asynchronous operation and returns the data.  
let! (result2 : byte[]) = stream.AsyncRead(bufferSize)
```

In addition to `let!`, you can use `use!` to perform asynchronous bindings. The difference between `let!` and `use!` is the same as the difference between `let` and `use`. For `use!`, the object is disposed of at the close of the current scope. Note that in the current release of the F# language, `use!` does not allow a value to be initialized to null, even though `use` does.

Asynchronous Primitives

A method that performs a single asynchronous task and returns the result is called an *asynchronous primitive*, and these are designed specifically for use with `let!`. Several asynchronous primitives are defined in the F# core library. Two such methods for Web applications are defined in the module

`Microsoft.FSharp.Control.WebExtensions` : `WebRequest.AsyncGetResponse` and `WebClient.AsyncDownloadString`.

Both primitives download data from a Web page, given a URL. `AsyncGetResponse` produces a `System.Net.WebResponse` object, and `AsyncDownloadString` produces a string that represents the HTML for a Web page.

Several primitives for asynchronous I/O operations are included in the

`Microsoft.FSharp.Control.CommonExtensions` module. These extension methods of the `System.IO.Stream` class are `Stream.AsyncRead` and `Stream.AsyncWrite`.

You can also write your own asynchronous primitives by defining a function whose complete body is enclosed in an `async` block.

To use asynchronous methods in the .NET Framework that are designed for other asynchronous models with the F# asynchronous programming model, you create a function that returns an F# `Async` object. The F# library has functions that make this easy to do.

One example of using asynchronous workflows is included here; there are many others in the documentation for the methods of the `Async` class.

This example shows how to use asynchronous workflows to perform computations in parallel.

In the following code example, a function `fetchAsync` gets the HTML text returned from a Web request. The `fetchAsync` function contains an asynchronous block of code. When a binding is made to the result of an asynchronous primitive, in this case `AsyncDownloadString`, `let!` is used instead of `let`.

You use the function `Async.RunSynchronously` to execute an asynchronous operation and wait for its result. As an example, you can execute multiple asynchronous operations in parallel by using the `Async.Parallel` function together with the `Async.RunSynchronously` function. The `Async.Parallel` function takes a list of the `Async` objects, sets up the code for each `Async` task object to run in parallel, and returns an `Async` object that represents the parallel computation. Just as for a single operation, you call `Async.RunSynchronously` to start the execution.

The `runAll` function launches three asynchronous workflows in parallel and waits until they have all completed.

```
open System.Net
open Microsoft.FSharp.Control.WebExtensions

let urlList = [ "Microsoft.com", "http://www.microsoft.com/"
               "MSDN", "http://msdn.microsoft.com/"
               "Bing", "http://www.bing.com"
             ]

let fetchAsync(name, url:string) =
    async {
        try
            let uri = new System.Uri(url)
            let webClient = new WebClient()
            let! html = webClient.AsyncDownloadString(uri)
            printfn "Read %d characters for %s" html.Length name
        with
            | ex -> printfn "%s" (ex.Message);
    }

let runAll() =
    urlList
    |> Seq.map fetchAsync
    |> Async.Parallel
    |> Async.RunSynchronously
    |> ignore

runAll()
```

Query Expressions

3/26/2019 • 41 minutes to read • [Edit Online](#)

NOTE

The API reference links in this article will take you to MSDN. The docs.microsoft.com API reference is not complete.

Query expressions enable you to query a data source and put the data in a desired form. Query expressions provide support for LINQ in F#.

Syntax

```
query { expression }
```

Remarks

Query expressions are a type of computation expression similar to sequence expressions. Just as you specify a sequence by providing code in a sequence expression, you specify a set of data by providing code in a query expression. In a sequence expression, the `yield` keyword identifies data to be returned as part of the resulting sequence. In query expressions, the `select` keyword performs the same function. In addition to the `select` keyword, F# also supports a number of query operators that are much like the parts of a SQL SELECT statement. Here is an example of a simple query expression, along with code that connects to the Northwind OData source.

```
// Use the OData type provider to create types that can be used to access the Northwind database.  
// Add References to FSharp.Data.TypeProviders and System.Data.Services.Client  
open Microsoft.FSharp.Data.TypeProviders  
  
type Northwind = ODataService<"http://services.odata.org/Northwind/Northwind.svc">  
let db = Northwind.GetDataContext()  
  
// A query expression.  
let query1 =  
    query {  
        for customer in db.Customers do  
            select customer  
    }  
  
// Print results  
query1  
|> Seq.iter (fun customer -> printfn "Company: %s Contact: %s" customer.CompanyName customer.ContactName)
```

In the previous code example, the query expression is in curly braces. The meaning of the code in the expression is, return every customer in the Customers table in the database in the query results. Query expressions return a type that implements `IQueryable<T>` and `IEnumerable<T>`, and so they can be iterated using the `Seq module` as the example shows.

Every computation expression type is built from a builder class. The builder class for the query computation expression is `QueryBuilder`. For more information, see [Computation Expressions](#) and [Linq.QueryBuilder Class](#).

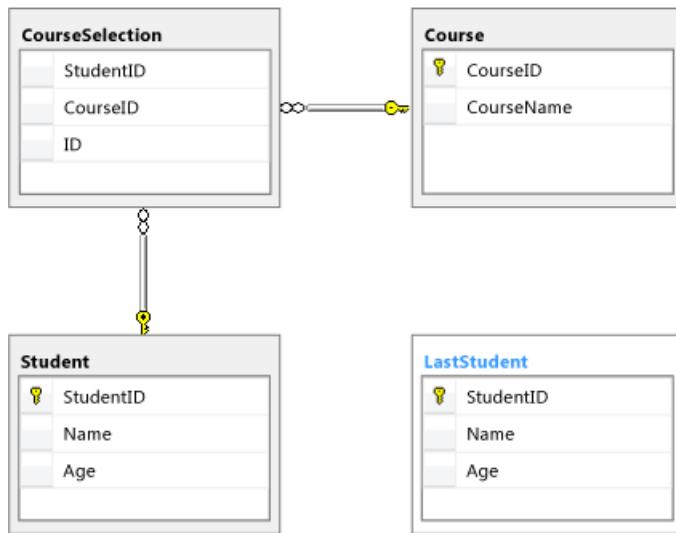

Query Operators

Query operators enable you to specify the details of the query, such as to put criteria on records to be returned, or specify the sorting order of results. The query source must support the query operator. If you attempt to use an unsupported query operator, `System.NotSupportedException` will be thrown.

Only expressions that can be translated to SQL are allowed in query expressions. For example, no function calls are allowed in the expressions when you use the `where` query operator.

Table 1 shows available query operators. In addition, see Table2, which compares SQL queries and the equivalent F# query expressions later in this topic. Some query operators aren't supported by some type providers. In particular, the OData type provider is limited in the query operators that it supports due to limitations in OData. For more information, see [ODataservice Type Provider \(F#\)](#).

This table assumes a database in the following form:

The code in the tables that follow also assumes the following database connection code. Projects should add references to `System.Data`, `System.Data.Linq`, and `FSharp.Data.TypeProviders` assemblies. The code that creates this database is included at the end of this topic.

```

open System
open Microsoft.FSharp.Data.TypeProviders
open System.Data.Linq.SqlClient
open System.Linq
open Microsoft.FSharp.Linq

type schema = SqlDataConnection< @"Data Source=SERVER\INSTANCE;Initial Catalog=MyDatabase;Integrated Security=SSPI;" >

let db = schema.GetDataContext()

// Needed for some query operator examples:
let data = [ 1; 5; 7; 11; 18; 21]
  
```

Table 1. Query Operators

OPERATOR	DESCRIPTION
----------	-------------

<code>contains</code>	Determines whether the selected elements include a specified element.
	<pre>query { for student in db.Student do select student.Age.Value contains 11 }</pre>
<code>count</code>	Returns the number of selected elements.
	<pre>query { for student in db.Student do select student count }</pre>
<code>last</code>	Selects the last element of those selected so far.
	<pre>query { for number in data do last }</pre>
<code>lastOrDefault</code>	Selects the last element of those selected so far, or a default value if no element is found.
	<pre>query { for number in data do where (number < 0) lastOrDefault }</pre>
<code>exactlyOne</code>	Selects the single, specific element selected so far. If multiple elements are present, an exception is thrown.
	<pre>query { for student in db.Student do where (student.StudentID = 1) select student exactlyOne }</pre>

```
exactlyOneOrDefault
```

Selects the single, specific element of those selected so far, or a default value if that element is not found.

```
query {  
    for student in db.Student do  
        where (student.StudentID = 1)  
        select student  
        exactlyOneOrDefault  
}
```

```
headOrDefault
```

Selects the first element of those selected so far, or a default value if the sequence contains no elements.

```
query {  
    for student in db.Student do  
        select student  
        headOrDefault  
}
```

```
select
```

Projects each of the elements selected so far.

```
query {  
    for student in db.Student do  
        select student  
}
```

```
where
```

Selects elements based on a specified predicate.

```
query {  
    for student in db.Student do  
        where (student.StudentID > 4)  
        select student  
}
```

```
minBy
```

Selects a value for each element selected so far and returns the minimum resulting value.

```
query {  
    for student in db.Student do  
        minBy student.StudentID  
}
```

<code>maxBy</code>	Selects a value for each element selected so far and returns the maximum resulting value.
	<pre>query { for student in db.Student do maxBy student.StudentID }</pre>
<code>groupBy</code>	Groups the elements selected so far according to a specified key selector.
	<pre>query { for student in db.Student do groupBy student.Age into g select (g.Key, g.Count()) }</pre>
<code>sortBy</code>	Sorts the elements selected so far in ascending order by the given sorting key.
	<pre>query { for student in db.Student do sortBy student.Name select student }</pre>
<code>sortByDescending</code>	Sorts the elements selected so far in descending order by the given sorting key.
	<pre>query { for student in db.Student do sortByDescending student.Name select student }</pre>
<code>thenBy</code>	Performs a subsequent ordering of the elements selected so far in ascending order by the given sorting key. This operator may only be used after a <code>sortBy</code> , <code>sortByDescending</code> , <code>thenBy</code> , or <code>thenByDescending</code> .
	<pre>query { for student in db.Student do where student.Age.HasValue sortBy student.Age.Value thenBy student.Name select student }</pre>

thenByDescending

Performs a subsequent ordering of the elements selected so far in descending order by the given sorting key. This operator may only be used after a `sortBy`, `sortByDescending`, `thenBy`, or `thenByDescending`.

```
query {  
    for student in db.Student do  
        where student.Age.HasValue  
        sortBy student.Age.Value  
        thenByDescending student.Name  
        select student  
}
```

groupValBy

Selects a value for each element selected so far and groups the elements by the given key.

```
query {  
    for student in db.Student do  
        groupValBy student.Name student.Age into g  
        select (g, g.Key, g.Count())  
}
```

join

Correlates two sets of selected values based on matching keys. Note that the order of the keys around the = sign in a join expression is significant. In all joins, if the line is split after the `->` symbol, the indentation must be indented at least as far as the keyword `for`.

```
query {  
    for student in db.Student do  
        join selection in db.CourseSelection  
            on (student.StudentID =  
                selection.StudentID)  
        select (student, selection)  
}
```

groupJoin

Correlates two sets of selected values based on matching keys and groups the results. Note that the order of the keys around the = sign in a join expression is significant.

```
query {  
    for student in db.Student do  
        groupJoin courseSelection in  
            db.CourseSelection  
            on (student.StudentID =  
                courseSelection.StudentID) into g  
        for courseSelection in g do  
            join course in db.Course  
                on (courseSelection.CourseID =  
                    course.CourseID)  
            select (student.Name, course.CourseName)  
}
```

```
leftOuterJoin
```

Correlates two sets of selected values based on matching keys and groups the results. If any group is empty, a group with a single default value is used instead. Note that the order of the keys around the = sign in a join expression is significant.

```
query {  
    for student in db.Student do  
        leftOuterJoin selection in  
            db.CourseSelection  
            on (student.StudentID =  
                selection.StudentID) into result  
            for selection in result.DefaultIfEmpty() do  
                select (student, selection)  
}
```

```
sumByNullable
```

Selects a nullable value for each element selected so far and returns the sum of these values. If any nullable does not have a value, it is ignored.

```
query {  
    for student in db.Student do  
        sumByNullable student.Age  
}
```

```
minByNullable
```

Selects a nullable value for each element selected so far and returns the minimum of these values. If any nullable does not have a value, it is ignored.

```
query {  
    for student in db.Student do  
        minByNullable student.Age  
}
```

```
maxByNullable
```

Selects a nullable value for each element selected so far and returns the maximum of these values. If any nullable does not have a value, it is ignored.

```
query {  
    for student in db.Student do  
        maxByNullable student.Age  
}
```

`averageByNullable`

Selects a nullable value for each element selected so far and returns the average of these values. If any nullable does not have a value, it is ignored.

```
query {  
    for student in db.Student do  
        averageByNullable (Nullable.float  
student.Age)  
}
```

`averageBy`

Selects a value for each element selected so far and returns the average of these values.

```
query {  
    for student in db.Student do  
        averageBy (float student.StudentID)  
}
```

`distinct`

Selects distinct elements from the elements selected so far.

```
query {  
    for student in db.Student do  
        join selection in db.CourseSelection  
            on (student.StudentID =  
selection.StudentID)  
        distinct  
}
```

`exists`

Determines whether any element selected so far satisfies a condition.

```
query {  
    for student in db.Student do  
        where  
            (query {  
                for courseSelection in  
db.CourseSelection do  
                    exists (courseSelection.StudentID =  
student.StudentID) })  
                select student  
}
```

`find`

Selects the first element selected so far that satisfies a specified condition.

```
query {  
    for student in db.Student do  
        find (student.Name = "Abercrombie, Kim")  
}
```

<code>all</code>	Determines whether all elements selected so far satisfy a condition.
	<pre>query { for student in db.Student do all (SqlMethods.Like(student.Name, "%,%")) }</pre>
<code>head</code>	Selects the first element from those selected so far.
	<pre>query { for student in db.Student do head }</pre>
<code>nth</code>	Selects the element at a specified index amongst those selected so far.
	<pre>query { for numbers in data do nth 3 }</pre>
<code>skip</code>	Bypasses a specified number of the elements selected so far and then selects the remaining elements.
	<pre>query { for student in db.Student do skip 1 }</pre>
<code>skipWhile</code>	Bypasses elements in a sequence as long as a specified condition is true and then selects the remaining elements.
	<pre>query { for number in data do skipWhile (number < 3) select student }</pre>
<code>sumBy</code>	Selects a value for each element selected so far and returns the sum of these values.
	<pre>query { for student in db.Student do sumBy student.StudentID }</pre>

<code>take</code>	Selects a specified number of contiguous elements from those selected so far.
	<pre>query { for student in db.Student do select student take 2 }</pre>
<code>takeWhile</code>	Selects elements from a sequence as long as a specified condition is true, and then skips the remaining elements.
	<pre>query { for number in data do takeWhile (number < 10) }</pre>
<code>sortByNullable</code>	Sorts the elements selected so far in ascending order by the given nullable sorting key.
	<pre>query { for student in db.Student do sortByNullable student.Age select student }</pre>
<code>sortByNullableDescending</code>	Sorts the elements selected so far in descending order by the given nullable sorting key.
	<pre>query { for student in db.Student do sortByNullableDescending student.Age select student }</pre>
<code>thenByNullable</code>	Performs a subsequent ordering of the elements selected so far in ascending order by the given nullable sorting key. This operator may only be used immediately after a <code>sortBy</code> , <code>sortByDescending</code> , <code>thenBy</code> , or <code>thenByDescending</code> , or their nullable variants.
	<pre>query { for student in db.Student do sortBy student.Name thenByNullable student.Age select student }</pre>

```
thenByNullableDescending
```

Performs a subsequent ordering of the elements selected so far in descending order by the given nullable sorting key. This operator may only be used immediately after a `sortBy`, `sortByDescending`, `thenBy`, or `thenByDescending`, or their nullable variants.

```
query {
    for student in db.Student do
        sortBy student.Name
        thenByNullableDescending student.Age
        select student
}
```

Comparison of Transact-SQL and F# Query Expressions

The following table shows some common Transact-SQL queries and their equivalents in F#. The code in this table also assumes the same database as the previous table and the same initial code to set up the type provider.

Table 2. Transact-SQL and F# Query Expressions

TRANSACT-SQL (NOT CASE SENSITIVE)	F# QUERY EXPRESSION (CASE SENSITIVE)
Select all fields from table.	<pre>// All students. query { for student in db.Student do select student }</pre>
Count records in a table.	<pre>// Count of students. query { for student in db.Student do count }</pre>
EXISTS	<pre>// Find students who have signed up at least one course. query { for student in db.Student do where (query { for courseSelection in db.CourseSelection do exists (courseSelection.StudentID = student.StudentID) }) select student }</pre>

```
SELECT * FROM Student
WHERE EXISTS
    (SELECT * FROM CourseSelection
     WHERE CourseSelection.StudentID =
         Student.StudentID)
```

```
// Find students who have signed up at least one course.
query {
    for student in db.Student do
        where
            (query {
                for courseSelection in
                    db.CourseSelection do
                        exists (courseSelection.StudentID =
                            student.StudentID) })
                select student
}
```

Grouping

```
SELECT Student.Age, COUNT( * ) FROM Student  
GROUP BY Student.Age
```

```
// Group by age and count.  
query {  
    for n in db.Student do  
        groupBy n.Age into g  
        select (g.Key, g.Count())  
    }  
// OR  
query {  
    for n in db.Student do  
        groupValBy n.Age n.Age into g  
        select (g.Key, g.Count())  
    }
```

Grouping with condition.

```
SELECT Student.Age, COUNT( * )  
FROM Student  
GROUP BY Student.Age  
HAVING student.Age > 10
```

```
// Group students by age where age > 10.  
query {  
    for student in db.Student do  
        groupBy student.Age into g  
        where (g.Key.HasValue && g.Key.Value > 10)  
        select (g.Key, g.Count())  
    }
```

Grouping with count condition.

```
SELECT Student.Age, COUNT( * )  
FROM Student  
GROUP BY Student.Age  
HAVING COUNT( * ) > 1
```

```
// Group students by age and count number of  
// students  
// at each age with more than 1 student.  
query {  
    for student in db.Student do  
        groupBy student.Age into group  
        where (group.Count() > 1)  
        select (group.Key, group.Count())  
    }
```

Grouping, counting, and summing.

```
SELECT Student.Age, COUNT( * ), SUM(Student.Age)  
as total  
FROM Student  
GROUP BY Student.Age
```

```
// Group students by age and sum ages.  
query {  
    for student in db.Student do  
        groupBy student.Age into g  
        let total =  
            query {  
                for student in g do  
                    sumByNullable student.Age  
            }  
        select (g.Key, g.Count(), total)  
    }
```

Grouping, counting, and ordering by count.

```
SELECT Student.Age, COUNT( * ) as myCount  
FROM Student  
GROUP BY Student.Age  
HAVING COUNT( * ) > 1  
ORDER BY COUNT( * ) DESC
```

```
// Group students by age, count number of  
// students  
// at each age, and display all with count > 1  
// in descending order of count.  
query {  
    for student in db.Student do  
        groupBy student.Age into g  
        where (g.Count() > 1)  
        sortByDescending (g.Count())  
        select (g.Key, g.Count())  
    }
```

IN a set of specified values

```
SELECT *
FROM Student
WHERE Student.StudentID IN (1, 2, 5, 10)
```

```
// Select students where studentID is one of a
given list.
let idQuery =
    query {
        for id in [1; 2; 5; 10] do
            select id
    }
query {
    for student in db.Student do
        where (idQuery.Contains(student.StudentID))
        select student
}
```

LIKE and **TOP**.

```
-- '_e%' matches strings where the second
character is 'e'
SELECT TOP 2 * FROM Student
WHERE Student.Name LIKE '_e%'
```

```
// Look for students with Name match _e% pattern
and take first two.
query {
    for student in db.Student do
        where (SqlMethods.Like( student.Name, "_e%"))
    )
    select student
    take 2
}
```

LIKE with pattern match set.

```
-- '[abc]%' matches strings where the first
character is
-- 'a', 'b', 'c', 'A', 'B', or 'C'
SELECT * FROM Student
WHERE Student.Name LIKE '[abc]%'
```

```
query {
    for student in db.Student do
        where (SqlMethods.Like( student.Name, "
[abc]%" ) )
        select student
}
```

LIKE with set exclusion pattern.

```
-- '[^abc]%' matches strings where the first
character is
-- not 'a', 'b', 'c', 'A', 'B', or 'C'
SELECT * FROM Student
WHERE Student.Name LIKE '[^abc]%'
```

```
// Look for students with name matching [^abc]%%
pattern.
query {
    for student in db.Student do
        where (SqlMethods.Like( student.Name, "
[^abc]%" ) )
        select student
}
```

LIKE on one field, but select a different field.

```
SELECT StudentID AS ID FROM Student
WHERE Student.Name LIKE '[^abc]%'
```

```
query {
    for n in db.Student do
        where (SqlMethods.Like( n.Name, "[^abc]%" ) )
        select n.StudentID
}
```

`LIKE`, with substring search.

```
SELECT * FROM Student
WHERE Student.Name like '%A%'
```

```
// Using Contains as a query filter.
query {
    for student in db.Student do
        where (student.Name.Contains("a"))
        select student
}
```

Simple `JOIN` with two tables.

```
SELECT * FROM Student
JOIN CourseSelection
ON Student.StudentID = CourseSelection.StudentID
```

```
// Join Student and CourseSelection tables.
query {
    for student in db.Student do
        join selection in db.CourseSelection
            on (student.StudentID =
selection.StudentID)
        select (student, selection)
}
```

`LEFT JOIN` with two tables.

```
SELECT * FROM Student
LEFT JOIN CourseSelection
ON Student.StudentID = CourseSelection.StudentID
```

```
//Left Join Student and CourseSelection tables.
query {
    for student in db.Student do
        leftOuterJoin selection in
db.CourseSelection
            on (student.StudentID =
selection.StudentID) into result
        for selection in result.DefaultIfEmpty() do
            select (student, selection)
}
```

`JOIN` with `COUNT`

```
SELECT COUNT( * ) FROM Student
JOIN CourseSelection
ON Student.StudentID = CourseSelection.StudentID
```

```
// Join with count.
query {
    for n in db.Student do
        join e in db.CourseSelection
            on (n.StudentID = e.StudentID)
        count
}
```

`DISTINCT`

```
SELECT DISTINCT StudentID FROM CourseSelection
```

```
// Join with distinct.
query {
    for student in db.Student do
        join selection in db.CourseSelection
            on (student.StudentID =
selection.StudentID)
        distinct
}
```

Distinct count.

```
SELECT DISTINCT COUNT(StudentID) FROM  
CourseSelection
```

```
// Join with distinct and count.  
query {  
    for n in db.Student do  
        join e in db.CourseSelection  
            on (n.StudentID = e.StudentID)  
        distinct  
        count  
}
```

BETWEEN

```
SELECT * FROM Student  
WHERE Student.Age BETWEEN 10 AND 15
```

```
// Selecting students with ages between 10 and  
15.  
query {  
    for student in db.Student do  
        where (student.Age ?>= 10 && student.Age ?<  
15)  
        select student  
}
```

OR

```
SELECT * FROM Student  
WHERE Student.Age = 11 OR Student.Age = 12
```

```
// Selecting students with age that's either 11  
or 12.  
query {  
    for student in db.Student do  
        where (student.Age.Value = 11 ||  
student.Age.Value = 12)  
        select student  
}
```

OR with ordering

```
SELECT * FROM Student  
WHERE Student.Age = 12 OR Student.Age = 13  
ORDER BY Student.Age DESC
```

```
// Selecting students in a certain age range and  
sorting.  
query {  
    for n in db.Student do  
        where (n.Age.Value = 12 || n.Age.Value = 13)  
        sortByNullbleDescending n.Age  
        select n  
}
```

TOP , OR , and ordering.

```
SELECT TOP 2 student.Name FROM Student  
WHERE Student.Age = 11 OR Student.Age = 12  
ORDER BY Student.Name DESC
```

```
// Selecting students with certain ages,  
// taking account of the possibility of nulls.  
query {  
    for student in db.Student do  
        where  
            ((student.Age.HasValue &&  
student.Age.Value = 11) ||  
            (student.Age.HasValue &&  
student.Age.Value = 12))  
        sortByDescending student.Name  
        select student.Name  
        take 2  
}
```

UNION of two queries.

```
SELECT * FROM Student
UNION
SELECT * FROM lastStudent
```

```
let query1 =
    query {
        for n in db.Student do
            select (n.Name, n.Age)
    }

let query2 =
    query {
        for n in db.LastStudent do
            select (n.Name, n.Age)
    }

query2.Union (query1)
```

Intersection of two queries.

```
SELECT * FROM Student
INTERSECT
SELECT * FROM LastStudent
```

```
let query1 =
    query {
        for n in db.Student do
            select (n.Name, n.Age)
    }

let query2 =
    query {
        for n in db.LastStudent do
            select (n.Name, n.Age)
    }

query1.Intersect(query2)
```

CASE condition.

```
SELECT student.StudentID,
CASE Student.Age
    WHEN -1 THEN 100
    ELSE Student.Age
END,
Student.Age
FROM Student
```

```
// Using if statement to alter results for
special value.
query {
    for student in db.Student do
        select
            (if student.Age.HasValue &&
student.Age.Value = -1 then
                (student.StudentID,
System.Nullable<int>(100), student.Age)
            else (student.StudentID, student.Age,
student.Age))
}
```

Multiple cases.

```
SELECT Student.StudentID,
CASE Student.Age
    WHEN -1 THEN 100
    WHEN 0 THEN 1000
    ELSE Student.Age
END,
Student.Age
FROM Student
```

```
// Using if statement to alter results for
special values.
query {
    for student in db.Student do
        select
            (if student.Age.HasValue &&
student.Age.Value = -1 then
                (student.StudentID,
System.Nullable<int>(100), student.Age)
            elif student.Age.HasValue &&
student.Age.Value = 0 then
                (student.StudentID,
System.Nullable<int>(1000), student.Age)
            else (student.StudentID, student.Age,
student.Age))
}
```

Multiple tables.

```
SELECT * FROM Student, Course
```

```
// Multiple table select.  
query {  
    for student in db.Student do  
        for course in db.Course do  
            select (student, course)  
}
```

Multiple joins.

```
SELECT Student.Name, Course.CourseName  
FROM Student  
JOIN CourseSelection  
ON CourseSelection.StudentID = Student.StudentID  
JOIN Course  
ON Course.CourseID = CourseSelection.CourseID
```

```
// Multiple joins.  
query {  
    for student in db.Student do  
        join courseSelection in db.CourseSelection  
            on (student.StudentID =  
                courseSelection.StudentID)  
        join course in db.Course  
            on (courseSelection.CourseID =  
                course.CourseID)  
        select (student.Name, course.CourseName)  
}
```

Multiple left outer joins.

```
SELECT Student.Name, Course.CourseName  
FROM Student  
LEFT OUTER JOIN CourseSelection  
ON CourseSelection.StudentID = Student.StudentID  
LEFT OUTER JOIN Course  
ON Course.CourseID = CourseSelection.CourseID
```

```
// Using leftOuterJoin with multiple joins.  
query {  
    for student in db.Student do  
        leftOuterJoin courseSelection in  
            db.CourseSelection  
            on (student.StudentID =  
                courseSelection.StudentID) into g1  
        for courseSelection in g1.DefaultIfEmpty()  
            do  
                leftOuterJoin course in db.Course  
                    on (courseSelection.CourseID =  
                        course.CourseID) into g2  
                for course in g2.DefaultIfEmpty() do  
                    select (student.Name, course.CourseName)  
}
```

The following code can be used to create the sample database for these examples.

```
SET ANSI_NULLS ON  
GO  
SET QUOTED_IDENTIFIER ON  
GO  
  
USE [master];  
GO  
  
IF EXISTS (SELECT * FROM sys.databases WHERE name = 'MyDatabase')  
DROP DATABASE MyDatabase;  
GO  
  
-- Create the MyDatabase database.  
CREATE DATABASE MyDatabase COLLATE SQL_Latin1_General_CI_AS;  
GO  
  
-- Specify a simple recovery model  
-- to keep the log growth to a minimum.  
ALTER DATABASE MyDatabase  
SET RECOVERY SIMPLE;  
GO  
  
USE MyDatabase;
```

```
GO
```

```
CREATE TABLE [dbo].[Course] (
[CourseID]      INT          NOT NULL,
[CourseName]    NVARCHAR (50) NOT NULL,
PRIMARY KEY CLUSTERED ([CourseID] ASC)
);

CREATE TABLE [dbo].[Student] (
[StudentID]     INT          NOT NULL,

Code Quotations

12/19/2018 • 7 minutes to read • [Edit Online](#)

NOTE

The API reference link will take you to MSDN. The docs.microsoft.com API reference is not complete.

This topic describes *code quotations*, a language feature that enables you to generate and work with F# code expressions programmatically. This feature lets you generate an abstract syntax tree that represents F# code. The abstract syntax tree can then be traversed and processed according to the needs of your application. For example, you can use the tree to generate F# code or generate code in some other language.

Quoted Expressions

A *quoted expression* is an F# expression in your code that is delimited in such a way that it is not compiled as part of your program, but instead is compiled into an object that represents an F# expression. You can mark a quoted expression in one of two ways: either with type information or without type information. If you want to include type information, you use the symbols `<@` and `@>` to delimit the quoted expression. If you do not need type information, you use the symbols `<@@` and `@@>`. The following code shows typed and untyped quotations.

```
open Microsoft.FSharp.Quotations
// A typed code quotation.
let expr : Expr<int> = <@ 1 + 1 @>
// An untyped code quotation.
let expr2 : Expr = <@@ 1 + 1 @@>
```

Traversing a large expression tree is faster if you do not include type information. The resulting type of an expression quoted with the typed symbols is `Expr<'T>`, where the type parameter has the type of the expression as determined by the F# compiler's type inference algorithm. When you use code quotations without type information, the type of the quoted expression is the non-generic type `Expr`. You can call the `Raw` property on the typed `Expr` class to obtain the untyped `Expr` object.

There are a variety of static methods that allow you to generate F# expression objects programmatically in the `Expr` class without using quoted expressions.

Note that a code quotation must include a complete expression. For a `let` binding, for example, you need both the definition of the bound name and an additional expression that uses the binding. In verbose syntax, this is an expression that follows the `in` keyword. At the top-level in a module, this is just the next expression in the module, but in a quotation, it is explicitly required.

Therefore, the following expression is not valid.

```
// Not valid:
// <@ let f x = x + 1 @>
```

But the following expressions are valid.

```
// Valid:  
<@ let f x = x + 10 in f 20 @>  
// Valid:  
<@  
    let f x = x + 10  
    f 20  
@>
```

To use code quotations, you must add an import declaration (by using the `open` keyword) that opens the [Microsoft.FSharp.Quotations](#) namespace.

The F# PowerPack provides support for evaluating and executing F# expression objects.

Expr Type

An instance of the `Expr` type represents an F# expression. Both the generic and the non-generic `Expr` types are documented in the F# library documentation. For more information, see [Microsoft.FSharp.Quotations Namespace](#) and [Quotations.Expr Class](#).

Splicing Operators

Splicing enables you to combine literal code quotations with expressions that you have created programmatically or from another code quotation. The `%` and `%%` operators enable you to add an F# expression object into a code quotation. You use the `%` operator to insert a typed expression object into a typed quotation; you use the `%%` operator to insert an untyped expression object into an untyped quotation. Both operators are unary prefix operators. Thus if `expr` is an untyped expression of type `Expr`, the following code is valid.

```
<@@ 1 + %%expr @@>
```

And if `expr` is a typed quotation of type `Expr<int>`, the following code is valid.

```
<@ 1 + %expr @>
```

Example

Description

The following example illustrates the use of code quotations to put F# code into an expression object and then print the F# code that represents the expression. A function `println` is defined that contains a recursive function `print` that displays an F# expression object (of type `Expr`) in a friendly format. There are several active patterns in the [Microsoft.FSharp.Quotations.Patterns](#) and [Microsoft.FSharp.Quotations.DerivedPatterns](#) modules that can be used to analyze expression objects. This example does not include all the possible patterns that might appear in an F# expression. Any unrecognized pattern triggers a match to the wildcard pattern (`_`) and is rendered by using the `ToString` method, which, on the `Expr` type, lets you know the active pattern to add to your match expression.

Code

```
module Print  
open Microsoft.FSharp.Quotations  
open Microsoft.FSharp.Quotations.Patterns  
open Microsoft.FSharp.Quotations.DerivedPatterns  
  
let println expr =  
    let rec print expr =
```

```

match expr with
| Application(expr1, expr2) ->
    // Function application.
    print expr1
    printf " "
    print expr2
| SpecificCall <@@ (+) @@> (_, _, exprList) ->
    // Matches a call to (+). Must appear before Call pattern.
    print exprList.Head
    printf " + "
    print exprList.Tail.Head
| Call(exprOpt, methodInfo, exprList) ->
    // Method or module function call.
    match exprOpt with
    | Some expr -> print expr
    | None -> printf "%s" methodInfo.DeclaringType.Name
    printf ".%s(" methodInfo.Name
    if (exprList.IsEmpty) then printf ")" else
    print exprList.Head
    for expr in exprList.Tail do
        printf ","
        print expr
    printf ")"
| Int32(n) ->
    printf "%d" n
| Lambda(param, body) ->
    // Lambda expression.
    printf "fun (%s:%s) -> " param.Name (param.Type.ToString())
    print body
| Let(var, expr1, expr2) ->
    // Let binding.
    if (var.IsMutable) then
        printf "let mutable %s = " var.Name
    else
        printf "let %s = " var.Name

println exprLambda
println exprCall
println <@@ let f x = x + 10 in f 10 @@>

```

Output

```

fun (x:System.Int32) -> x + 1
a + 1
let f = fun (x:System.Int32) -> x + 10 in f 10

```

Example

Description

You can also use the three active patterns in the [ExprShape module](#) to traverse expression trees with fewer active patterns. These active patterns can be useful when you want to traverse a tree but you do not need all the information in most of the nodes. When you use these patterns, any F# expression matches one of the following three patterns: `ShapeVar` if the expression is a variable, `ShapeLambda` if the expression is a lambda expression, or `ShapeCombination` if the expression is anything else. If you traverse an expression tree by using the active patterns as in the previous code example, you have to use many more patterns to handle all possible F# expression types, and your code will be more complex. For more information, see [ExprShape.ShapeVar|ShapeLambda|ShapeCombination Active Pattern](#).

The following code example can be used as a basis for more complex traversals. In this code, an expression tree is created for an expression that involves a function call, `add`. The `SpecificCall` active pattern is used to detect any call to `add` in the expression tree. This active pattern assigns the arguments of the call to the `exprList` value. In this case, there are only two, so these are pulled out and the function is called recursively on the arguments. The results are inserted into a code quotation that represents a call to `mul` by using the splice operator (`%%`). The `printfn` function from the previous example is used to display the results.

The code in the other active pattern branches just regenerates the same expression tree, so the only change in the resulting expression is the change from `add` to `mul`.

Code

```

module Module1
open Print
open Microsoft.FSharp.Quotations
open Microsoft.FSharp.Quotations.DerivedPatterns
open Microsoft.FSharp.Quotations.ExprShape

let add x y = x + y
let mul x y = x * y

let rec substituteExpr expression =
    match expression with
    | SpecificCall <@@ add @@> (_, _, exprList) ->
        let lhs = substituteExpr exprList.Head
        let rhs = substituteExpr exprList.Tail.Head
        <@@ mul %%lhs %%rhs @@>
    | ShapeVar var -> Expr.Var var
    | ShapeLambda (var, expr) -> Expr.Lambda (var, substituteExpr expr)
    | ShapeCombination(shapeComboObject, exprList) ->
        RebuildShapeCombination(shapeComboObject, List.map substituteExpr exprList)

let expr1 = <@@ 1 + (add 2 (add 3 4)) @@>
printfn expr1
let expr2 = substituteExpr expr1
printfn expr2

```

Output

```

1 + Module1.add(2,Module1.add(3,4))
1 + Module1.mul(2,Module1.mul(3,4))

```

The fixed keyword

12/19/2018 • 2 minutes to read • [Edit Online](#)

F# 4.1 introduces the `fixed` keyword, which allows you to "pin" a local onto the stack to prevent it from being collected or moved during garbage-collection. It is used for low-level programming scenarios.

Syntax

```
use ptr = fixed expression
```

Remarks

This extends the syntax of expressions to allow extracting a pointer and binding it to a name which is prevented from being collected or moved during garbage-collection.

A pointer from an expression is fixed via the `fixed` keyword is bound to an identifier via the `use` keyword. The semantics of this are similar to resource management via the `use` keyword. The pointer is fixed while it is in scope, and once it is out of scope, it is no longer fixed. `fixed` cannot be used outside the context of a `use` binding. You must bind the pointer to a name with `use`.

Use of `fixed` must occur within an expression in a function or a method. It cannot be used at a script-level or module-level scope.

Like all pointer code, this is an unsafe feature and will emit a warning when used.

Example

```
open Microsoft.FSharp.NativeInterop

type Point = { mutable X: int; mutable Y: int}

let squareWithPointer (p: nativeptr<int>) =
    // Dereference the pointer at the 0th address.
    let mutable value = NativePtr.get p 0

    // Perform some work
    value <- value * value

    // Set the value in the pointer at the 0th address.
    NativePtr.set p 0 value

let pnt = { X = 1; Y = 2 }
printfn "pnt before - X: %d Y: %d" pnt.X pnt.Y // prints 1 and 2

// Note that the use of 'fixed' is inside a function.
// You cannot fix a pointer at a script-level or module-level scope.
let doPointerWork() =
    use ptr = fixed &pnt.Y

    // Square the Y value
    squareWithPointer ptr
    printfn "pnt after - X: %d Y: %d" pnt.X pnt.Y // prints 1 and 4

doPointerWork()
```

Byrefs

2/28/2019 • 6 minutes to read • [Edit Online](#)

F# has two major feature areas that deal in the space of low-level programming:

- The `byref` / `inref` / `outref` types, which are managed pointers. They have restrictions on usage so that you cannot compile a program that is invalid at runtime.
- A `byref`-like struct, which is a [structure](#) that has similar semantics and the same compile-time restrictions as `byref<'T>`. One example is `Span<T>`.

Syntax

```
// Byref types as parameters
let f (x: byref<'T>) = ()
let g (x: inref<'T>) = ()
let h (x: outref<'T>) = ()

// Calling a function with a byref parameter
let mutable x = 3
f &x

// Declaring a byref-like struct
open System.Runtime.CompilerServices

[<Struct; IsByRefLike>]
type S(count1: int, count2: int) =
    member x.Count1 = count1
    member x.Count2 = count2
```

Byref, inref, and outref

There are three forms of `byref`:

- `inref<'T>`, a managed pointer for reading the underlying value.
- `outref<'T>`, a managed pointer for writing to the underlying value.
- `byref<'T>`, a managed pointer for reading and writing the underlying value.

A `byref<'T>` can be passed where an `inref<'T>` is expected. Similarly, a `byref<'T>` can be passed where an `outref<'T>` is expected.

Using byrefs

To use a `inref<'T>`, you need to get a pointer value with `&`:

```
open System

let f (dt: inref<DateTime>) =
    printfn "Now: %s" (dt.ToString())

let dt = DateTime.Now
f &dt // Pass a pointer to 'dt'
```

To write to the pointer by using an `outref<'T>` or `byref<'T>`, you must also make the value you grab a pointer to

```
mutable .
```

```
open System

let f (dt: byref<DateTime>) =
    printfn "Now: %s" (dt.ToString())
    dt <- DateTime.Now

// Make 'dt' mutable
let mutable dt = DateTime.Now

// Now you can pass the pointer to 'dt'
f &dt
```

If you are only writing the pointer instead of reading it, consider using `outref<'T>` instead of `byref<'T>`.

Inref semantics

Consider the following code:

```
let f (x: inref<SomeStruct>) = s.SomeField
```

Semantically, this means the following:

- The holder of the `x` pointer may only use it to read the value.
- Any pointer acquired to `struct` fields nested within `SomeStruct` are given type `inref<_>`.

The following is also true:

- There is no implication that other threads or aliases do not have write access to `x`.
- There is no implication that `SomeStruct` is immutable by virtue of `x` being an `inref`.

However, for F# value types that **are** immutable, the `this` pointer is inferred to be an `inref`.

All of these rules together mean that the holder of an `inref` pointer may not modify the immediate contents of the memory being pointed to.

Outref semantics

The purpose of `outref<'T>` is to indicate that the pointer should only be read from. Unexpectedly, `outref<'T>` permits reading the underlying value despite its name. This is for compatibility purposes. Semantically, `outref<'T>` is no different than `byref<'T>`.

Interop with C#

C# supports the `in ref` and `out ref` keywords, in addition to `ref` returns. The following table shows how F# interprets what C# emits:

C# CONSTRUCT	F# INFERS
<code>ref</code> return value	<code>outref<'T></code>
<code>ref readonly</code> return value	<code>inref<'T></code>
<code>in ref</code> parameter	<code>inref<'T></code>
<code>out ref</code> parameter	<code>outref<'T></code>

The following table shows what F# emits:

F# CONSTRUCT	EMITTED CONSTRUCT
<code>inref<'T></code> argument	<code>[In]</code> attribute on argument
<code>inref<'T></code> return	<code>modreq</code> attribute on value
<code>inref<'T></code> in abstract slot or implementation	<code>modreq</code> on argument or return
<code>outref<'T></code> argument	<code>[Out]</code> attribute on argument

Type inference and overloading rules

An `inref<'T>` type is inferred by the F# compiler in the following cases:

1. A .NET parameter or return type that has an `IsReadOnly` attribute.
2. The `this` pointer on a struct type that has no mutable fields.
3. The address of a memory location derived from another `inref<_>` pointer.

When an implicit address of an `inref` is being taken, an overload with an argument of type `SomeType` is preferred to an overload with an argument of type `inref<SomeType>`. For example:

```
type C() =
    static member M(x: System.DateTime) = x.AddDays(1.0)
    static member M(x: inref<System.DateTime>) = x.AddDays(2.0)
    static member M2(x: System.DateTime, y: int) = x.AddDays(1.0)
    static member M2(x: inref<System.DateTime>, y: int) = x.AddDays(2.0)

let res = System.DateTime.Now
let v = C.M(res)
let v2 = C.M2(res, 4)
```

In both cases, the overloads taking `System.DateTime` are resolved rather than the overloads taking `inref<System.DateTime>`.

Byref-like structs

In addition to the `byref` / `inref` / `outref` trio, you can define your own structs that can adhere to `byref`-like semantics. This is done with the [IsByRefLikeAttribute](#) attribute:

```
open System
open System.Runtime.CompilerServices

[<IsByRefLike; Struct>]
type S(count1: Span<int>, count2: Span<int>) =
    member x.Count1 = count1
    member x.Count2 = count2
```

`IsByRefLike` does not imply `Struct`. Both must be present on the type.

A "`byref`-like" struct in F# is a stack-bound value type. It is never allocated on the managed heap. A `byref`-like struct is useful for high-performance programming, as it is enforced with set of strong checks about lifetime and non-capture. The rules are:

- They can be used as function parameters, method parameters, local variables, method returns.
- They cannot be static or instance members of a class or normal struct.
- They cannot be captured by any closure construct (`async` methods or lambda expressions).

- They cannot be used as a generic parameter.

This last point is crucial for F# pipeline-style programming, as `|>` is a generic function that parameterizes its input types. This restriction may be relaxed for `|>` in the future, as it is inline and does not make any calls to non-inlined generic functions in its body.

Although these rules very strongly restrict usage, they do so to fulfill the promise of high-performance computing in a safe manner.

Byref returns

Byref returns from F# functions or members can be produced and consumed. When consuming a `byref`-returning method, the value is implicitly dereferenced. For example:

```
let safeSum(bytes: Span<byte>) =
    let mutable sum = 0
    for i in 0 .. bytes.Length - 1 do
        sum <- sum + int bytes.[i]
    sum

let sum = safeSum(mySpanOfBytes)
printfn "%d" sum // 'sum' is of type 'int'
```

To avoid the implicit dereference, such as passing a reference through multiple chained calls, use `&x` (where `x` is the value).

You can also directly assign to a return `byref`. Consider the following (highly imperative) program:

```
type C() =
    let mutable nums = [| 1; 3; 7; 15; 31; 63; 127; 255; 511; 1023 |]

    override __.ToString() = String.Join(' ', nums)

    member __.FindLargestSmallerThan(target: int) =
        let mutable ctr = nums.Length - 1

        while ctr > 0 && nums.[ctr] >= target do ctr <- ctr - 1

        if ctr > 0 then &nums.[ctr] else &nums.[0]

[<EntryPoint>]
let main argv =
    let c = C()
    printfn "Original sequence: %s" (c.ToString())

    let v = &c.FindLargestSmallerThan 16

    v <- v*2 // Directly assign to the byref return

    printfn "New sequence:      %s" (c.ToString())

    0 // return an integer exit code
```

This is the output:

```
Original sequence: 1 3 7 15 31 63 127 255 511 1023
New sequence:      1 3 7 30 31 63 127 255 511 1023
```

Scoping for byrefs

A `let`-bound value cannot have its reference exceed the scope in which it was defined. For example, the following is disallowed:

```
let test2 () =
    let x = 12
    &x // Error: 'x' exceeds its defined scope!

let test () =
    let x =
        let y = 1
        &y // Error: `y` exceeds its defined scope!
()
```

This prevents you from getting different results depending on if you compile with optimizations on or off.

Reference Cells

12/19/2018 • 2 minutes to read • [Edit Online](#)

Reference cells are storage locations that enable you to create mutable values with reference semantics.

Syntax

```
ref expression
```

Remarks

You use the `ref` operator before a value to create a new reference cell that encapsulates the value. You can then change the underlying value because it is mutable.

A reference cell holds an actual value; it is not just an address. When you create a reference cell by using the `ref` operator, you create a copy of the underlying value as an encapsulated mutable value.

You can dereference a reference cell by using the `!` (bang) operator.

The following code example illustrates the declaration and use of reference cells.

```
// Declare a reference.  
let refVar = ref 6  
  
// Change the value referred to by the reference.  
refVar := 50  
  
// Dereference by using the ! operator.  
printfn "%d" !refVar
```

The output is `50`.

Reference cells are instances of the `Ref` generic record type, which is declared as follows.

```
type Ref<'a> =  
{ mutable contents: 'a }
```

The type `'a ref` is a synonym for `Ref<'a>`. The compiler and IntelliSense in the IDE display the former for this type, but the underlying definition is the latter.

The `ref` operator creates a new reference cell. The following code is the declaration of the `ref` operator.

```
let ref x = { contents = x }
```

The following table shows the features that are available on the reference cell.

OPERATOR, MEMBER, OR FIELD	DESCRIPTION	TYPE	DEFINITION
<code>!</code> (dereference operator)	Returns the underlying value.	<code>'a ref -> 'a</code>	<code>let (!) r = r.contents</code>

OPERATOR, MEMBER, OR FIELD	DESCRIPTION	TYPE	DEFINITION
<code>:=</code> (assignment operator)	Changes the underlying value.	<code>'a ref -> 'a -> unit</code>	<code>let (:=) r x = r.contents <- x</code>
<code>ref</code> (operator)	Encapsulates a value into a new reference cell.	<code>'a -> 'a ref</code>	<code>let ref x = { contents = x }</code>
<code>Value</code> (property)	Gets or sets the underlying value.	<code>unit -> 'a</code>	<code>member x.Value = x.contents</code>
<code>contents</code> (record field)	Gets or sets the underlying value.	<code>'a</code>	<code>let ref x = { contents = x }</code>

There are several ways to access the underlying value. The value returned by the dereference operator (`!`) is not an assignable value. Therefore, if you are modifying the underlying value, you must use the assignment operator (`:=`) instead.

Both the `Value` property and the `contents` field are assignable values. Therefore, you can use these to either access or change the underlying value, as shown in the following code.

```
let xRef : int ref = ref 10

printfn "%d" (xRef.Value)
printfn "%d" (xRef.contents)

xRef.Value <- 11
printfn "%d" (xRef.Value)
xRef.contents <- 12
printfn "%d" (xRef.contents)
```

The output is as follows.

```
10
10
11
12
```

The field `contents` is provided for compatibility with other versions of ML and will produce a warning during compilation. To disable the warning, use the `--mlcompatibility` compiler option. For more information, see [Compiler Options](#).

C# programmers should know that `ref` in C# is not the same thing as `ref` in F#. The equivalent constructs in F# are [byrefs](#), which are a different concept from reference cells.

Values marked as `mutable` may be automatically promoted to `'a ref` if captured by a closure; see [Values](#).

Compiler Directives

12/19/2018 • 4 minutes to read • [Edit Online](#)

This topic describes processor directives and compiler directives.

Preprocessor Directives

A preprocessor directive is prefixed with the # symbol and appears on a line by itself. It is interpreted by the preprocessor, which runs before the compiler itself.

The following table lists the preprocessor directives that are available in F#.

DIRECTIVE	DESCRIPTION
<code>#if symbol</code>	Supports conditional compilation. Code in the section after the <code>#if</code> is included if the <i>symbol</i> is defined. The symbol can also be negated with <code>!</code> .
<code>#else</code>	Supports conditional compilation. Marks a section of code to include if the symbol used with the previous <code>#if</code> is not defined.
<code>#endif</code>	Supports conditional compilation. Marks the end of a conditional section of code.
<code># [line] int,</code> <code># [line] int string,</code> <code># [line] int verbatim-string</code>	Indicates the original source code line and file name, for debugging. This feature is provided for tools that generate F# source code.
<code>#nowarn warningcode</code>	Disables a compiler warning or warnings. To disable a warning, find its number from the compiler output and include it in quotation marks. Omit the "FS" prefix. To disable multiple warning numbers on the same line, include each number in quotation marks, and separate each string by a space. For example:

`#nowarn "9" "40"`

The effect of disabling a warning applies to the entire file, including portions of the file that precede the directive.|

Conditional Compilation Directives

Code that is deactivated by one of these directives appears dimmed in the Visual Studio Code Editor.

NOTE

The behavior of the conditional compilation directives is not the same as it is in other languages. For example, you cannot use Boolean expressions involving symbols, and `true` and `false` have no special meaning. Symbols that you use in the `if` directive must be defined by the command line or in the project settings; there is no `define` preprocessor directive.

The following code illustrates the use of the `#if`, `#else`, and `#endif` directives. In this example, the code contains two versions of the definition of `function1`. When `VERSION1` is defined by using the `-define` compiler

option, the code between the `#if` directive and the `#else` directive is activated. Otherwise, the code between `#else` and `#endif` is activated.

```
#if VERSION1
let function1 x y =
    printfn "x: %d y: %d" x y
    x + 2 * y
#else
let function1 x y =
    printfn "x: %d y: %d" x y
    x - 2*y
#endif

let result = function1 10 20
```

There is no `#define` preprocessor directive in F#. You must use the compiler option or project settings to define the symbols used by the `#if` directive.

Conditional compilation directives can be nested. Indentation is not significant for preprocessor directives.

You can also negate a symbol with `!`. In this example, a string's value is something only when *not* debugging:

```
#if !DEBUG
let str = "Not debugging!"
#else
let str = "Debugging!"
#endif
```

Line Directives

When building, the compiler reports errors in F# code by referencing line numbers on which each error occurs. These line numbers start at 1 for the first line in a file. However, if you are generating F# source code from another tool, the line numbers in the generated code are generally not of interest, because the errors in the generated F# code most likely arise from another source. The `#line` directive provides a way for authors of tools that generate F# source code to pass information about the original line numbers and source files to the generated F# code.

When you use the `#line` directive, file names must be enclosed in quotation marks. Unless the verbatim token (`@`) appears in front of the string, you must escape backslash characters by using two backslash characters instead of one in order to use them in the path. The following are valid line tokens. In these examples, assume that the original file `Script1` results in an automatically generated F# code file when it is run through a tool, and that the code at the location of these directives is generated from some tokens at line 25 in file `Script1`.

```
# 25
#line 25
#line 25 "C:\\Projects\\MyProject\\MyProject\\Script1"
#line 25 @"C:\\Projects\\MyProject\\MyProject\\Script1"
# 25 @"C:\\Projects\\MyProject\\MyProject\\Script1"
```

These tokens indicate that the F# code generated at this location is derived from some constructs at or near line 25 in `Script1`.

Compiler Directives

Compiler directives resemble preprocessor directives, because they are prefixed with a # sign, but instead of being interpreted by the preprocessor, they are left for the compiler to interpret and act on.

The following table lists the compiler directive that is available in F#.

DIRECTIVE	DESCRIPTION
<code>#light ["on" "off"]</code>	Enables or disables lightweight syntax, for compatibility with other versions of ML. By default, lightweight syntax is enabled. Verbose syntax is always enabled. Therefore, you can use both lightweight syntax and verbose syntax. The directive <code>#light</code> by itself is equivalent to <code>#light "on"</code> . If you specify <code>#light "off"</code> , you must use verbose syntax for all language constructs. Syntax in the documentation for F# is presented with the assumption that you are using lightweight syntax. For more information, see Verbose Syntax .

For interpreter (fsi.exe) directives, see [Interactive Programming with F#](#).

Compiler Options

12/19/2018 • 7 minutes to read • [Edit Online](#)

This topic describes compiler command-line options for the F# compiler, fsc.exe. The compilation environment can also be controlled by setting the project properties.

Compiler Options Listed Alphabetically

The following table shows compiler options listed alphabetically. Some of the F# compiler options are similar to the C# compiler options. If that is the case, a link to the C# compiler options topic is provided.

COMPILER OPTION	DESCRIPTION
<code>-a filename.fs</code>	Generates a library from the specified file. This option is a short form of <code>--target:library filename.fs</code> .
<code>--baseaddress:address</code>	Specifies the preferred base address at which to load a DLL. This compiler option is equivalent to the C# compiler option of the same name. For more information, see /baseaddress (C# Compiler Options) .
<code>--codepage:id</code>	Specifies which code page to use during compilation if the required page isn't the current default code page for the system. This compiler option is equivalent to the C# compiler option of the same name. For more information, see /code pages (C# Compiler Options) .
<code>--consolecolors</code>	Specifies that errors and warnings use color-coded text on the console.
<code>--crossoptimize[+ -]</code>	Enables or disables cross-module optimizations.
<code>--delaysign[+ -]</code>	Delay-signs the assembly using only the public portion of the strong name key. This compiler option is equivalent to the C# compiler option of the same name. For more information, see /delaysign (C# Compiler Options) .
<code>--checked[+ -]</code>	Enables or disables the generation of overflow checks. This compiler option is equivalent to the C# compiler option of the same name. For more information, see /checked (C# Compiler Options) .

COMPILER OPTION	DESCRIPTION
<pre>--debug[+ -]</pre> <pre>-g[+ -]</pre> <pre>--debug:[full pdbonly]</pre> <pre>-g: [full pdbonly]</pre>	<p>Enables or disables the generation of debug information, or specifies the type of debug information to generate. The default is full, which allows attaching to a running program. Choose pbonly to get limited debugging information stored in a pdb (program database) file.</p> <p>Equivalent to the C# compiler option of the same name. For more information, see /debug (C# Compiler Options).</p>
<pre>--define:symbol</pre> <pre>-d:symbol</pre>	<p>Defines a symbol for use in conditional compilation.</p>
<pre>--deterministic[+ -]</pre>	<p>Produces a deterministic assembly (including module version GUID and timestamp). This option cannot be used with wildcard version numbers, and only supports embedded and portable debugging types</p>
<pre>--doc:xmldoc-filename</pre>	<p>Instructs the compiler to generate XML documentation comments to the file specified. For more information, see XML Documentation.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /doc (C# Compiler Options).</p>
<pre>--fullpaths</pre>	<p>Instructs the compiler to generate fully qualified paths.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /fullpaths (C# Compiler Options).</p>
<pre>--help</pre> <pre>-?</pre>	<p>Displays usage information, including a brief description of all the compiler options.</p>
<pre>--highentropyva[+ -]</pre>	<p>Enable or disable high-entropy address space layout randomization (ASLR), an enhanced security feature. The OS randomizes the locations in memory where infrastructure for applications (such as the stack and heap) are loaded. If you enable this option, operating systems can use this randomization to use the full 64-bit address-space on a 64-bit machine.</p>
<pre>--keycontainer:key-container-name</pre>	<p>Specifies a strong name key container.</p>
<pre>--keyfile:filename</pre>	<p>Specifies the name of a public key file for signing the generated assembly.</p>
<pre>--lib:folder-name</pre> <pre>-I:folder-name</pre>	<p>Specifies a directory to be searched for assemblies that are referenced.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /lib (C# Compiler Options).</p>

COMPILER OPTION	DESCRIPTION
<code>--linkresource:resource-info</code>	<p>Links a specified resource to the assembly. The format of <code>resource-info</code> is <code>filename[name[public private]]</code></p> <p>Linking a single resource with this option is an alternative to embedding an entire resource file with the <code>--resource</code> option.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /linkresource (C# Compiler Options).</p>
<code>--mlcompatibility</code>	<p>Ignores warnings that appear when you use features that are designed for compatibility with other versions of ML.</p>
<code>--noframework</code>	<p>Disables the default reference to the .NET Framework assembly.</p>
<code>--nointerfacedata</code>	<p>Instructs the compiler to omit the resource it normally adds to an assembly that includes F#-specific metadata.</p>
<code>--nologo</code>	<p>Doesn't show the banner text when launching the compiler.</p>
<code>--nooptimizationdata</code>	<p>Instructs the compiler to only include optimization essential for implementing inlined constructs. Inhibits cross-module inlining but improves binary compatibility.</p>
<code>--nowin32manifest</code>	<p>Instructs the compiler to omit the default Win32 manifest.</p>
<code>--nowarn:warning-number-list</code>	<p>Disables specific warnings listed by number. Separate each warning number by a comma. You can discover the warning number for any warning from the compilation output.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /nowarn (C# Compiler Options).</p>
<code>--optimize[+ -][optimization-option-list]</code> <code>-O[+ -] [optimization-option-list]</code>	<p>Enables or disables optimizations. Some optimization options can be disabled or enabled selectively by listing them. These are: <code>nojitoptimize</code> , <code>nojittracking</code> , <code>nolocaloptimize</code> , <code>nocrossoptimize</code> , <code>notailcalls</code> .</p>
<code>--out:output-filename</code> <code>-o:output-filename</code>	<p>Specifies the name of the compiled assembly or module.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /out (C# Compiler Options).</p>
<code>--pdb:pdb-filename</code>	<p>Names the output debug PDB (program database) file. This option only applies when <code>--debug</code> is also enabled.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /pdb (C# Compiler Options).</p>

COMPILER OPTION	DESCRIPTION
<code>--platform:platform-name</code>	<p>Specifies that the generated code will only run on the specified platform (<code>x86</code>, <code>Itanium</code>, or <code>x64</code>), or, if the platform-name <code>anycpu</code> is chosen, specifies that the generated code can run on any platform.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /platform (C# Compiler Options).</p>
<code>--preferreduilang:lang</code>	<p>Specifies the preferred output language culture name (for example, <code>es-ES</code>, <code>ja-JP</code>).</p>
<code>--quotations-debug</code>	<p>Specifies that extra debugging information should be emitted for expressions that are derived from F# quotation literals and reflected definitions. The debug information is added to the custom attributes of an F# expression tree node. See Code Quotations and Expr.CustomAttributes.</p>
<code>--reference:assembly-filename</code> <code>-r:assembly-filename</code>	<p>Makes code from an F# or .NET Framework assembly available to the code being compiled.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /reference (C# Compiler Options).</p>
<code>--resource:resource-filename</code>	<p>Embeds a managed resource file into the generated assembly.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /resource (C# Compiler Options).</p>
<code>--sig:signature-filename</code>	<p>Generates a signature file based on the generated assembly. For more information about signature files, see Signatures.</p>
<code>--simpleresolution</code>	<p>Specifies that assembly references should be resolved using directory-based Mono rules rather than MSBuild resolution. The default is to use MSBuild resolution except when running under Mono.</p>
<code>--standalone</code>	<p>Specifies to produce an assembly that contains all of its dependencies so that it runs by itself without the need for additional assemblies, such as the F# library.</p>
<code>--staticlink:assembly-name</code>	<p>Statically links the given assembly and all referenced DLLs that depend on this assembly. Use the assembly name, not the DLL name.</p>
<code>--subsystemversion</code>	<p>Specifies the version of the OS subsystem to be used by the generated executable. Use 6.02 for Windows 8.1, 6.01 for Windows 7, 6.00 for Windows Vista. This option only applies to executables, not DLLs, and need only be used if your application depends on specific security features available only on certain versions of the OS. If this option is used, and a user attempts to execute your application on a lower version of the OS, it will fail with an error message.</p>

COMPILER OPTION	DESCRIPTION
<code>--tailcalls[+ -]</code>	Enables or disables the use of the tail IL instruction, which causes the stack frame to be reused for tail recursive functions. This option is enabled by default.
<code>--target:[exe winexe library module] filename</code>	<p>Specifies the type and file name of the generated compiled code.</p> <ul style="list-style-type: none"> • <code>exe</code> means a console application. • <code>winexe</code> means a Windows application, which differs from the console application in that it does not have standard input/output streams (stdin, stdout, and stderr) defined. • <code>library</code> is an assembly without an entry point. • <code>module</code> is a .NET Framework module (.netmodule), which can later be combined with other modules into an assembly. <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /target (C# Compiler Options).</p>
<code>--times</code>	Displays timing information for compilation.
<code>--utf8output</code>	Enables printing compiler output in the UTF-8 encoding.
<code>--warn:warning-level</code>	<p>Sets a warning level (0 to 5). The default level is 3. Each warning is given a level based on its severity. Level 5 gives more, but less severe, warnings than level 1.</p> <p>Level 5 warnings are: 21 (recursive use checked at runtime), 22 (<code>let rec</code> evaluated out of order), 45 (full abstraction), and 52 (defensive copy). All other warnings are level 2.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /warn (C# Compiler Options).</p>
<code>--warnon:warning-number-list</code>	Enable specific warnings that might be off by default or disabled by another command-line option. In F# 3.0, only the 1182 (unused variables) warning is off by default.
<code>--warnaserror[+ -] [warning-number-list]</code>	<p>Enables or disables the option to report warnings as errors. You can provide specific warning numbers to be disabled or enabled. Options later in the command line override options earlier in the command line. For example, to specify the warnings that you don't want reported as errors, specify <code>--warnaserror+ --warnaserror- :warning-number-list</code>.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /warnaserror (C# Compiler Options).</p>
<code>--win32manifest:manifest-filename</code>	Adds a Win32 manifest file to the compilation. This compiler option is equivalent to the C# compiler option of the same name. For more information, see /win32manifest (C# Compiler Options) .

COMPILER OPTION	DESCRIPTION
--win32res:resource-filename	<p>Adds a Win32 resource file to the compilation.</p> <p>This compiler option is equivalent to the C# compiler option of the same name. For more information, see /win32res ((C#) Compiler Options).</p>

F# Interactive Options

11/13/2018 • 3 minutes to read • [Edit Online](#)

NOTE

This article currently describes the experience for Windows only. It will be rewritten.

This topic describes the command-line options supported by F# Interactive, `fsi.exe`. F# Interactive accepts many of the same command line options as the F# compiler, but also accepts some additional options.

Using F# Interactive for Scripting

F# Interactive, `fsi.exe`, can be launched interactively, or it can be launched from the command line to run a script. The command line syntax is

```
> fsi.exe [options] [ script-file [arguments] ]
```

The file extension for F# script files is `.fsx`.

Table of F# Interactive Options

The following table summarizes the options supported by F# Interactive. You can set these options on the command-line or through the Visual Studio IDE. To set these options in the Visual Studio IDE, open the **Tools** menu, select **Options...**, then expand the **F# Tools** node and select **F# Interactive**.

Where lists appear in F# Interactive option arguments, list elements are separated by semicolons (;).

OPTION	DESCRIPTION
--	Used to instruct F# Interactive to treat remaining arguments as command line arguments to the F# program or script, which you can access in code by using the list <code>fsi.CommandLineArgs</code> .
--checked[+ -]	Same as the <code>fsc.exe</code> compiler option. For more information, see Compiler Options .
--codepage:<int>	Same as the <code>fsc.exe</code> compiler option. For more information, see Compiler Options .
--consolecolors[+ -]	Outputs warning and error messages in color.
--crossoptimize[+ -]	Enable or disable cross-module optimizations.

OPTION	DESCRIPTION
--debug[+ -] --debug:[full pdbonly portable embedded]	Same as the fsc.exe compiler option. For more information, see Compiler Options .
-g[+ -] -g:[full pdbonly portable embedded]	
--define:<string>	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--deterministic[+ -]	Produces a deterministic assembly (including module version GUID and timestamp).
--exec	Instructs F# interactive to exit after loading the files or running the script file given on the command line.
--fullpaths	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--gui[+ -]	Enables or disables the Windows Forms event loop. The default is enabled.
--help -?	Used to display the command line syntax and a brief description of each option.
--lib:<folder-list> -l:<folder-list>	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--load:<filename>	Compiles the given source code at startup and loads the compiled F# constructs into the session. If the target source contains scripting directives such as #use or #load , then you must use --use or #use instead of --load or #load .
--mlcompatibility	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--noframework	Same as the fsc.exe compiler option. For more information, see Compiler Options
--nologo	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--nowarn:<warning-list>	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--optimize[+ -]	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--preferreduilang:<lang>	Specifies the preferred output language culture name (for example, es-ES, ja-JP).
--quiet	Suppress F# Interactive's output to the stdout stream.

OPTION	DESCRIPTION
--quotations-debug	Specifies that extra debugging information should be emitted for expressions that are derived from F# quotation literals and reflected definitions. The debug information is added to the custom attributes of an F# expression tree node. See Code Quotations and Expr.CustomAttributes .
--readline[+ -]	Enable or disable tab completion in interactive mode.
--reference:<filename> -r:<filename>	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--shadowcopyreferences[+ -]	Prevents references from being locked by the F# Interactive process.
--simpleresolution	Resolves assembly references using directory-based rules rather than MSBuild resolution.
--tailcalls[+ -]	Enable or disable the use of the tail IL instruction, which causes the stack frame to be reused for tail recursive functions. This option is enabled by default.
--targetprofile:<string>	Specifies target framework profile of this assembly. Valid values are mscorlib, netcore or netstandard. The default is mscorlib.
--use:<filename>	Tells the interpreter to use the given file on startup as initial input.
--utf8output	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--warn:<warning-level>	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--warnaserror[+ -]	Same as the fsc.exe compiler option. For more information, see Compiler Options .
--warnaserror[+ -]:<int-list>	Same as the fsc.exe compiler option. For more information, see Compiler Options .

Source Line, File, and Path Identifiers

12/20/2018 • 2 minutes to read • [Edit Online](#)

The identifiers `__LINE__`, `__SOURCE_DIRECTORY__` and `__SOURCE_FILE__` are built-in values that enable you to access the source line number, directory and file name in your code.

Syntax

```
__LINE__
__SOURCE_DIRECTORY__
__SOURCE_FILE__
```

Remarks

Each of these values has type `string`.

The following table summarizes the source line, file, and path identifiers that are available in F#. These identifiers are not preprocessor macros; they are built-in values that are recognized by the compiler.

PREDEFINED IDENTIFIER	DESCRIPTION
<code>__LINE__</code>	Evaluates to the current line number, considering <code>#line</code> directives.
<code>__SOURCE_DIRECTORY__</code>	Evaluates to the current full path of the source directory, considering <code>#line</code> directives.
<code>__SOURCE_FILE__</code>	Evaluates to the current source file name and its path, considering <code>#line</code> directives.

For more information about the `#line` directive, see [Compiler Directives](#).

Example

The following code example demonstrates the use of these values.

```
let printSourceLocation() =
    printfn "Line: %s" __LINE__
    printfn "Source Directory: %s" __SOURCE_DIRECTORY__
    printfn "Source File: %s" __SOURCE_FILE__
printSourceLocation()
```

Output:

```
Line: 4
Source Directory: C:\Users\username\Documents\Visual Studio 2017\Projects\SourceInfo\SourceInfo
Source File: C:\Users\username\Documents\Visual Studio 2017\Projects\SourceInfo\SourceInfo\Program.fs
```

Caller information

12/19/2018 • 2 minutes to read • [Edit Online](#)

By using Caller Info attributes, you can obtain information about the caller to a method. You can obtain file path of the source code, the line number in the source code, and the member name of the caller. This information is helpful for tracing, debugging, and creating diagnostic tools.

To obtain this information, you use attributes that are applied to optional parameters, each of which has a default value. The following table lists the Caller Info attributes that are defined in the [System.Runtime.CompilerServices](#) namespace:

ATTRIBUTE	DESCRIPTION	TYPE
CallerFilePath	Full path of the source file that contains the caller. This is the file path at compile time.	String
CallerLineNumber	Line number in the source file at which the method is called.	Integer
CallerMemberName	Method or property name of the caller. See the Member Names section later in this topic.	String

Example

The following example shows how you might use these attributes to trace a caller.

```
open System.Diagnostics
open System.Runtime.CompilerServices

type Tracer() =
    member ___.DoTrace(msg: string,
                        [<>CallerMemberName>] ?memberName: string,
                        [<>CallerFilePath>] ?path: string
                        [<>CallerLineNumber>] ?line: int) =
        Trace.WriteLine(sprintf "Message: %s" message)
        match (memberName, path, line) with
        | Some m, Some p, Some l ->
            Trace.WriteLine(sprintf "Member name: %s" m)
            Trace.WriteLine(sprintf "Source file path: %s" p)
            Trace.WriteLine(sprintf "Source line number: %d" l)
        | _,_,_ -> ()
```

Remarks

Caller Info attributes can only be applied to optional parameters. You must supply an explicit value for each optional parameter. The Caller Info attributes cause the compiler to write the proper value for each optional parameter decorated with a Caller Info attribute.

Caller Info values are emitted as literals into the Intermediate Language (IL) at compile time. Unlike the results of the [StackTrace](#) property for exceptions, the results aren't affected by obfuscation.

You can explicitly supply the optional arguments to control the caller information or to hide caller information.

Member names

You can use the `CallerMemberName` attribute to avoid specifying the member name as a `String` argument to the called method. By using this technique, you avoid the problem that Rename Refactoring doesn't change the `String` values. This benefit is especially useful for the following tasks:

- Using tracing and diagnostic routines.
- Implementing the `INotifyPropertyChanged` interface when binding data. This interface allows the property of an object to notify a bound control that the property has changed, so that the control can display the updated information. Without the `CallerMemberName` attribute, you must specify the property name as a literal.

The following chart shows the member names that are returned when you use the `CallerMemberName` attribute.

CALLS OCCURS WITHIN	MEMBER NAME RESULT
Method, property, or event	The name of the method, property, or event from which the call originated.
Constructor	The string ".ctor"
Static constructor	The string ".cctor"
Destructor	The string "Finalize"
User-defined operators or conversions	The generated name for the member, for example, "op>Addition".
Attribute constructor	The name of the member to which the attribute is applied. If the attribute is any element within a member (such as a parameter, a return value, or a generic type parameter), this result is the name of the member that's associated with that element.
No containing member (for example, assembly-level or attributes that are applied to types)	The default value of the optional parameter.

Verbose Syntax

12/19/2018 • 2 minutes to read • [Edit Online](#)

There are two forms of syntax available for many constructs in the F# language: *verbose syntax* and *lightweight syntax*. The verbose syntax is not as commonly used, but has the advantage of being less sensitive to indentation. The lightweight syntax is shorter and uses indentation to signal the beginning and end of constructs, rather than additional keywords like `begin`, `end`, `in`, and so on. The default syntax is the lightweight syntax. This topic describes the syntax for F# constructs when lightweight syntax is not enabled. Verbose syntax is always enabled, so even if you enable lightweight syntax, you can still use verbose syntax for some constructs. You can disable lightweight syntax by using the `#light "off"` directive.

Table of Constructs

The following table shows the lightweight and verbose syntax for F# language constructs in contexts where there is a difference between the two forms. In this table, angle brackets (<>) enclose user-supplied syntax elements. Refer to the documentation for each language construct for more detailed information about the syntax used within these constructs.

LANGUAGE CONSTRUCT	LIGHTWEIGHT SYNTAX	VERBOSE SYNTAX
compound expressions	<pre><expression1> <expression2></pre>	<pre><expression1>; <expression2></pre>
nested <code>let</code> bindings	<pre>let f x = let a = 1 let b = 2 x + a + b</pre>	<pre>let f x = let a = 1 in let b = 2 in x + a + b</pre>
code block	<pre>(<expression1> <expression2>)</pre>	<pre>begin <expression1>; <expression2>; end</pre>
`for...do`	<pre>for counter = start to finish do ...</pre>	<pre>for counter = start to finish do ... done</pre>
`while...do`	<pre>while <condition> do ...</pre>	<pre>while <condition> do ... done</pre>

'for...in'	<pre>for var in start .. finish do ... </pre>	<pre>for var in start .. finish do ... done</pre>
'do'	<pre>do ... </pre>	<pre>do ... in</pre>
record	<pre>type <record-name> = { <field-declarations> } <value-or-member- definitions></pre>	<pre>type <record-name> = { <field-declarations> } with <value-or-member- definitions> end</pre>
class	<pre>type <class-name>(<params>) = ... </pre>	<pre>type <class-name>(<params>) = class ... end</pre>
structure	<pre>[<StructAttribute>] type <structure-name> = ... </pre>	<pre>type <structure-name> = struct ... end</pre>
discriminated union	<pre>type <union-name> = <value-or-member definitions></pre>	<pre>type <union-name> = with <value-or-member- definitions> end</pre>
interface	<pre>type <interface-name> = ... </pre>	<pre>type <interface-name> = interface ... end</pre>

object expression	<pre>{ new <type-name> with <value-or-member- definitions> <interface- implementations> }</pre>	<pre>{ new <type-name> with <value-or-member- definitions> end <interface- implementations> }</pre>
interface implementation	<pre>interface <interface-name> with <value-or-member- definitions></pre>	<pre>interface <interface-name> with <value-or-member- definitions> end</pre>
type extension	<pre>type <type-name> with <value-or-member- definitions></pre>	<pre>type <type-name> with <value-or-member- definitions> end</pre>
module	<pre>module <module-name> = ...</pre>	<pre>module <module-name> = begin ... end</pre>

F# style guide

1/4/2019 • 2 minutes to read • [Edit Online](#)

The following articles describe guidelines for formatting F# code and topical guidance for features of the language and how they should be used.

This guidance has been formulated based on the use of F# in large codebases with a diverse group of programmers. This guidance generally leads to successful use of F# and minimizes frustrations when requirements for programs change over time.

Five principles of good F# code

Keep the following principles in mind any time you write F# code, especially in systems that will change over time. Every piece of guidance in further articles stems from these five points.

1. Good F# code is succinct, expressive, and composable

F# has many features that allow you to express actions in fewer lines of code and reuse generic functionality. The F# core library also contains many useful types and functions for working with common collections of data. Composition of your own functions and those in the F# core library (or other libraries) is a part of routine idiomatic F# programming. As a general rule, if you can express a solution to a problem in fewer lines of code, other developers (or your future self) will be appreciative. It's also highly recommended that you use a library such as FSharp.Core, the [vast .NET libraries](#) that F# runs on, or a third-party package on [NuGet](#) when you need to do a nontrivial task.

2. Good F# code is interoperable

Interoperation can take multiple forms, including consuming code in different languages. The boundaries of your code that other callers interoperate with are critical pieces to get right, even if the callers are also in F#. When writing F#, you should always be thinking about how other code will call into the code you're writing, including if they do so from another language like C#. The [F# Component Design Guidelines](#) describe interoperability in detail.

3. Good F# code makes use of object programming, not object orientation

F# has full support for programming with objects in .NET, including [classes](#), [interfaces](#), [access modifiers](#), [abstract classes](#), and so on. For more complicated functional code, such as functions that must be context-aware, objects can easily encapsulate contextual information in ways that functions cannot. Features such as [optional parameters](#) and careful use of [overloading](#) can make consumption of this functionality easier for callers.

4. Good F# code performs well without exposing mutation

It's no secret that to write high-performance code, you must use mutation. It's how computers work, after all. Such code is often error-prone and difficult to get right. Avoid exposing mutation to callers. Instead, [build a functional interface that hides a mutation-based implementation](#) when performance is critical.

5. Good F# code is toolable

Tools are invaluable for working in large codebases, and you can write F# code such that it can be used more effectively with F# language tooling. One example is making sure you don't overdo it with a point-free style of programming, so that intermediate values can be inspected with a debugger. Another example is using [XML documentation comments](#) describing constructs such that tooltips in editors can display those

comments at the call site. Always think about how your code will be read, navigated, debugged, and manipulated by other programmers with their tools.

Next steps

The [F# code formatting guidelines](#) provide guidance on how to format code so that it is easy to read.

The [F# coding conventions](#) provide guidance for F# programming idioms that will help the long-term maintenance of larger F# codebases.

The [F# component design guidelines](#) provide guidance for authoring F# components, such as libraries.

F# code formatting guidelines

2/12/2019 • 16 minutes to read • [Edit Online](#)

This article offers guidelines for how to format your code so that your F# code is:

- Generally viewed as more legible
- Is in accordance with conventions applied by formatting tools in Visual Studio and other editors
- Similar to other code online

These guidelines are based on [A comprehensive guide to F# Formatting Conventions](#) by Anh-Dung Phan.

General rules for indentation

F# uses significant white space by default. The following guidelines are intended to provide guidance as to how to juggle some challenges this can impose.

Using spaces

When indentation is required, you must use spaces, not tabs. At least one space is required. Your organization can create coding standards to specify the number of spaces to use for indentation; two, three or four spaces of indentation at each level where indentation occurs is typical.

We recommend 4 spaces per indentation.

That said, indentation of programs is a subjective matter. Variations are OK, but the first rule you should follow is *consistency of indentation*. Choose a generally accepted style of indentation and use it systematically throughout your codebase.

Formatting white space

F# is white space sensitive. Although most semantics from white space are covered by proper indentation, there are some other things to consider.

Formatting operators in arithmetic expressions

Always use white space around binary arithmetic expressions:

```
let subtractThenAdd x = x - 1 + 3
```

Unary `-` operators should always have the value they are negating immediately follow:

```
// OK
let negate x = -x

// Bad
let negateBad x = - x
```

Adding a white-space character after the `-` operator can lead to confusion for others.

In summary, it's important to always:

- Surround binary operators with white space
- Never have trailing white space after a unary operator

The binary arithmetic operator guideline is especially important. Failing to surround a binary `-` operator, when combined with certain formatting choices, could lead to interpreting it as a unary `-`.

Surround a custom operator definition with white space

Always use white space to surround an operator definition:

```
// OK
let ( !> ) x f = f x

// Bad
let (!>) x f = f x
```

For any custom operator that starts with `*`, you'll need to add a white space to the beginning of the definition to avoid a compiler ambiguity. Because of this, it's recommended that you simply surround the definitions of all operators with a single white-space character.

Surround function parameter arrows with white space

When defining the signature of a function, use white space around the `->` symbol:

```
// OK
type MyFun = int -> int -> string

// Bad
type MyFunBad = int->int->string
```

Formatting blank lines

- Separate top-level function and class definitions with two blank lines.
- Method definitions inside a class are separated by a single blank line.
- Extra blank lines may be used (sparingly) to separate groups of related functions. Blank lines may be omitted between a bunch of related one-liners (for example, a set of dummy implementations).
- Use blank lines in functions, sparingly, to indicate logical sections.

Formatting comments

Generally prefer multiple double-slash comments over ML-style block comments.

```
// Prefer this style of comments when you want
// to express written ideas on multiple lines.

(*
  ML-style comments are fine, but not a .NET-ism.
  They are useful when needing to modify multi-line comments, though.
*)
```

Inline comments should capitalize the first letter.

```
let f x = x + 1 // Increment by one.
```

Naming conventions

Use camelCase for class-bound, expression-bound and pattern-bound values and functions

It is common and accepted F# style to use camelCase for all names bound as local variables or in pattern matches

and function definitions.

```
// OK
let addIAndJ i j = i + j

// Bad
let addIAndJ I J = I+J

// Bad
let AddIAndJ i j = i + j
```

Locally-bound functions in classes should also use camelCase.

```
type MyClass() =
    let doSomething () =
        let firstResult = ...
        let secondResult = ...
        member x.Result = doSomething()
```

Use camelCase for module-bound public functions

When a module-bound function is part of a public API, it should use camelCase:

```
module MyAPI =
    let publicFunctionOne param1 param2 = ...
    let publicFunctionTwo param1 param2 param3 = ...
```

Use camelCase for internal and private module-bound values and functions

Use camelCase for private module-bound values, including the following:

- Ad hoc functions in scripts
- Values making up the internal implementation of a module or type

```
let emailMyBossTheLatestResults =
    ...
```

Use camelCase for parameters

All parameters should use camelCase in accordance with .NET naming conventions.

```
module MyModule =
    let myFunction paramOne paramTwo = ...

type MyClass() =
    member this.MyMethod(paramOne, paramTwo) = ...
```

Use PascalCase for modules

All modules (top-level, internal, private, nested) should use PascalCase.

```
module MyTopLevelModule

module Helpers =
    module private SuperHelpers =
        ...
        ...

...
```

Use PascalCase for type declarations, members, and labels

Classes, interfaces, structs, enumerations, delegates, records, and discriminated unions should all be named with PascalCase. Members within types and labels for records and discriminated unions should also use PascalCase.

```
type IMyInterface =
    abstract Something: int

type MyClass() =
    member this.MyMethod(x, y) = x + y

type MyRecord = { IntVal: int; StringVal: string }

type SchoolPerson =
    | Professor
    | Student
    | Advisor
    | Administrator
```

Use PascalCase for constructs intrinsic to .NET

Namespaces, exceptions, events, and project/ `.dll` names should also use PascalCase. Not only does this make consumption from other .NET languages feel more natural to consumers, it's also consistent with .NET naming conventions that you are likely to encounter.

Avoid underscores in names

Historically, some F# libraries have used underscores in names. However, this is no longer widely accepted, partly because it clashes with .NET naming conventions. That said, some F# programmers use underscores heavily, partly for historical reasons, and tolerance and respect is important. However, be aware that the style is often disliked by others who have a choice about whether to use it.

Some exceptions includes interoperating with native components, where underscores are very common.

Use standard F# operators

The following operators are defined in the F# standard library and should be used instead of defining equivalents. Using these operators is recommended as it tends to make code more readable and idiomatic. Developers with a background in OCaml or other functional programming language may be accustomed to different idioms. The following list summarizes the recommended F# operators.

```

x |> f // Forward pipeline
f >> g // Forward composition
x |> ignore // Discard away a value
x + y // Overloaded addition (including string concatenation)
x - y // Overloaded subtraction
x * y // Overloaded multiplication
x / y // Overloaded division
x % y // Overloaded modulus
x && y // Lazy/short-cut "and"
x || y // Lazy/short-cut "or"
x <<< y // Bitwise left shift
x >>> y // Bitwise right shift
x ||| y // Bitwise or, also for working with "flags" enumeration
x &&& y // Bitwise and, also for working with "flags" enumeration
x ^^^ y // Bitwise xor, also for working with "flags" enumeration

```

Use prefix syntax for generics (`Foo<T>`) in preference to postfix syntax (`T Foo`)

F# inherits both the postfix ML style of naming generic types (for example, `int list`) as well as the prefix .NET style (for example, `list<int>`). Prefer the .NET style, except for four specific types:

1. For F# Lists, use the postfix form: `int list` rather than `list<int>`.
2. For F# Options, use the postfix form: `int option` rather than `option<int>`.
3. For F# arrays, use the syntactic name `int[]` rather than `int array` or `array<int>`.
4. For Reference Cells, use `int ref` rather than `ref<int>` or `Ref<int>`.

For all other types, use the prefix form.

Formatting tuples

A tuple instantiation should be parenthesized, and the delimiting commas within should be followed by a single space, for example: `(1, 2)`, `(x, y, z)`.

It is commonly accepted to omit parentheses in pattern matching of tuples:

```

let (x, y) = z // Destructuring
let x, y = z // OK

// OK
match x, y with
| 1, _ -> 0
| x, 1 -> 0
| x, y -> 1

```

It is also commonly accepted to omit parentheses if the tuple is the return value of a function:

```

// OK
let update model msg =
    match msg with
    | 1 -> model + 1, []
    | _ -> model, [ msg ]

```

In summary, prefer parenthesized tuple instantiations, but when using tuples for pattern matching or a return value, it is considered fine to avoid parentheses.

Formatting discriminated union declarations

Indent `|` in type definition by 4 spaces:

```
// OK
type Volume =
| Liter of float
| FluidOunce of float
| ImperialPint of float

// Not OK
type Volume =
| Liter of float
| USPint of float
| ImperialPint of float
```

Formatting discriminated unions

Instantiated Discriminated Unions that split across multiple lines should give contained data a new scope with indentation:

```
let tree1 =
    BinaryNode(
        BinaryNode(BinaryValue 1, BinaryValue 2),
        BinaryNode(BinaryValue 3, BinaryValue 4))
```

The closing parenthesis can also be on a new line:

```
let tree1 =
    BinaryNode(
        BinaryNode(BinaryValue 1, BinaryValue 2),
        BinaryNode(BinaryValue 3, BinaryValue 4)
    )
```

Formatting record declarations

Indent `{` in type definition by 4 spaces and start the field list on the same line:

```
// OK
type PostalAddress =
{ Address: string
  City: string
  Zip: string }
member x.ZipAndCity = sprintf "%s %s" x.Zip x.City

// Not OK
type PostalAddress =
{ Address: string
  City: string
  Zip: string }
member x.ZipAndCity = sprintf "%s %s" x.Zip x.City

// Unusual in F#
type PostalAddress =
{
  Address: string
  City: string
  Zip: string
}
```

Placing the opening token on a new line and the closing token on a new line is preferable if you are declaring interface implementations or members on the record:

```
// Declaring additional members on PostalAddress
type PostalAddress =
{
    Address: string
    City: string
    Zip: string
} with
member x.ZipAndCity = sprintf "%s %s" x.Zip x.City

type MyRecord =
{
    SomeField: int
}
interface IMyInterface
```

Formatting records

Short records can be written in one line:

```
let point = { X = 1.0; Y = 0.0 }
```

Records that are longer should use new lines for labels:

```
let rainbow =
{ Boss = "Jeffrey"
Lackeys = ["Zippy"; "George"; "Bungle"] }
```

Placing the opening token on a new line, the contents tabbed over one scope, and the closing token on a new line is preferable if you are:

- Moving records around in code with different indentation scopes
- Piping them into a function

```
let rainbow =
{
    Boss1 = "Jeffrey"
    Boss2 = "Jeffrey"
    Boss3 = "Jeffrey"
    Boss4 = "Jeffrey"
    Boss5 = "Jeffrey"
    Boss6 = "Jeffrey"
    Boss7 = "Jeffrey"
    Boss8 = "Jeffrey"
    Lackeys = ["Zippy"; "George"; "Bungle"]
}

type MyRecord =
{
    SomeField: int
}
interface IMyInterface

let foo a =
    a
    |> Option.map (fun x ->
        {
            MyField = x
        })
```

The same rules apply for list and array elements.

Formatting copy-and-update record expressions

A copy-and-update record expression is still a record, so similar guidelines apply.

Short expressions can fit on one line:

```
let point2 = { point with X = 1; Y = 2 }
```

Longer expressions should use new lines:

```
let rainbow2 =
  { rainbow with
    Boss = "Jeffrey"
    Lackeys = ["Zippy"; "George"; "Bungle"] }
```

And as with the record guidance, you may want to dedicate separate lines for the braces and indent one scope to the right with the expression. Note that in some special cases, such as wrapping a value with an optional without parentheses, you may need to keep a brace on one line:

```
type S = { F1: int; F2: string }
type State = { F: S option }

let state = { F = Some { F1 = 1; F2 = "Hello" } }
let newState =
  {
    state with
      F = Some {
        F1 = 0
        F2 = ""
      }
  }
```

Formatting lists and arrays

Write `x :: 1` with spaces around the `::` operator (`::` is an infix operator, hence surrounded by spaces).

List and arrays declared on a single line should have a space after the opening bracket and before the closing bracket:

```
let xs = [ 1; 2; 3 ]
let ys = [| 1; 2; 3; |]
```

Always use at least one space between two distinct brace-like operators. For example, leave a space between a `[` and a `{`.

```
// OK
[ { IngredientName = "Green beans"; Quantity = 250 }
{ IngredientName = "Pine nuts"; Quantity = 250 }
{ IngredientName = "Feta cheese"; Quantity = 250 }
{ IngredientName = "Olive oil"; Quantity = 10 }
{ IngredientName = "Lemon"; Quantity = 1 } ]

// Not OK
[{ IngredientName = "Green beans"; Quantity = 250 }
{ IngredientName = "Pine nuts"; Quantity = 250 }
{ IngredientName = "Feta cheese"; Quantity = 250 }
{ IngredientName = "Olive oil"; Quantity = 10 }
{ IngredientName = "Lemon"; Quantity = 1 }]
```

The same guideline applies for lists or arrays of tuples.

Lists and arrays that split across multiple lines follow a similar rule as records do:

```
let pascalsTriangle =
[]
  []
  [1]
  [1; 1]
  [1; 2; 1]
  [1; 3; 3; 1]
  [1; 4; 6; 4; 1]
  [1; 5; 10; 10; 5; 1]
  [1; 6; 15; 20; 15; 6; 1]
  [1; 7; 21; 35; 35; 21; 7; 1]
  [1; 8; 28; 56; 70; 56; 28; 8; 1]
[]
```

And as with records, declaring the opening and closing brackets on their own line will make moving code around and piping into functions easier.

Formatting if expressions

Indentation of conditionals depends on the sizes of the expressions that make them up. If `cond`, `e1` and `e2` are short, simply write them on one line:

```
if cond then e1 else e2
```

If either `cond`, `e1` or `e2` are longer, but not multi-line:

```
if cond
then e1
else e2
```

If any of the expressions are multi-line:

```
if cond then
  e1
else
  e2
```

Multiple conditionals with `elif` and `else` are indented at the same scope as the `if`:

```
if cond1 then e1
elif cond2 then e2
elif cond3 then e3
else e4
```

Pattern matching constructs

Use a `|` for each clause of a match with no indentation. If the expression is short, you can consider using a single line if each subexpression is also simple.

```
// OK
match l with
| { him = x; her = "Posh" } :: tail -> x
| _ :: tail -> findDavid tail
| [] -> failwith "Couldn't find David"

// Not OK
match l with
| { him = x; her = "Posh" } :: tail -> x
| _ :: tail -> findDavid tail
| [] -> failwith "Couldn't find David"
```

If the expression on the right of the pattern matching arrow is too large, move it to the following line, indented one step from the `match / |`.

```
match lam with
| Var v -> 1
| Abs(x, body) ->
    1 + sizeLambda body
| App(lam1, lam2) ->
    sizeLambda lam1 + sizeLambda lam2
```

Pattern matching of anonymous functions, starting by `function`, should generally not indent too far. For example, indenting one scope as follows is fine:

```
lambdaList
|> List.map (function
    | Abs(x, body) -> 1 + sizeLambda 0 body
    | App(lam1, lam2) -> sizeLambda (sizeLambda 0 lam1) lam2
    | Var v -> 1)
```

Pattern matching in functions defined by `let` or `let rec` should be indented 4 spaces after starting of `let`, even if `function` keyword is used:

```
let rec sizeLambda acc = function
    | Abs(x, body) -> sizeLambda (succ acc) body
    | App(lam1, lam2) -> sizeLambda (sizeLambda acc lam1) lam2
    | Var v -> succ acc
```

We do not recommend aligning arrows.

Formatting try/with expressions

Pattern matching on the exception type should be indented at the same level as `with`.

```

try
    if System.DateTime.Now.Second % 3 = 0 then
        raise (new System.Exception())
    else
        raise (new System.ApplicationException())
with
| :? System.ApplicationException ->
    printfn "A second that was not a multiple of 3"
| _ ->
    printfn "A second that was a multiple of 3"

```

Formatting function parameter application

In general, most function parameter application is done on the same line.

If you wish to apply parameters to a function on a new line, indent them by one scope.

```

// OK
sprintf "\t%s - %i\n\r"
    x.IngredientName x.Quantity

// OK
sprintf
    "\t%s - %i\n\r"
    x.IngredientName x.Quantity

// OK
let printVolumes x =
    printf "Volume in liters = %f, in us pints = %f, in imperial = %f"
        (convertVolumeToLiter x)
        (convertVolumeUSPint x)
        (convertVolumeImperialPint x)

```

The same guidelines apply for lambda expressions as function arguments. If the body of a lambda expression, the body can have another line, indented by one scope

```

let printListWithOffset a list1 =
    List.iter
        (fun elem -> printfn "%d" (a + elem))
    list1

// OK if lambda body is long enough
let printListWithOffset a list1 =
    List.iter
        (fun elem ->
            printfn "%d" (a + elem))
    list1

```

However, if the body of a lambda expression is more than one line, consider factoring it out into a separate function rather than have a multi-line construct applied as a single argument to a function.

Formatting infix operators

Separate operators by spaces. Obvious exceptions to this rule are the `!` and `.` operators.

Infix expressions are OK to lineup on same column:

```

acc +
(sprintf "\t%s - %i\n\r"
    x.IngredientName x.Quantity)

let function1 arg1 arg2 arg3 arg4 =
    arg1 + arg2 +
    arg3 + arg4

```

Formatting pipeline operators

Pipeline `|>` operators should go underneath the expressions they operate on.

```

// Preferred approach
let methods2 =
    System.AppDomain.CurrentDomain.GetAssemblies()
    |> List.ofArray
    |> List.map (fun assm -> assm.GetTypes())
    |> Array.concat
    |> List.ofArray
    |> List.map (fun t -> t.GetMethods())
    |> Array.concat

// Not OK
let methods2 = System.AppDomain.CurrentDomain.GetAssemblies()
    |> List.ofArray
    |> List.map (fun assm -> assm.GetTypes())
    |> Array.concat
    |> List.ofArray
    |> List.map (fun t -> t.GetMethods())
    |> Array.concat

```

Formatting modules

Code in a local module must be indented relative to the module, but code in a top-level module should not be indented. Namespace elements do not have to be indented.

```

// A is a top-level module.
module A

let function1 a b = a - b * b

```

```

// A1 and A2 are local modules.
module A1 =
    let function1 a b = a*a + b*b

module A2 =
    let function2 a b = a*a - b*b

```

Formatting object expressions and interfaces

Object expressions and interfaces should be aligned in the same way with `member` being indented after 4 spaces.

```

let comparer =
    { new IComparer<string> with
        member x.Compare(s1, s2) =
            let rev (s: String) =
                new String (Array.rev (s.ToCharArray()))
            let reversed = rev s1
            reversed.CompareTo (rev s2) }

```

Formatting white space in expressions

Avoid extraneous white space in F# expressions.

```
// OK
spam (ham.[1])

// Not OK
spam ( ham.[ 1 ] )
```

Named arguments should also not have space surrounding the `=`:

```
// OK
let makeStreamReader x = new System.IO.StreamReader(path=x)

// Not OK
let makeStreamReader x = new System.IO.StreamReader(path = x)
```

Formatting attributes

[Attributes](#) are placed above a construct:

```
[<SomeAttribute>]
type MyClass() = ...

[<RequireQualifiedAccess>]
module M =
    let f x = x

[<Struct>]
type MyRecord =
    { Label1: int
      Label2: string }
```

Formatting attributes on parameters

Attributes can also be places on parameters. In this case, place them on the same line as the parameter and before the name:

```
// Defines a class that takes an optional value as input defaulting to false.
type C() =
    member __.M([<Optional; DefaultValue(false)>] doSomething: bool)
```

Formatting multiple attributes

When multiple attributes are applied to a construct that is not a parameter, they should be placed such that there is one attribute per line:

```
[<Struct>]
[<IsByRefLike>]
type MyRecord =
    { Label1: int
      Label2: string }
```

When applied to a parameter, they must be on the same line and separated by a `;` separator.

Formatting literals

F# literals using the `Literal` attribute should place the attribute on its own line and use camelCase naming:

```
[<Literal>]  
let path = __SOURCE_DIRECTORY__ + "/" + __SOURCE_FILE__  
  
[<Literal>]  
let myUrl = "www.mywebsitethatiamworkingwith.com"
```

Avoid placing the attribute on the same line as the value.

F# coding conventions

10/6/2018 • 22 minutes to read • [Edit Online](#)

The following conventions are formulated from experience working with large F# codebases. The [Five principles of good F# code](#) are the foundation of each recommendation. They are related to the [F# component design guidelines](#), but are applicable for any F# code, not just components such as libraries.

Organizing code

F# features two primary ways to organize code: modules and namespaces. These are similar, but do have the following differences:

- Namespaces are compiled as .NET namespaces. Modules are compiled as static classes.
- Namespaces are always top level. Modules can be top-level and nested within other modules.
- Namespaces can span multiple files. Modules cannot.
- Modules can be decorated with `[<RequireQualifiedAccess>]` and `[<AutoOpen>]`.

The following guidelines will help you use these to organize your code.

Prefer namespaces at the top level

For any publicly consumable code, namespaces are preferential to modules at the top level. Because they are compiled as .NET namespaces, they are consumable from C# with no issue.

```
// Good!
namespace MyCode

type MyClass() =
    ...
```

Using a top-level module may not appear different when called only from F#, but for C# consumers, callers may be surprised by having to qualify `MyClass` with the `MyCode` module.

```
// Bad!
module MyCode

type MyClass() =
    ...
```

Carefully apply `[<AutoOpen>]`

The `[<AutoOpen>]` construct can pollute the scope of what is available to callers, and the answer to where something comes from is "magic". This is generally not a good thing. An exception to this rule is the F# Core Library itself (though this fact is also a bit controversial).

However, it is a convenience if you have helper functionality for a public API that you wish to organize separately from that public API.

```
module MyAPI =
    []
    module private Helpers =
        let helper1 x y z =
            ...

        let myFunction1 x =
            let y = ...
            let z = ...
            helper1 x y z
```

This lets you cleanly separate implementation details from the public API of a function without having to fully qualify a helper each time you call it.

Additionally, exposing extension methods and expression builders at the namespace level can be neatly expressed with [`<AutoOpen>`].

Use [`<RequireQualifiedAccess>`] **whenever names could conflict or you feel it helps with readability**

Adding the [`<RequireQualifiedAccess>`] attribute to a module indicates that the module may not be opened and that references to the elements of the module require explicit qualified access. For example, the

`Microsoft.FSharp.Collections.List` module has this attribute.

This is useful when functions and values in the module have names that are likely to conflict with names in other modules. Requiring qualified access can greatly increase the long-term maintainability and evolvability of a library.

```
[<RequireQualifiedAccess>]
module StringTokenizer =
    let parse s = ...

    ...

    let s = getAString()
    let parsed = StringTokenizer.parse s // Must qualify to use 'parse'
```

Sort `open` **statements topologically**

In F#, the order of declarations matters, including with `open` statements. This is unlike C#, where the effect of `using` and `using static` is independent of the ordering of those statements in a file.

In F#, elements opened into a scope can shadow others already present. This means that reordering `open` statements could alter the meaning of code. As a result, any arbitrary sorting of all `open` statements (for example, alphanumerically) is generally not recommended, lest you generate different behavior than you might expect.

Instead, we recommend that you sort them [topologically](#); that is, order your `open` statements in the order in which *layers* of your system are defined. Doing alphanumeric sorting within different topological layers may also be considered.

As an example, here is the topological sorting for the F# compiler service public API file:

```

namespace Microsoft.FSharp.Compiler.SourceCodeServices

open System
open System.Collections.Generic
open System.Collections.Concurrent
open System.Diagnostics
open System.IO
open System.Reflection
open System.Text

open Microsoft.FSharp.Compiler
open Microsoft.FSharp.Compiler.AbstractIL
open Microsoft.FSharp.Compiler.AbstractIL.Diagnostics
open Microsoft.FSharp.Compiler.AbstractIL.IL
open Microsoft.FSharp.Compiler.AbstractIL.ILBinaryReader
open Microsoft.FSharp.Compiler.AbstractIL.Internal
open Microsoft.FSharp.Compiler.AbstractIL.Internal.Library

open Microsoft.FSharp.Compiler.AccessibilityLogic
open Microsoft.FSharp.Compiler.Ast
open Microsoft.FSharp.Compiler.CompileOps
open Microsoft.FSharp.Compiler.CompileOptions
open Microsoft.FSharp.Compiler.Driver
open Microsoft.FSharp.Compiler.ErrorLogger
open Microsoft.FSharp.Compiler.Infos
open Microsoft.FSharp.Compiler.InfoReader
open Microsoft.FSharp.Compiler.Lexhelp
open Microsoft.FSharp.Compiler.Layout
open Microsoft.FSharp.Compiler.Lib
open Microsoft.FSharp.Compiler.NameResolution
open Microsoft.FSharp.Compiler.PrettyNaming
open Microsoft.FSharp.Compiler.Parser
open Microsoft.FSharp.Compiler.Range
open Microsoft.FSharp.Compiler.Tast
open Microsoft.FSharp.Compiler.Tastops
open Microsoft.FSharp.Compiler.TcGlobals
open Microsoft.FSharp.Compiler.TypeChecker
open Microsoft.FSharp.Compiler.SourceCodeServices.SymbolHelpers

open Internal.Utilities
open Internal.Utilities.Collections

```

Note that a line break separates topological layers, with each layer being sorted alphanumerically afterwards. This cleanly organizes code without accidentally shadowing values.

Use classes to contain values that have side effects

There are many times when initializing a value can have side effects, such as instantiating a context to a database or other remote resource. It is tempting to initialize such things in a module and use it in subsequent functions:

```

// This is bad!
module MyApi =
    let dep1 = File.ReadAllText "/Users/{your name}/connectionstring.txt"
    let dep2 = Environment.GetEnvironmentVariable "DEP_2"

    let private r = Random()
    let dep3() = r.Next() // Problematic if multiple threads use this

    let function1 arg = doStuffWith dep1 dep2 dep3 arg
    let function2 arg = doSutffWith dep1 dep2 dep3 arg

```

This is frequently a bad idea for a few reasons:

First, application configuration is pushed into the codebase with `dep1` and `dep2`. This is difficult to maintain in larger codebases.

Second, statically initialized data should not include values that are not thread safe if your component will itself use multiple threads. This is clearly violated by `dep3`.

Finally, module initialization compiles into a static constructor for the entire compilation unit. If any error occurs in let-bound value initialization in that module, it manifests as a `TypeInitializationException` that is then cached for the entire lifetime of the application. This can be difficult to diagnose. There is usually an inner exception that you can attempt to reason about, but if there is not, then there is no telling what the root cause is.

Instead, just use a simple class to hold dependencies:

```
type MyParametricApi(dep1, dep2, dep3) =
    member ___.Function1 arg1 = doStuffWith dep1 dep2 dep3 arg1
    member ___.Function2 arg2 = doStuffWith dep1 dep2 dep3 arg2
```

This enables the following:

1. Pushing any dependent state outside of the API itself.
2. Configuration can now be done outside of the API.
3. Errors in initialization for dependent values are not likely to manifest as a `TypeInitializationException`.
4. The API is now easier to test.

Error management

Error management in large systems is a complex and nuanced endeavor, and there are no silver bullets in ensuring your systems are fault-tolerant and behave well. The following guidelines should offer guidance in navigating this difficult space.

Represent error cases and illegal state in types intrinsic to your domain

With [Discriminated Unions](#), F# gives you the ability to represent faulty program state in your type system. For example:

```
type MoneyWithdrawalResult =
    | Success of amount:decimal
    | InsufficientFunds of balance:decimal
    | CardExpired of DateTime
    | UndisclosedFailure
```

In this case, there are three known ways that withdrawing money from a bank account can fail. Each error case is represented in the type, and can thus be dealt with safely throughout the program.

```
let handleWithdrawal amount =
    let w = withdrawMoney amount
    match w with
    | Success am -> printfn "Successfully withdrew %f" am
    | InsufficientFunds balance -> printfn "Failed: balance is %f" balance
    | CardExpired expiredDate -> printfn "Failed: card expired on %O" expiredDate
    | UndisclosedFailure -> printfn "Failed: unknown"
```

In general, if you can model the different ways that something can **fail** in your domain, then error handling code is no longer treated as something you must deal with in addition to regular program flow. It is simply a part of normal program flow, and not considered **exceptional**. There are two primary benefits to this:

1. It is easier to maintain as your domain changes over time.

2. Error cases are easier to unit test.

Use exceptions when errors cannot be represented with types

Not all errors can be represented in a problem domain. These kinds of faults are *exceptional* in nature, hence the ability to raise and catch exceptions in F#.

First, it is recommended that you read the [Exception Design Guidelines](#). These are also applicable to F#.

The main constructs available in F# for the purposes of raising exceptions should be considered in the following order of preference:

FUNCTION	SYNTAX	PURPOSE
<code>nullArg</code>	<code>nullArg "argumentName"</code>	Raises a <code>System.ArgumentNullException</code> with the specified argument name.
<code>invalidArg</code>	<code>invalidArg "argumentName" "message"</code>	Raises a <code>System.ArgumentException</code> with a specified argument name and message.
<code>invalidOp</code>	<code>invalidOp "message"</code>	Raises a <code>System.InvalidOperationException</code> with the specified message.
<code>raise</code>	<code>raise (ExceptionType("message"))</code>	General-purpose mechanism for throwing exceptions.
<code>failwith</code>	<code>failwith "message"</code>	Raises a <code>System.Exception</code> with the specified message.
<code>failwithf</code>	<code>failwithf "format string" argForFormatString</code>	Raises a <code>System.Exception</code> with a message determined by the format string and its inputs.

Use `nullArg`, `invalidArg` and `invalidOp` as the mechanism to throw `ArgumentNullException`, `ArgumentException` and `InvalidOperationException` when appropriate.

The `failwith` and `failwithf` functions should generally be avoided because they raise the base `Exception` type, not a specific exception. As per the [Exception Design Guidelines](#), you want to raise more specific exceptions when you can.

Using exception-handling syntax

F# supports exception patterns via the `try...with` syntax:

```
try
    tryGetFileContents()
with
| :? System.IO.FileNotFoundException as e -> // Do something with it here
| :? System.Security.SecurityException as e -> // Do something with it here
```

Reconciling functionality to perform in the face of an exception with pattern matching can be a bit tricky if you wish to keep the code clean. One such way to handle this is to use [active patterns](#) as a means to group functionality surrounding an error case with an exception itself. For example, you may be consuming an API that, when it throws an exception, encloses valuable information in the exception metadata. Unwrapping a useful value in the body of the captured exception inside the Active Pattern and returning that value can be helpful in some situations.

Do not use monadic error handling to replace exceptions

Exceptions are seen as somewhat taboo in functional programming. Indeed, exceptions violate purity, so it's safe to consider them not-quite functional. However, this ignores the reality of where code must run, and that runtime errors can occur. In general, write code on the assumption that most things are neither pure nor total, to minimize unpleasant surprises.

It is important to consider the following core strengths/aspects of Exceptions with respect to their relevance and appropriateness in the .NET runtime and cross-language ecosystem as a whole:

1. They contain detailed diagnostic information, which is very helpful when debugging an issue.
2. They are well-understood by the runtime and other .NET languages.
3. They can reduce significant boilerplate when compared with code that goes out of its way to *avoid* exceptions by implementing some subset of their semantics on an ad-hoc basis.

This third point is critical. For nontrivial complex operations, failing to use exceptions can result in dealing with structures like this:

```
Result<Result<MyType, string>, string list>
```

Which can easily lead to fragile code like pattern matching on "stringly-typed" errors:

```
let result = doStuff()
match result with
| Ok r -> ...
| Error e ->
    if e.Contains "Error string 1" then ...
    elif e.Contains "Error string 2" then ...
    else ... // Who knows?
```

Additionally, it can be tempting to swallow any exception in the desire for a "simple" function that returns a "nicer" type:

```
// This is bad!
let tryReadAllText (path : string) =
    try System.IO.File.ReadAllText path |> Some
    with _ -> None
```

Unfortunately, `tryReadAllText` can throw numerous exceptions based on the myriad of things that can happen on a file system, and this code discards away any information about what might actually be going wrong in your environment. If you replace this code with a result type, then you're back to "stringly-typed" error message parsing:

```
// This is bad!
let tryReadAllText (path : string) =
    try System.IO.File.ReadAllText path |> Ok
    with e -> Error e.Message

let r = tryReadAllText "path-to-file"
match r with
| Ok text -> ...
| Error e ->
    if e.Contains "uh oh, here we go again..." then ...
    else ...
```

And placing the exception object itself in the `Error` constructor just forces you to properly deal with the exception type at the call site rather than in the function. Doing this effectively creates checked exceptions, which are notoriously unfun to deal with as a caller of an API.

A good alternative to the above examples is to catch *specific* exceptions and return a meaningful value in the context of that exception. If you modify the `tryReadAllText` function as follows, `None` has more meaning:

```
let tryReadAllTextIfPresent (path : string) =
    try System.IO.File.ReadAllText path |> Some
    with :? FileNotFoundException -> None
```

Instead of functioning as a catch-all, this function will now properly handle the case when a file was not found and assign that meaning to a return. This return value can map to that error case, while not discarding any contextual information or forcing callers to deal with a case that may not be relevant at that point in the code.

Types such as `Result<'Success, 'Error>` are appropriate for basic operations where they aren't nested, and F# optional types are perfect for representing when something could either return *something* or *nothing*. They are not a replacement for exceptions, though, and should not be used in an attempt to replace exceptions. Rather, they should be applied judiciously to address specific aspects of exception and error management policy in targeted ways.

Partial application and point-free programming

F# supports partial application, and thus, various ways to program in a point-free style. This can be beneficial for code reuse within a module or the implementation of something, but it is generally not something to expose publicly. In general, point-free programming is not a virtue in and of itself, and can add a significant cognitive barrier for people who are not immersed in the style.

Do not use partial application and currying in public APIs

With little exception, the use of partial application in public APIs can be confusing for consumers. Usually, `let`-bound values in F# code are **values**, not **function values**. Mixing together values and function values can result in saving a small number of lines of code in exchange for quite a bit of cognitive overhead, especially if combined with operators such as `>>` to compose functions.

Consider the tooling implications for point-free programming

Curried functions do not label their arguments. This has tooling implications. Consider the following two functions:

```
let func name age =
    printfn "My name is %s and I am %d years old!" name age

let funcWithApplication =
    printfn "My name is %s and I am %d years old!"
```

Both are valid functions, but `funcWithApplication` is a curried function. When you hover over their types in an editor, you see this:

```
val func : name:string -> age:int -> unit

val funcWithApplication : (string -> int -> unit)
```

At the call site, tooltips in tooling such as Visual Studio will not give you meaningful information as to what the `string` and `int` input types actually represent.

If you encounter point-free code like `funcWithApplication` that is publicly consumable, it is recommended to do a full η -expansion so that tooling can pick up on meaningful names for arguments.

Furthermore, debugging point-free code can be challenging, if not impossible. Debugging tools rely on values bound to names (for example, `let` bindings) so that you can inspect intermediate values midway through

execution. When your code has no values to inspect, there is nothing to debug. In the future, debugging tools may evolve to synthesize these values based on previously executed paths, but it's not a good idea to hedge your bets on *potential* debugging functionality.

Consider partial application as a technique to reduce internal boilerplate

In contrast to the previous point, partial application is a wonderful tool for reducing boilerplate inside of an application or the deeper internals of an API. It can be helpful for unit testing the implementation of more complicated APIs, where boilerplate is often a pain to deal with. For example, the following code shows how you can accomplish what most mocking frameworks give you without taking an external dependency on such a framework and having to learn a related bespoke API.

For example, consider the following solution topography:

```
MySolution.sln
|_ImplementationLogic.fsproj
|_ImplementationLogic.Tests.fsproj
|_API.fsproj
```

`ImplementationLogic.fsproj` might expose code such as:

```
module Transactions =
    let doTransaction txnContext txnType balance =
        ...

type Transactor(ctx, currentBalance) =
    member __.ExecuteTransaction(txnType) =
        Transactions.doTransaction ctx txtType currentBalance
    ...
```

Unit testing `Transactions.doTransaction` in `ImplementationLogic.Tests.fspoj` is easy:

```
namespace TransactionsTestingUtil

open Transactions

module TransactionsTestable =
    let getTestableTransactionRoutine mockContext = Transactions.doTransaction mockContext
```

Partially applying `doTransaction` with a mocking context object lets you call the function in all of your unit tests without needing to construct a mocked context each time:

```

namespace TransactionTests

open Xunit
open TransactionTypes
open TransactionsTestingUtil
open TransactionsTestingUtil.TransactionsTestable

let testableContext =
    { new ITransactionContext with
        member __.TheFirstMember() = ...
        member __.TheSecondMember() = ... }

let transactionRoutine = getTestableTransactionRoutine testableContext

[<Fact>]
let ``Test withdrawal transaction with 0.0 for balance``() =
    let expected = ...
    let actual = transactionRoutine TransactionType.Withdraw 0.0
    Assert.Equal(expected, actual)

```

This technique should not be universally applied to your entire codebase, but it is a good way to reduce boilerplate for complicated internals and unit testing those internals.

Access control

F# has multiple options for [Access control](#), inherited from what is available in the .NET runtime. These are not just usable for types - you can use them for functions, too.

- Prefer non-`public` types and members until you need them to be publicly consumable. This also minimizes what consumers couple to.
- Strive to keep all helper functionality `private`.
- Consider the use of `[<AutoOpen>]` on a private module of helper functions if they become numerous.

Type inference and generics

Type inference can save you from typing a lot of boilerplate. And automatic generalization in the F# compiler can help you write more generic code with almost no extra effort on your part. However, these features are not universally good.

- Consider labeling argument names with explicit types in public APIs and do not rely on type inference for this.

The reason for this is that **you** should be in control of the shape of your API, not the compiler. Although the compiler can do a fine job at inferring types for you, it is possible to have the shape of your API change if the internals it relies on have changed types. This may be what you want, but it will almost certainly result in a breaking API change that downstream consumers will then have to deal with. Instead, if you explicitly control the shape of your public API, then you can control these breaking changes. In DDD terms, this can be thought of as an Anti-corruption layer.

- Consider giving a meaningful name to your generic arguments.

Unless you are writing truly generic code that is not specific to a particular domain, a meaningful name can help other programmers understanding the domain they're working in. For example, a type parameter named `'Document` in the context of interacting with a document database makes it clearer that generic document types can be accepted by the function or member you are working with.

- Consider naming generic type parameters with PascalCase.

This is the general way to do things in .NET, so it's recommended that you use PascalCase rather than snake\_case or camelCase.

Finally, automatic generalization is not always a boon for people who are new to F# or a large codebase. There is cognitive overhead in using components that are generic. Furthermore, if automatically generalized functions are not used with different input types (let alone if they are intended to be used as such), then there is no real benefit to them being generic at that point in time. Always consider if the code you are writing will actually benefit from being generic.

Performance

F# values are immutable by default, which allows you to avoid certain classes of bugs (especially those involving concurrency and parallelism). However, in certain cases, in order to achieve optimal (or even reasonable) efficiency of execution time or memory allocations, a span of work may best be implemented by using in-place mutation of state. This is possible in an opt-in basis with F# with the `mutable` keyword.

However, use of `mutable` in F# may feel at odds with functional purity. This is fine, if you adjust expectations from purity to [referential transparency](#). Referential transparency - not purity - is the end goal when writing F# functions. This allows you to write a functional interface over a mutation-based implementation for performance critical code.

Wrap mutable code in immutable interfaces

With referential transparency as a goal, it is critical to write code that does not expose the mutable underbelly of performance-critical functions. For example, the following code implements the `Array.contains` function in the F# core library:

```
[<CompiledName("Contains")>]
let inline contains value (array:T[]) =
    checkNotNull "array" array
    let mutable state = false
    let mutable i = 0
    while not state && i < array.Length do
        state <- value = array.[i]
        i <- i + 1
    state
```

Calling this function multiple times does not change the underlying array, nor does it require you to maintain any mutable state in consuming it. It is referentially transparent, even though almost every line of code within it uses mutation.

Consider encapsulating mutable data in classes

The previous example used a single function to encapsulate operations using mutable data. This is not always sufficient for more complex sets of data. Consider the following sets of functions:

```
open System.Collections.Generic

let addToClosureTable (key, value) (t: Dictionary<_,_>) =
    if not (t.ContainsKey(key)) then
        t.Add(key, value)
    else
        t.[key] <- value

let closureTableCount (t: Dictionary<_,_>) = t.Count

let closureTableContains (key, value) (t: Dictionary<_, HashSet<_>>) =
    match t.TryGetValue(key) with
    | (true, v) -> v.Equals(value)
    | (false, _) -> false
```

This code is performant, but it exposes the mutation-based data structure that callers are responsible for maintaining. This can be wrapped inside of a class with no underlying members that can change:

```
open System.Collections.Generic

/// The results of computing the LALR(1) closure of an LR(0) kernel
type Closure1Table() =
    let t = Dictionary<Item0, HashSet<TerminalIndex>>()

    member __.Add(key, value) =
        if not (t.ContainsKey(key)) then
            t.Add(key, value)
        else
            t.[key] <- value

    member __.Count = t.Count

    member __.Contains(key, value) =
        match t.TryGetValue(key) with
        | (true, v) -> v.Equals(value)
        | (false, _) -> false
```

`Closure1Table` encapsulates the underlying mutation-based data structure, thereby not forcing callers to maintain the underlying data structure. Classes are a powerful way to encapsulate data and routines that are mutation-based without exposing the details to callers.

Prefer `let mutable` to reference cells

Reference cells are a way to represent the reference to a value rather than the value itself. Although they can be used for performance-critical code, they are generally not recommended. Consider the following example:

```
let kernels =
    let acc = ref Set.empty

    processWorkList startKernels (fun kernel ->
        if not ((!acc).Contains(kernel)) then
            acc := (!acc).Add(kernel)
        ...)

    !acc |> Seq.toList
```

The use of a reference cell now "pollutes" all subsequent code with having to dereference and re-reference the underlying data. Instead, consider `let mutable`:

```
let kernels =
    let mutable acc = Set.empty

    processWorkList startKernels (fun kernel ->
        if not (acc.Contains(kernel)) then
            acc <- acc.Add(kernel)
        ...)

    acc |> Seq.toList
```

Aside from the single point of mutation in the middle of the lambda expression, all other code that touches `acc` can do so in a manner that is no different to the usage of a normal `let`-bound immutable value. This will make it easier to change over time.

Object programming

F# has full support for objects and object-oriented (OO) concepts. Although many OO concepts are powerful and useful, not all of them are ideal to use. The following lists offer guidance on categories of OO features at a high level.

Consider using these features in many situations:

- Dot notation (`x.Length`)
- Instance members
- Implicit constructors
- Static members
- Indexer notation (`arr.[x]`)
- Named and Optional arguments
- Interfaces and interface implementations

Don't reach for these features first, but do judiciously apply them when they are convenient to solve a problem:

- Method overloading
- Encapsulated mutable data
- Operators on types
- Auto properties
- Implementing `IDisposable` and `IEnumerable`
- Type extensions
- Events
- Structs
- Delegates
- Enums

Generally avoid these features unless you must use them:

- Inheritance-based type hierarchies and implementation inheritance
- Nulls and `Unchecked.defaultof<_>`

Prefer composition over inheritance

[Composition over inheritance](#) is a long-standing idiom that good F# code can adhere to. The fundamental principle is that you should not expose a base class and force callers to inherit from that base class to get functionality.

Use object expressions to implement interfaces if you don't need a class

[Object Expressions](#) allow you to implement interfaces on the fly, binding the implemented interface to a value without needing to do so inside of a class. This is convenient, especially if you *only* need to implement the interface and have no need for a full class.

For example, here is the code that is run in [Ionide](#) to provide a code fix action if you've added a symbol that you don't have an `open` statement for:

```

let private createProvider () =
    { new CodeActionProvider with
        member this.provideCodeActions(doc, range, context, ct) =
            let diagnostics = context.diagnostics
            let diagnostic = diagnostics |> Seq.tryFind (fun d -> d.message.Contains "Unused open
statement")
            let res =
                match diagnostic with
                | None -> []
                | Some d -
                    let line = doc.lineAt d.range.start.line
                    let cmd = createEmpty<Command>
                    cmd.title <- "Remove unused open"
                    cmd.command <- "fsharp.unusedOpenFix"
                    cmd.arguments <- Some ([| doc |> unbox; line.range |> unbox; |] |> ResizeArray)
                    [|cmd|]
            res
        |> ResizeArray
        |> U2.Case1
    }
}

```

Because there is no need for a class when interacting with the Visual Studio Code API, Object Expressions are an ideal tool for this. They are also valuable for unit testing, when you want to stub out an interface with test routines in an ad hoc manner.

Type Abbreviations

Type Abbreviations are a convenient way to assign a label to another type, such as a function signature or a more complex type. For example, the following alias assigns a label to what's needed to define a computation with [CNTK](#), a deep learning library:

```

open CNTK

// DeviceDescriptor, Variable, and Function all come from CNTK
type Computation = DeviceDescriptor -> Variable -> Function

```

The `Computation` name is a convenient way to denote any function that matches the signature it is aliasing. Using Type Abbreviations like this is convenient and allows for more succinct code.

Avoid using Type Abbreviations to represent your domain

Although Type Abbreviations are convenient for giving a name to function signatures, they can be confusing when abbreviating other types. Consider this abbreviation:

```

// Does not actually abstract integers.
type BufferSize = int

```

This can be confusing in multiple ways:

- `BufferSize` is not an abstraction; it is just another name for an integer.
- If `BufferSize` is exposed in a public API, it can easily be misinterpreted to mean more than just `int`. Generally, domain types have multiple attributes to them and are not primitive types like `int`. This abbreviation violates that assumption.
- The casing of `BufferSize` (PascalCase) implies that this type holds more data.
- This alias does not offer increased clarity compared with providing a named argument to a function.
- The abbreviation will not manifest in compiled IL; it is just an integer and this alias is a compile-time construct.

```
module Networking =
...
let send data (bufferSize: int) =
...
```

In summary, the pitfall with Type Abbreviations is that they are **not** abstractions over the types they are abbreviating. In the previous example, `BufferSize` is just an `int` under the covers, with no additional data, nor any benefits from the type system besides what `int` already has.

F# component design guidelines

1/25/2019 • 27 minutes to read • [Edit Online](#)

This document is a set of component design guidelines for F# programming, based on the F# Component Design Guidelines, v14, Microsoft Research, and [another version](#) originally curated and maintained by the F# Software Foundation.

This document assumes you are familiar with F# programming. Many thanks to the F# community for their contributions and helpful feedback on various versions of this guide.

Overview

This document looks at some of the issues related to F# component design and coding. A component can mean any of the following:

- A layer in your F# project that has external consumers within that project.
- A library intended for consumption by F# code across assembly boundaries.
- A library intended for consumption by any .NET language across assembly boundaries.
- A library intended for distribution via a package repository, such as [NuGet](#).

Techniques described in this article follow the [Five principles of good F# code](#), and thus utilize both functional and object programming as appropriate.

Regardless of the methodology, the component and library designer faces a number of practical and prosaic issues when trying to craft an API that is most easily usable by developers. Conscientious application of the [.NET Library Design Guidelines](#) will steer you towards creating a consistent set of APIs that are pleasant to consume.

General guidelines

There are a few universal guidelines that apply to F# libraries, regardless of the intended audience for the library.

Learn the .NET Library Design Guidelines

Regardless of the kind of F# coding you are doing, it is valuable to have a working knowledge of the [.NET Library Design Guidelines](#). Most other F# and .NET programmers will be familiar with these guidelines, and expect .NET code to conform to them.

The .NET Library Design Guidelines provide general guidance regarding naming, designing classes and interfaces, member design (properties, methods, events, etc.) and more, and are a useful first point of reference for a variety of design guidance.

Add XML documentation comments to your code

XML documentation on public APIs ensure that users can get great Intellisense and Quickinfo when using these types and members, and enable building documentation files for the library. See the [XML Documentation](#) about various xml tags that can be used for additional markup within xmldoc comments.

```
/// A class for representing (x,y) coordinates
type Point =

    /// Computes the distance between this point and another
    member DistanceTo: otherPoint:Point -> float
```

You can use either the short form XML comments (`/// comment`), or standard XML comments (`///<summary>comment</summary>`).

Consider using explicit signature files (.fsi) for stable library and component APIs

Using explicit signatures files in an F# library provides a succinct summary of public API, which both helps to ensure that you know the full public surface of your library, as well as provides a clean separation between public documentation and internal implementation details. Note that signature files add friction to changing the public API, by requiring changes to be made in both the implementation and signature files. As a result, signature files should typically only be introduced when an API has become solidified and is no longer expected to change significantly.

Always follow best practices for using strings in .NET

Follow [Best Practices for Using Strings in .NET](#) guidance. In particular, always explicitly state *cultural intent* in the conversion and comparison of strings (where applicable).

Guidelines for F#-facing libraries

This section presents recommendations for developing public F#-facing libraries; that is, libraries exposing public APIs that are intended to be consumed by F# developers. There are a variety of library-design recommendations applicable specifically to F#. In the absence of the specific recommendations that follow, the .NET Library Design Guidelines are the fallback guidance.

Naming conventions

Use .NET naming and capitalization conventions

The following table follows .NET naming and capitalization conventions. There are small additions to also include F# constructs.

CONSTRUCT	CASE	PART	EXAMPLES	NOTES
Concrete types	PascalCase	Noun/ adjective	List, Double, Complex	Concrete types are structs, classes, enumerations, delegates, records, and unions. Though type names are traditionally lowercase in OCaml, F# has adopted the .NET naming scheme for types.
DLLs	PascalCase		Fabrikam.Core.dll	
Union tags	PascalCase	Noun	Some, Add, Success	Do not use a prefix in public APIs. Optionally use a prefix when internal, such as <pre>type Teams = TAlpha TBeta TDelta.</pre>
Event	PascalCase	Verb	ValueChanged / ValueChanging	
Exceptions	PascalCase		WebException	Name should end with "Exception".

CONSTRUCT	CASE	PART	EXAMPLES	NOTES
Field	PascalCase	Noun	CurrentName	
Interface types	PascalCase	Noun/ adjective	IDisposable	Name should start with "I".
Method	PascalCase	Verb	ToString	
Namespace	PascalCase		Microsoft.FSharp.Core	Generally use <code><Organization>. <Technology>[. <Subnamespace>]</code> , though drop the organization if the technology is independent of organization.
Parameters	camelCase	Noun	typeName, transform, range	
let values (internal)	camelCase or PascalCase	Noun/ verb	getValue, myTable	
let values (external)	camelCase or PascalCase	Noun/verb	List.map, Dates.Today	let-bound values are often public when following traditional functional design patterns. However, generally use PascalCase when the identifier can be used from other .NET languages.
Property	PascalCase	Noun/ adjective	IsEndOfFile, BackColor	Boolean properties generally use Is and Can and should be affirmative, as in IsEndOfFile, not IsNotEndOfFile.

Avoid abbreviations

The .NET guidelines discourage the use of abbreviations (for example, "use `onButtonClick` rather than `OnBtnClick`"). Common abbreviations, such as `Async` for "Asynchronous", are tolerated. This guideline is sometimes ignored for functional programming; for example, `List.iter` uses an abbreviation for "iterate". For this reason, using abbreviations tends to be tolerated to a greater degree in F#-to-F# programming, but should still generally be avoided in public component design.

Avoid casing name collisions

The .NET guidelines say that casing alone cannot be used to disambiguate name collisions, since some client languages (for example, Visual Basic) are case-insensitive.

Use acronyms where appropriate

Acronyms such as XML are not abbreviations and are widely used in .NET libraries in uncapitalized form (Xml). Only well-known, widely recognized acronyms should be used.

Use PascalCase for generic parameter names

Do use PascalCase for generic parameter names in public APIs, including for F#-facing libraries. In particular, use names like `T`, `U`, `T1`, `T2` for arbitrary generic parameters, and when specific names make sense, then for F#-facing libraries use names like `Key`, `Value`, `Arg` (but not for example, `TKey`).

Use either PascalCase or camelCase for public functions and values in F# modules

camelCase is used for public functions that are designed to be used unqualified (for example, `invalidArg`), and for the “standard collection functions” (for example, `List.map`). In both these cases, the function names act much like keywords in the language.

Object, Type, and Module design

Use namespaces or modules to contain your types and modules

Each F# file in a component should begin with either a namespace declaration or a module declaration.

```
namespace Fabrikam.BasicOperationsAndTypes

type ObjectType1() =
    ...

type ObjectType2() =
    ...

module CommonOperations =
    ...
```

or

```
module Fabrikam.BasicOperationsAndTypes

type ObjectType1() =
    ...

type ObjectType2() =
    ...

module CommonOperations =
    ...
```

The differences between using modules and namespaces to organize code at the top level are as follows:

- Namespaces can span multiple files
- Namespaces cannot contain F# functions unless they are within an inner module
- The code for any given module must be contained within a single file
- Top-level modules can contain F# functions without the need for an inner module

The choice between a top-level namespace or module affects the compiled form of the code, and thus will affect the view from other .NET languages should your API eventually be consumed outside of F# code.

Use methods and properties for operations intrinsic to object types

When working with objects, it is best to ensure that consumable functionality is implemented as methods and properties on that type.

```

type HardwareDevice() =
    member this.ID = ...
    member this.SupportedProtocols = ...

type HashTable<'Key, 'Value>(comparer: IEqualityComparer<'Key>) =
    member this.Add(key, value) = ...
    member this.ContainsKey(key) = ...
    member this.ContainsValue(value) = ...

```

The bulk of functionality for a given member need not necessarily be implemented in that member, but the consumable piece of that functionality should be.

Use classes to encapsulate mutable state

In F#, this only needs to be done where that state is not already encapsulated by another language construct, such as a closure, sequence expression, or asynchronous computation.

```

type Counter() =
    // let-bound values are private in classes.
    let mutable count = 0

    member this.Next() =
        count <- count + 1
        count

```

Use interfaces to group related operations

Use interface types to represent a set of operations. This is preferred to other options, such as tuples of functions or records of functions.

```

type Serializer =
    abstract Serialize<'T>: preserveRefEq: bool -> value: 'T -> string
    abstract Deserialize<'T>: preserveRefEq: bool -> pickle: string -> 'T

```

In preference to:

```

type Serializer<'T> = {
    Serialize: bool -> 'T -> string
    Deserialize: bool -> string -> 'T
}

```

Interfaces are first-class concepts in .NET, which you can use to achieve what Functors would normally give you. Additionally, they can be used to encode existential types into your program, which records of functions cannot.

Use a module to group functions which act on collections

When you define a collection type, consider providing a standard set of operations like `CollectionType.map` and `CollectionType.iter`) for new collection types.

```

module CollectionType =
    let map f c =
        ...
    let iter f c =
        ...

```

If you include such a module, follow the standard naming conventions for functions found in FSharp.Core.

Use a module to group functions for common, canonical functions, especially in math and DSL libraries

For example, `Microsoft.FSharp.Core.Operators` is an automatically opened collection of top-level functions (like `abs` and `sin`) provided by FSharp.Core.dll.

Likewise, a statistics library might include a module with functions `erf` and `erfc`, where this module is designed to be explicitly or automatically opened.

Consider using `RequireQualifiedAccess` and carefully apply `AutoOpen` attributes

Adding the `[<RequireQualifiedAccess>]` attribute to a module indicates that the module may not be opened and that references to the elements of the module require explicit qualified access. For example, the `Microsoft.FSharp.Collections.List` module has this attribute.

This is useful when functions and values in the module have names that are likely to conflict with names in other modules. Requiring qualified access can greatly increase the long-term maintainability and evolvability of a library.

Adding the `[<AutoOpen>]` attribute to a module means the module will be opened when the containing namespace is opened. The `[<AutoOpen>]` attribute may also be applied to an assembly to indicate a module that is automatically opened when the assembly is referenced.

For example, a statistics library **MathsHeaven.Statistics** might contain a

```
module MathsHeaven.Statistics.Operators containing functions erf and erfc. It is reasonable to mark this module as [<AutoOpen>]. This means open MathsHeaven.Statistics will also open this module and bring the names erf and erfc into scope. Another good use of [<AutoOpen>] is for modules containing extension methods.
```

Overuse of `[<AutoOpen>]` leads to polluted namespaces, and the attribute should be used with care. For specific libraries in specific domains, judicious use of `[<AutoOpen>]` can lead to better usability.

Consider defining operator members on classes where using well-known operators is appropriate

Sometimes classes are used to model mathematical constructs such as Vectors. When the domain being modeled has well-known operators, defining them as members intrinsic to the class is helpful.

```
type Vector(x: float) =  
  
    member v.X = x  
  
    static member (*) (vector: Vector, scalar: float) = Vector(vector.X * scalar)  
  
    static member (+) (vector1: Vector, vector2: Vector) = Vector(vector1.X + vector2.X)  
  
let v = Vector(5.0)  
  
let u = v * 10.0
```

This guidance corresponds to general .NET guidance for these types. However, it can be additionally important in F# coding as this allows these types to be used in conjunction with F# functions and methods with member constraints, such as `List.sumBy`.

Consider using `CompiledName` to provide a .NET-friendly name for other .NET language consumers

Sometimes you may wish to name something in one style for F# consumers (such as a static member in lower case so that it appears as if it were a module-bound function), but have a different style for the name when it is compiled into an assembly. You can use the `[<CompiledName>]` attribute to provide a different style for non F# code consuming the assembly.

```

type Vector(x:float, y:float) =
    member v.X = x
    member v.Y = y
    [<CompiledName("Create")>]
    static member create x y = Vector (x, y)

let v = Vector.create 5.0 3.0

```

By using [`<CompiledName>`], you can use .NET naming conventions for non F# consumers of the assembly.

Use method overloading for member functions, if doing so provides a simpler API

Method overloading is a powerful tool for simplifying an API that may need to perform similar functionality, but with different options or arguments.

```

type Logger() =
    member this.Log(message) =
        ...
    member this.Log(message, retryPolicy) =
        ...

```

In F#, it is more common to overload on number of arguments rather than types of arguments.

Hide the representations of record and union types if the design of these types is likely to evolve

Avoid revealing concrete representations of objects. For example, the concrete representation of `DateTime` values is not revealed by the external, public API of the .NET library design. At run time, the Common Language Runtime knows the committed implementation that will be used throughout execution. However, compiled code doesn't itself pick up dependencies on the concrete representation.

Avoid the use of implementation inheritance for extensibility

In F#, implementation inheritance is rarely used. Furthermore, inheritance hierarchies are often complex and difficult to change when new requirements arrive. Inheritance implementation still exists in F# for compatibility and rare cases where it is the best solution to a problem, but alternative techniques should be sought in your F# programs when designing for polymorphism, such as interface implementation.

Function and member signatures

Use tuples for return values when returning a small number of multiple unrelated values

Here is a good example of using a tuple in a return type:

```

val divrem: BigInteger -> BigInteger -> BigInteger * BigInteger

```

For return types containing many components, or where the components are related to a single identifiable entity, consider using a named type instead of a tuple.

Use `Async<T>` for async programming at F# API boundaries

If there is a corresponding synchronous operation named `Operation` that returns a `T`, then the async operation should be named `AsyncOperation` if it returns `Async<T>` or `OperationAsync` if it returns `Task<T>`. For commonly used .NET types that expose Begin/End methods, consider using `Async.FromBeginEnd` to write extension methods as a façade to provide the F# async programming model to those .NET APIs.

```

type SomeType =
    member this.Compute(x:int): int =
        ...
    member this.AsyncCompute(x:int): Async<int> =
        ...

type System.ServiceModel.Channels.IInputChannel with
    member this.AsyncReceive() =
        ...

```

Exceptions

See [Error Management](#) to learn about appropriate use of exceptions, results, and options.

Extension Members

Carefully apply F# extension members in F#-to-F# components

F# extension members should generally only be used for operations that are in the closure of intrinsic operations associated with a type in the majority of its modes of use. One common use is to provide APIs that are more idiomatic to F# for various .NET types:

```

type System.ServiceModel.Channels.IInputChannel with
    member this.AsyncReceive() =
        Async.FromBeginEnd(this.BeginReceive, this.EndReceive)

type System.Collections.Generic.IDictionary<'Key, 'Value> with
    member this.TryGet key =
        let ok, v = this.TryGetValue key
        if ok then Some v else None

```

Union Types

Use discriminated unions instead of class hierarchies for tree-structured data

Tree-like structures are recursively defined. This is awkward with inheritance, but elegant with Discriminated Unions.

```

type BST<'T> =
| Empty
| Node of 'T * BST<'T> * BST<'T>

```

Representing tree-like data with Discriminated Unions also allows you to benefit from exhaustiveness in pattern matching.

Use [`<RequireQualifiedAccess>`] on union types whose case names are not sufficiently unique

You may find yourself in a domain where the same name is the best name for different things, such as Discriminated Union cases. You can use [`<RequireQualifiedAccess>`] to disambiguate case names in order to avoid triggering confusing errors due to shadowing dependent on the ordering of `open` statements

Hide the representations of discriminated unions for binary compatible APIs if the design of these types is likely to evolve

Unions types rely on F# pattern-matching forms for a succinct programming model. As mentioned previously, you should avoid revealing concrete data representations if the design of these types is likely to evolve.

For example, the representation of a discriminated union can be hidden using a private or internal declaration, or by using a signature file.

```
type Union =
    private
    | CaseA of int
    | CaseB of string
```

If you reveal discriminated unions indiscriminately, you may find it hard to version your library without breaking user code. Instead, consider revealing one or more active patterns to permit pattern matching over values of your type.

Active patterns provide an alternate way to provide F# consumers with pattern matching while avoiding exposing F# Union Types directly.

Inline Functions and Member Constraints

Define generic numeric algorithms using inline functions with implied member constraints and statically resolved generic types

Arithmetic member constraints and F# comparison constraints are a standard for F# programming. For example, consider the following code:

```
let inline highestCommonFactor a b =
    let rec loop a b =
        if a = LanguagePrimitives.GenericZero<_> then b
        elif a < b then loop a (b - a)
        else loop (a - b) b
    loop a b
```

The type of this function is as follows:

```
val inline highestCommonFactor : ^T -> ^T -> ^T
    when ^T : (static member Zero : ^T)
    and ^T : (static member ( - ) : ^T * ^T -> ^T)
    and ^T : equality
    and ^T : comparison
```

This is a suitable function for a public API in a mathematical library.

Avoid using member constraints to simulate type classes and duck typing

It is possible to simulate “duck typing” using F# member constraints. However, members that make use of this should not in general be used in F#-to-F# library designs. This is because library designs based on unfamiliar or non-standard implicit constraints tend to cause user code to become inflexible and tied to one particular framework pattern.

Additionally, there is a good chance that heavy use of member constraints in this manner can result in very long compile times.

Operator Definitions

Avoid defining custom symbolic operators

Custom operators are essential in some situations and are highly useful notational devices within a large body of implementation code. For new users of a library, named functions are often easier to use. In addition, custom symbolic operators can be hard to document, and users find it more difficult to look up help on operators, due to existing limitations in IDE and search engines.

As a result, it is best to publish your functionality as named functions and members, and additionally expose operators for this functionality only if the notational benefits outweigh the documentation and cognitive cost of having them.

Units of Measure

Carefully use units of measure for added type safety in F# code

Additional typing information for units of measure is erased when viewed by other .NET languages. Be aware that .NET components, tools, and reflection will see types-sans-units. For example, C# consumers will see `float` rather than `float<kg>`.

Type Abbreviations

Carefully use type abbreviations to simplify F# code

.NET components, tools, and reflection will not see abbreviated names for types. Significant usage of type abbreviations can also make a domain appear more complex than it actually is, which could confuse consumers.

Avoid type abbreviations for public types whose members and properties should be intrinsically different to those available on the type being abbreviated

In this case, the type being abbreviated reveals too much about the representation of the actual type being defined. Instead, consider wrapping the abbreviation in a class type or a single-case discriminated union (or, when performance is essential, consider using a struct type to wrap the abbreviation).

For example, it is tempting to define a multi-map as a special case of an F# map, for example:

```
type MultiMap<'Key, 'Value> = Map<'Key, 'Value list>
```

However, the logical dot-notation operations on this type are not the same as the operations on a Map – for example, it is reasonable that the lookup operator `map.[key]` return the empty list if the key is not in the dictionary, rather than raising an exception.

Guidelines for libraries for Use from other .NET Languages

When designing libraries for use from other .NET languages, it is important to adhere to the [.NET Library Design Guidelines](#). In this document, these libraries are labeled as vanilla .NET libraries, as opposed to F#-facing libraries that use F# constructs without restriction. Designing vanilla .NET libraries means providing familiar and idiomatic APIs consistent with the rest of the .NET Framework by minimizing the use of F#-specific constructs in the public API. The rules are explained in the following sections.

Namespace and Type design (for libraries for use from other .NET Languages)

Apply the .NET naming conventions to the public API of your components

Pay special attention to the use of abbreviated names and the .NET capitalization guidelines.

```
type pCoord = ...
member this.theta = ...

type PolarCoordinate = ...
member this.Theta = ...
```

Use namespaces, types, and members as the primary organizational structure for your components

All files containing public functionality should begin with a `namespace` declaration, and the only public-facing entities in namespaces should be types. Do not use F# modules.

Use non-public modules to hold implementation code, utility types, and utility functions.

Static types should be preferred over modules, as they allow for future evolution of the API to use overloading and other .NET API design concepts that may not be used within F# modules.

For example, in place of the following public API:

```
module Fabrikam

module Utilities =
    let Name = "Bob"
    let Add2 x y = x + y
    let Add3 x y z = x + y + z
```

Consider instead:

```
namespace Fabrikam

[<AbstractClass; Sealed>]
type Utilities =
    static member Name = "Bob"
    static member Add(x,y) = x + y
    static member Add(x,y,z) = x + y + z
```

Use F# record types in vanilla .NET APIs if the design of the types won't evolve

F# record types compile to a simple .NET class. These are suitable for some simple, stable types in APIs. You should consider using the [`<NoEquality>`] and [`<NoComparison>`] attributes to suppress the automatic generation of interfaces. Also avoid using mutable record fields in vanilla .NET APIs as these exposes a public field. Always consider whether a class would provide a more flexible option for future evolution of the API.

For example, the following F# code exposes the public API to a C# consumer:

F#:

```
[<NoEquality; NoComparison>]
type MyRecord =
    { FirstThing: int
      SecondThing: string }
```

C#:

```
public sealed class MyRecord
{
    public MyRecord(int firstThing, string secondThing);
    public int FirstThing { get; }
    public string SecondThing { get; }
}
```

Hide the representation of F# union types in vanilla .NET APIs

F# union types are not commonly used across component boundaries, even for F#-to-F# coding. They are an excellent implementation device when used internally within components and libraries.

When designing a vanilla .NET API, consider hiding the representation of a union type by using either a private declaration or a signature file.

```
type PropLogic =
    private
    | And of PropLogic * PropLogic
    | Not of PropLogic
    | True
```

You may also augment types that use a union representation internally with members to provide a desired .NET-facing API.

```

type PropLogic =
    private
    | And of PropLogic * PropLogic
    | Not of PropLogic
    | True

    /// A public member for use from C#
    member x.Evaluate =
        match x with
        | And(a,b) -> a.Evaluate && b.Evaluate
        | Not a -> not a.Evaluate
        | True -> true

    /// A public member for use from C#
    static member CreateAnd(a,b) = And(a,b)

```

Design GUI and other components using the design patterns of the framework

There are many different frameworks available within .NET, such as WinForms, WPF, and ASP.NET. Naming and design conventions for each should be used if you are designing components for use in these frameworks. For example, for WPF programming, adopt WPF design patterns for the classes you are designing. For models in user interface programming, use design patterns such as events and notification-based collections such as those found in [System.Collections.ObjectModel](#).

Object and Member design (for libraries for use from other .NET Languages)

Use the CLIEvent attribute to expose .NET events

Construct a `DelegateEvent` with a specific .NET delegate type that takes an object and `EventArgs` (rather than an `Event`, which just uses the `FSharpHandler` type by default) so that the events are published in the familiar way to other .NET languages.

```

type MyBadType() =
    let myEv = new Event<int>()

    [<CLIEvent>]
    member this.MyEvent = myEv.Publish

type MyEventArgs(x: int) =
    inherit System.EventArgs()
    member this.X = x

    /// A type in a component designed for use from other .NET languages
type MyGoodType() =
    let myEv = new DelegateEvent<EventHandler<MyEventArgs>>()

    [<CLIEvent>]
    member this.MyEvent = myEv.Publish

```

Expose asynchronous operations as methods which return .NET tasks

Tasks are used in .NET to represent active asynchronous computations. Tasks are in general less compositional than F# `Async<T>` objects, since they represent “already executing” tasks and can’t be composed together in ways that perform parallel composition, or which hide the propagation of cancellation signals and other contextual parameters.

However, despite this, methods which return Tasks are the standard representation of asynchronous programming on .NET.

```

/// A type in a component designed for use from other .NET languages
type MyType() =
    let compute (x: int): Async<int> = async { ... }

    member this.ComputeAsync(x) = compute x |> Async.StartAsTask

```

You will frequently also want to accept an explicit cancellation token:

```

/// A type in a component designed for use from other .NET languages
type MyType() =
    let compute(x: int): Async<int> = async { ... }
    member this.ComputeAsTask(x, cancellationToken) = Async.StartAsTask(compute x, cancellationToken)

```

Use .NET delegate types instead of F# function types

Here "F# function types" mean "arrow" types like `int -> int`.

Instead of this:

```

member this.Transform(f: int->int) =
    ...

```

Do this:

```

member this.Transform(f: Func<int,int>) =
    ...

```

The F# function type appears as `class FSharpFunc<T,U>` to other .NET languages, and is less suitable for language features and tooling that understand delegate types. When authoring a higher-order method targeting .NET Framework 3.5 or higher, the `System.Func` and `System.Action` delegates are the right APIs to publish to enable .NET developers to consume these APIs in a low-friction manner. (When targeting .NET Framework 2.0, the system-defined delegate types are more limited; consider using predefined delegate types such as `System.Converter<T,U>` or defining a specific delegate type.)

On the flip side, .NET delegates are not natural for F#-facing libraries (see the next Section on F#-facing libraries). As a result, a common implementation strategy when developing higher-order methods for vanilla .NET libraries is to author all the implementation using F# function types, and then create the public API using delegates as a thin façade atop the actual F# implementation.

Use the TryGetValue pattern instead of returning F# option values, and prefer method overloading to taking F# option values as arguments

Common patterns of use for the F# option type in APIs are better implemented in vanilla .NET APIs using standard .NET design techniques. Instead of returning an F# option value, consider using the bool return type plus an out parameter as in the "TryGetValue" pattern. And instead of taking F# option values as parameters, consider using method overloading or optional arguments.

```

member this.ReturnOption() = Some 3

member this.ReturnBoolAndOut(outVal: byref<int>) =
    outVal <- 3
    true

member this.ParamOption(x: int, y: int option) =
    match y with
    | Some y2 -> x + y2
    | None -> x

member this.ParamOverload(x: int) = x

member this.ParamOverload(x: int, y: int) = x + y

```

Use the .NET collection interface types `IEnumerable<T>` and `IDictionary<Key,Value>` for parameters and return values

Avoid the use of concrete collection types such as .NET arrays `T[]`, F# types `list<T>`, `Map<Key,Value>` and `Set<T>`, and .NET concrete collection types such as `Dictionary<Key,Value>`. The .NET Library Design Guidelines have good advice regarding when to use various collection types like `IEnumerable<T>`. Some use of arrays (`T[]`) is acceptable in some circumstances, on performance grounds. Note especially that `seq<T>` is just the F# alias for `IEnumerable<T>`, and thus seq is often an appropriate type for a vanilla .NET API.

Instead of F# lists:

```

member this.PrintNames(names: string list) =
    ...

```

Use F# sequences:

```

member this.PrintNames(names: seq<string>) =
    ...

```

Use the unit type as the only input type of a method to define a zero-argument method, or as the only return type to define a void-returning method

Avoid other uses of the unit type. These are good:

- ✓ member this.NoArguments() = 3
- ✓ member this.ReturnVoid(x: int) = ()

This is bad:

```

member this.WrongUnit( x: unit, z: int) = (((), ()))

```

Check for null values on vanilla .NET API boundaries

F# implementation code tends to have fewer null values, due to immutable design patterns and restrictions on use of null literals for F# types. Other .NET languages often use null as a value much more frequently. Because of this, F# code that is exposing a vanilla .NET API should check parameters for null at the API boundary, and prevent these values from flowing deeper into the F# implementation code. The `isNull` function or pattern matching on the `null` pattern can be used.

```

let checkNonNull argName (arg: obj) =
    match arg with
    | null -> nullArg argName
    | _ -> ()

let checkNonNull` argName (arg: obj) =
    ifisNull arg then nullArg argName
    else ()

```

Avoid using tuples as return values

Instead, prefer returning a named type holding the aggregate data, or using out parameters to return multiple values. Although tuples and struct tuples exist in .NET (including C# language support for struct tuples), they will most often not provide the ideal and expected API for .NET developers.

Avoid the use of currying of parameters

Instead, use .NET calling conventions `Method(arg1,arg2,...,argN)`.

```
member this.TupledArguments(str, num) = String.replicate num str
```

Tip: If you're designing libraries for use from any .NET language, then there's no substitute for actually doing some experimental C# and Visual Basic programming to ensure that your libraries "feel right" from these languages. You can also use tools such as .NET Reflector and the Visual Studio Object Browser to ensure that libraries and their documentation appear as expected to developers.

Appendix

End-to-end example of designing F# code for use by other .NET languages

Consider the following class:

```

open System

type Point1(angle, radius) =
    new() = Point1(angle=0.0, radius=0.0)
    member x.Angle = angle
    member x.Radius = radius
    member x.Stretch(l) = Point1(angle=x.Angle, radius=x.Radius * l)
    member x.Warp(f) = Point1(angle=f(x.Angle), radius=x.Radius)
    static member Circle(n) =
        [ for i in 1..n -> Point1(angle=2.0*Math.PI/float(n), radius=1.0) ]

```

The inferred F# type of this class is as follows:

```

type Point1 =
    new : unit -> Point1
    new : angle:double * radius:double -> Point1
    static member Circle : n:int -> Point1 list
    member Stretch : l:double -> Point1
    member Warp : f:(double -> double) -> Point1
    member Angle : double
    member Radius : double

```

Let's take a look at how this F# type appears to a programmer using another .NET language. For example, the approximate C# "signature" is as follows:

```
// C# signature for the unadjusted Point1 class
public class Point1
{
    public Point1();

    public Point1(double angle, double radius);

    public static Microsoft.FSharp.Collections.List<Point1> Circle(int count);

    public Point1 Stretch(double factor);

    public Point1 Warp(Microsoft.FSharp.Core.FastFunc<double,double> transform);

    public double Angle { get; }

    public double Radius { get; }
}
```

There are some important points to notice about how F# represents constructs here. For example:

- Metadata such as argument names has been preserved.
- F# methods that take two arguments become C# methods that take two arguments.
- Functions and lists become references to corresponding types in the F# library.

The following code shows how to adjust this code to take these things into account.

```
namespace SuperDuperFSharpLibrary.Types

type RadialPoint(angle:double, radius:double) =
    /// Return a point at the origin
    new() = RadialPoint(angle=0.0, radius=0.0)

    /// The angle to the point, from the x-axis
    member x.Angle = angle

    /// The distance to the point, from the origin
    member x.Radius = radius

    /// Return a new point, with radius multiplied by the given factor
    member x.Stretch(factor) =
        RadialPoint(angle=angle, radius=radius * factor)

    /// Return a new point, with angle transformed by the function
    member x.Warp(transform:Func<_,_>) =
        RadialPoint(angle=transform.Invoke angle, radius=radius)

    /// Return a sequence of points describing an approximate circle using
    /// the given count of points
    static member Circle(count) =
        seq { for i in 1..count ->
                RadialPoint(angle=2.0*Math.PI/float(count), radius=1.0) }
```

The inferred F# type of the code is as follows:

```

type RadialPoint =
    new : unit -> RadialPoint
    new : angle:double * radius:double -> RadialPoint
    static member Circle : count:int -> seq<RadialPoint>
    member Stretch : factor:double -> RadialPoint
    member Warp : transform:System.Func<double,double> -> RadialPoint
    member Angle : double
    member Radius : double

```

The C# signature is now as follows:

```

public class RadialPoint
{
    public RadialPoint();

    public RadialPoint(double angle, double radius);

    public static System.Collections.Generic.IEnumerable<RadialPoint> Circle(int count);

    public RadialPoint Stretch(double factor);

    public RadialPoint Warp(System.Func<double,double> transform);

    public double Angle { get; }

    public double Radius { get; }
}

```

The fixes made to prepare this type for use as part of a vanilla .NET library are as follows:

- Adjusted several names: `Point1`, `n`, `l`, and `f` became `RadialPoint`, `count`, `factor`, and `transform`, respectively.
- Used a return type of `seq<RadialPoint>` instead of `RadialPoint list` by changing a list construction using `[...]` to a sequence construction using `IEnumerable<RadialPoint>`.
- Used the .NET delegate type `System.Func` instead of an F# function type.

This makes it far nicer to consume in C# code.

Using F# on Azure

3/5/2019 • 4 minutes to read • [Edit Online](#)

F# is a superb language for cloud programming and is frequently used to write web applications, cloud services, cloud-hosted microservices, and for scalable data processing.

In the following sections, you will find resources on how to use a range of Azure services with F#.

NOTE

If a particular Azure service isn't in this documentation set, please consult either the Azure Functions or .NET documentation for that service. Some Azure services are language-independent and require no language-specific documentation and are not listed here.

Using Azure Virtual Machines with F#

Azure supports a wide range of virtual machine (VM) configurations, see [Linux and Azure Virtual Machines](#).

To install F# on a virtual machine for execution, compilation and/or scripting see [Using F# on Linux](#) and [Using F# on Windows](#).

Using Azure Functions with F#

[Azure Functions](#) is a solution for easily running small pieces of code, or "functions," in the cloud. You can write just the code you need for the problem at hand, without worrying about a whole application or the infrastructure to run it. Your functions are connected to events in Azure storage and other cloud-hosted resources. Data flows into your F# functions via function arguments. You can use your development language of choice, trusting Azure to scale as needed.

Azure Functions support F# as a first-class language with efficient, reactive, scalable execution of F# code. See the [Azure Functions F# Developer Reference](#) for reference documentation on how to use F# with Azure Functions.

Other resources for using Azure Functions and F#:

- [Scale Up Azure Functions in F# Using Suave](#)
- [How to create Azure function in F#](#)
- [Using the Azure Type Provider with Azure Functions](#)

Using Azure Storage with F#

Azure Storage is a base layer of storage services for modern applications that rely on durability, availability, and scalability to meet the needs of customers. F# programs can interact directly with Azure storage services, using the techniques described in the following articles.

- [Get started with Azure Blob storage using F#](#)
- [Get started with Azure File storage using F#](#)
- [Get started with Azure Queue storage using F#](#)
- [Get started with Azure Table storage using F#](#)

Azure Storage can also be used in conjunction with Azure Functions through declarative configuration rather than explicit API calls. See [Azure Functions triggers and bindings for Azure Storage](#) which includes F# examples.

Using Azure App Service with F#

Azure App Service is a cloud platform to build powerful web and mobile apps that connect to data anywhere, in the cloud or on-premises.

- [F# Azure Web API example](#)
- [Hosting F# in a web application on Azure](#)

Using Apache Spark with F# with Azure HDInsight

Apache Spark for Azure HDInsight is an open source processing framework that runs large-scale data analytics applications. Azure makes Apache Spark easy and cost effective to deploy. Develop your Spark application in F# using [Mobius](#), a .NET API for Spark.

- [Implementing Spark Apps in F# using Mobius](#)
- [Example F# Spark Apps using Mobius](#)

Using Azure Cosmos DB with F#

Azure Cosmos DB is a NoSQL service for highly available, globally distributed apps.

Azure Cosmos DB can be used with F# in two ways:

1. Through the creation of F# Azure Functions which react to or cause changes to Azure Cosmos DB collections.
See [Azure Cosmos DB bindings for Azure Functions](#), or
2. By using the [Azure Cosmos DB .NET SDK for SQL API](#). The related samples are in C#.

Using Azure Event Hubs with F#

Azure Event Hubs provide cloud-scale telemetry ingestion from websites, apps, and devices.

Azure Event Hubs can be used with F# in two ways:

1. Through the creation of F# Azure Functions which are triggered by events. See [Azure Function triggers for Event Hubs](#), or
2. By using the [.NET SDK for Azure](#). Note these examples are in C#.

Using Azure Notification Hubs with F#

Azure Notification Hubs are multiplatform, scaled-out push infrastructure that enable you to send mobile push notifications from any backend (in the cloud or on-premises) to any mobile platform.

Azure Notification Hubs can be used with F# in two ways:

1. Through the creation of F# Azure Functions which send results to a notification hub. See [Azure Function output triggers for Notification Hubs](#), or
2. By using the [.NET SDK for Azure](#). Note these examples are in C#.

Implementing WebHooks on Azure with F#

A [Webhook](#) is a callback triggered via a web request. Webhooks are used by sites such as GitHub to signal events.

Webhooks can be implemented in F# and hosted on Azure via an [Azure Function in F# with a Webhook Binding](#).

Using Webjobs with F#

[Webjobs](#) are programs you can run in your App Service web app in three ways: on demand, continuously, or on a

schedule.

Example F# Webjob

Implementing Timers on Azure with F#

Timer triggers call functions based on a schedule, one time or recurring.

Timers can be implemented in F# and hosted on Azure via an [Azure Function in F# with a Timer Trigger](#).

Deploying and Managing Azure Resources with F# Scripts

Azure VMs may be programmatically deployed and managed from F# scripts by using the Microsoft.Azure.Management packages and APIs. For example, see [Get Started with the Management Libraries for .NET](#) and [Using Azure Resource Manager](#).

Likewise, other Azure resources may also be deployed and managed from F# scripts using the same components. For example, you can create storage accounts, deploy Azure Cloud Services, create Azure Cosmos DB instances and manage Azure Notification Hubs programmatically from F# scripts.

Using F# scripts to deploy and manage resources is not normally necessary. For example, Azure resources may also be deployed directly from JSON template descriptions, which can be parameterized. See [Azure Resource Manager Templates](#) including examples such as the [Azure Quickstart Templates](#).

Other resources

- [Full documentation on all Azure services](#)

Get started with Azure Blob storage using F#

3/14/2019 • 12 minutes to read • [Edit Online](#)

Azure Blob storage is a service that stores unstructured data in the cloud as objects/blobs. Blob storage can store any type of text or binary data, such as a document, media file, or application installer. Blob storage is also referred to as object storage.

This article shows you how to perform common tasks using Blob storage. The samples are written using F# using the Azure Storage Client Library for .NET. The tasks covered include how to upload, list, download, and delete blobs.

For a conceptual overview of blob storage, see [the .NET guide for blob storage](#).

Prerequisites

To use this guide, you must first [create an Azure storage account](#). You also need your storage access key for this account.

Create an F# Script and Start F# Interactive

The samples in this article can be used in either an F# application or an F# script. To create an F# script, create a file with the `.fsx` extension, for example `blobs.fsx`, in your F# development environment.

Next, use a [package manager](#) such as [Paket](#) or [NuGet](#) to install the `WindowsAzure.Storage` and `Microsoft.WindowsAzure.ConfigurationManager` packages and reference `WindowsAzure.Storage.dll` and `Microsoft.WindowsAzure.Configuration.dll` in your script using a `#r` directive.

Add namespace declarations

Add the following `open` statements to the top of the `blobs.fsx` file:

```
open System
open System.IO
open Microsoft.Azure // Namespace for CloudConfigurationManager
open Microsoft.WindowsAzure.Storage // Namespace for CloudStorageAccount
open Microsoft.WindowsAzure.Storage.Blob // Namespace for Blob storage types
```

Get your connection string

You need an Azure Storage connection string for this tutorial. For more information about connection strings, see [Configure Storage Connection Strings](#).

For the tutorial, you enter your connection string in your script, like this:

```
let storageConnString = "..." // fill this in from your storage account
```

However, this is **not recommended** for real projects. Your storage account key is similar to the root password for your storage account. Always be careful to protect your storage account key. Avoid distributing it to other users, hard-coding it, or saving it in a plain-text file that is accessible to others. You can regenerate your key using the Azure Portal if you believe it may have been compromised.

For real applications, the best way to maintain your storage connection string is in a configuration file. To fetch the connection string from a configuration file, you can do this:

```
// Parse the connection string and return a reference to the storage account.  
let storageConnString =  
    CloudConfigurationManager.GetSetting("StorageConnectionString")
```

Using Azure Configuration Manager is optional. You can also use an API such as the .NET Framework's `ConfigurationManager` type.

Parse the connection string

To parse the connection string, use:

```
// Parse the connection string and return a reference to the storage account.  
let storageAccount = CloudStorageAccount.Parse(storageConnString)
```

This returns a `CloudStorageAccount`.

Create some local dummy data

Before you begin, create some dummy local data in the directory of our script. Later you upload this data.

```
// Create a dummy file to upload  
let localFile = __SOURCE_DIRECTORY__ + "/myfile.txt"  
File.WriteAllText(localFile, "some data")
```

Create the Blob service client

The `CloudBlobClient` type enables you to retrieve containers and blobs stored in Blob storage. Here's one way to create the service client:

```
let blobClient = storageAccount.CreateCloudBlobClient()
```

Now you are ready to write code that reads data from and writes data to Blob storage.

Create a container

This example shows how to create a container if it does not already exist:

```
// Retrieve a reference to a container.  
let container = blobClient.GetContainerReference("mydata")  
  
// Create the container if it doesn't already exist.  
container.CreateIfNotExists()
```

By default, the new container is private, meaning that you must specify your storage access key to download blobs from this container. If you want to make the files within the container available to everyone, you can set the container to be public using the following code:

```
let permissions = BlobContainerPermissions(PublicAccess=BlobContainerPublicAccessType.Blob)  
container.SetPermissions(permissions)
```

Anyone on the Internet can see blobs in a public container, but you can modify or delete them only if you have the appropriate account access key or a shared access signature.

Upload a blob into a container

Azure Blob Storage supports block blobs and page blobs. In most cases, a block blob is the recommended type to use.

To upload a file to a block blob, get a container reference and use it to get a block blob reference. Once you have a blob reference, you can upload any stream of data to it by calling the `UploadFromFile` method. This operation creates the blob if it didn't previously exist, or overwrite it if it does exist.

```
// Retrieve reference to a blob named "myblob.txt".
let blockBlob = container.GetBlockBlobReference("myblob.txt")

// Create or overwrite the "myblob.txt" blob with contents from the local file.
do blockBlob.UploadFromFile(localFile)
```

List the blobs in a container

To list the blobs in a container, first get a container reference. You can then use the container's `ListBlobs` method to retrieve the blobs and/or directories within it. To access the rich set of properties and methods for a returned `IListBlobItem`, you must cast it to a `CloudBlockBlob`, `CloudPageBlob`, or `CloudBlobDirectory` object. If the type is unknown, you can use a type check to determine which to cast it to. The following code demonstrates how to retrieve and output the URI of each item in the `mydata` container:

```
// Loop over items within the container and output the length and URI.
for item in container.ListBlobs(null, false) do
    match item with
    | :? CloudBlockBlob as blob ->
        printfn "Block blob of length %d: %o" blob.Properties.Length blob.Uri

    | :? CloudPageBlob as pageBlob ->
        printfn "Page blob of length %d: %o" pageBlob.Properties.Length pageBlob.Uri

    | :? CloudBlobDirectory as directory ->
        printfn "Directory: %o" directory.Uri

    | _ ->
        printfn "Unknown blob type: %o" (item.GetType())
```

You can also name blobs with path information in their names. This creates a virtual directory structure that you can organize and traverse as you would a traditional file system. Note that the directory structure is virtual only - the only resources available in Blob storage are containers and blobs. However, the storage client library offers a `CloudBlobDirectory` object to refer to a virtual directory and simplify the process of working with blobs that are organized in this way.

For example, consider the following set of block blobs in a container named `photos`:

```
photo1.jpg
2015/architecture/description.txt
2015/architecture/photo3.jpg
2015/architecture/photo4.jpg
2016/architecture/photo5.jpg
2016/architecture/photo6.jpg
2016/architecture/description.txt
2016/photo7.jpg\
```

When you call `ListBlobs` on a container (as in the above sample), a hierarchical listing is returned. If it contains both `CloudBlobDirectory` and `CloudBlockBlob` objects, representing the directories and blobs in the container, respectively, then the resulting output looks similar to this:

```
Directory: https://<accountname>.blob.core.windows.net/photos/2015/
Directory: https://<accountname>.blob.core.windows.net/photos/2016/
Block blob of length 505623: https://<accountname>.blob.core.windows.net/photos/photo1.jpg
```

Optionally, you can set the `UseFlatBlobListing` parameter of the `ListBlobs` method to `true`. In this case, every blob in the container is returned as a `CloudBlockBlob` object. The call to `ListBlobs` to return a flat listing looks like this:

```
// Loop over items within the container and output the length and URI.
for item in container.ListBlobs(null, true) do
    match item with
    | :? CloudBlockBlob as blob ->
        printfn "Block blob of length %d: %0" blob.Properties.Length blob.Uri

    | _ ->
        printfn "Unexpected blob type: %0" (item.GetType())
```

and, depending on the current contents of your container, the results look like this:

```
Block blob of length 4: https://<accountname>.blob.core.windows.net/photos/2015/architecture/description.txt
Block blob of length 314618: https://<accountname>.blob.core.windows.net/photos/2015/architecture/photo3.jpg
Block blob of length 522713: https://<accountname>.blob.core.windows.net/photos/2015/architecture/photo4.jpg
Block blob of length 4: https://<accountname>.blob.core.windows.net/photos/2016/architecture/description.txt
Block blob of length 419048: https://<accountname>.blob.core.windows.net/photos/2016/architecture/photo5.jpg
Block blob of length 506388: https://<accountname>.blob.core.windows.net/photos/2016/architecture/photo6.jpg
Block blob of length 399751: https://<accountname>.blob.core.windows.net/photos/2016/photo7.jpg
Block blob of length 505623: https://<accountname>.blob.core.windows.net/photos/photo1.jpg
```

Download blobs

To download blobs, first retrieve a blob reference and then call the `DownloadToStream` method. The following example uses the `DownloadToStream` method to transfer the blob contents to a stream object that you can then persist to a local file.

```
// Retrieve reference to a blob named "myblob.txt".
let blobToDownload = container.GetBlockBlobReference("myblob.txt")

// Save blob contents to a file.
do
    use fileStream = File.OpenWrite(__SOURCE_DIRECTORY__ + "/path/download.txt")
    blobToDownload.DownloadToStream(fileStream)
```

You can also use the `DownloadToStream` method to download the contents of a blob as a text string.

```
let text =
    use memoryStream = new MemoryStream()
    blobToDownload.DownloadToStream(memoryStream)
    Text.Encoding.UTF8.GetString(memoryStream.ToArray())
```

Delete blobs

To delete a blob, first get a blob reference and then call the `Delete` method on it.

```
// Retrieve reference to a blob named "myblob.txt".
let blobToDelete = container.GetBlockBlobReference("myblob.txt")

// Delete the blob.
blobToDelete.Delete()
```

List blobs in pages asynchronously

If you are listing a large number of blobs, or you want to control the number of results you return in one listing operation, you can list blobs in pages of results. This example shows how to return results in pages asynchronously, so that execution is not blocked while waiting to return a large set of results.

This example shows a flat blob listing, but you can also perform a hierarchical listing, by setting the `useFlatBlobListing` parameter of the `ListBlobsSegmentedAsync` method to `false`.

The sample defines an asynchronous method, using an `async` block. The `let!` keyword suspends execution of the sample method until the listing task completes.

```
let ListBlobsSegmentedInFlatListing(container:CloudBlobContainer) =
    async {

        // List blobs to the console window, with paging.
        printfn "List blobs in pages:"

        // Call ListBlobsSegmentedAsync and enumerate the result segment
        // returned, while the continuation token is non-null.
        // When the continuation token is null, the last page has been
        // returned and execution can exit the loop.

        let rec loop continuationToken (i:int) =
            async {
                let! ct = Async.CancellationToken
                // This overload allows control of the page size. You can return
                // all remaining results by passing null for the maxResults
                // parameter, or by calling a different overload.
                let! resultSegment =
                    container.ListBlobsSegmentedAsync(
                        "", true, BlobListingDetails.All, Nullable 10,
                        continuationToken, null, null, ct)
                |> Async.AwaitTask

                if (resultSegment.Results |> Seq.length > 0) then
                    printfn "Page %d:" i

                    for blobItem in resultSegment.Results do
                        printfn "\t%O" blobItem.StorageUri.PrimaryUri

                    printfn ""

                // Get the continuation token.
                let continuationToken = resultSegment.ContinuationToken
                if (continuationToken <> null) then
                    do! loop continuationToken (i+1)
            }

            do! loop null 1
    }
```

We can now use this asynchronous routine as follows. First you upload some dummy data (using the local file created earlier in this tutorial).

```
// Create some dummy data by uploading the same file over and over again
for i in 1 .. 100 do
    let blob = container.GetBlockBlobReference("myblob" + string i + ".txt")
    use fileStream = System.IO.File.OpenRead(localFile)
    blob.UploadFromFile(localFile)
```

Now, call the routine. You use `Async.RunSynchronously` to force the execution of the asynchronous operation.

```
ListBlobsSegmentedInFlatListing container |> Async.RunSynchronously
```

Writing to an append blob

An append blob is optimized for append operations, such as logging. Like a block blob, an append blob is comprised of blocks, but when you add a new block to an append blob, it is always appended to the end of the blob. You cannot update or delete an existing block in an append blob. The block IDs for an append blob are not exposed as they are for a block blob.

Each block in an append blob can be a different size, up to a maximum of 4 MB, and an append blob can include a maximum of 50,000 blocks. The maximum size of an append blob is therefore slightly more than 195 GB (4 MB X 50,000 blocks).

The following example creates a new append blob and appends some data to it, simulating a simple logging operation.

```
// Get a reference to a container.
let appendContainer = blobClient.GetContainerReference("my-append-blobs")

// Create the container if it does not already exist.
appendContainer.CreateIfNotExists() |> ignore

// Get a reference to an append blob.
let appendBlob = appendContainer.GetAppendBlobReference("append-blob.log")

// Create the append blob. Note that if the blob already exists, the
// CreateOrReplace() method will overwrite it. You can check whether the
// blob exists to avoid overwriting it by using CloudAppendBlob.Exists().
appendBlob.CreateOrReplace()

let numBlocks = 10

// Generate an array of random bytes.
let rnd = new Random()
let bytes = Array.zeroCreate<byte>(numBlocks)
rnd.NextBytes(bytes)

// Simulate a logging operation by writing text data and byte data to the
// end of the append blob.
for i in 0 .. numBlocks - 1 do
    let msg = sprintf "Timestamp: %u \tLog Entry: %d\n" DateTime.UtcNow bytes.[i]
    appendBlob.AppendText(msg)

// Read the append blob to the console window.
let downloadedText = appendBlob.DownloadText()
printfn "%s" downloadedText
```

See [Understanding Block Blobs, Page Blobs, and Append Blobs](#) for more information about the differences between the three types of blobs.

Concurrent access

To support concurrent access to a blob from multiple clients or multiple process instances, you can use **ETags** or **leases**.

- **Etag** - provides a way to detect that the blob or container has been modified by another process
- **Lease** - provides a way to obtain exclusive, renewable, write or delete access to a blob for a period of time

For more information, see [Managing Concurrency in Microsoft Azure Storage](#).

Naming containers

Every blob in Azure storage must reside in a container. The container forms part of the blob name. For example, `mydata` is the name of the container in these sample blob URIs:

```
https://storagesample.blob.core.windows.net/mydata/blob1.txt  
https://storagesample.blob.core.windows.net/mydata/photos/myphoto.jpg
```

A container name must be a valid DNS name, conforming to the following naming rules:

1. Container names must start with a letter or number, and can contain only letters, numbers, and the dash (-) character.
2. Every dash (-) character must be immediately preceded and followed by a letter or number; consecutive dashes are not permitted in container names.
3. All letters in a container name must be lowercase.
4. Container names must be from 3 through 63 characters long.

Note that the name of a container must always be lowercase. If you include an upper-case letter in a container name, or otherwise violate the container naming rules, you may receive a 400 error (Bad Request).

Managing security for blobs

By default, Azure Storage keeps your data secure by limiting access to the account owner, who is in possession of the account access keys. When you need to share blob data in your storage account, it is important to do so without compromising the security of your account access keys. Additionally, you can encrypt blob data to ensure that it is secure going over the wire and in Azure Storage.

Controlling access to blob data

By default, the blob data in your storage account is accessible only to storage account owner. Authenticating requests against Blob storage requires the account access key by default. However, you might want to make certain blob data available to other users.

Encrypting blob data

Azure Storage supports encrypting blob data both at the client and on the server.

Next steps

Get started with Azure File storage using F#

2/28/2019 • 6 minutes to read • [Edit Online](#)

Azure File storage is a service that offers file shares in the cloud using the standard [Server Message Block \(SMB\) Protocol](#). Both SMB 2.1 and SMB 3.0 are supported. With Azure File storage, you can migrate legacy applications that rely on file shares to Azure quickly and without costly rewrites. Applications running in Azure virtual machines or cloud services or from on-premises clients can mount a file share in the cloud, just as a desktop application mounts a typical SMB share. Any number of application components can then mount and access the File storage share simultaneously.

For a conceptual overview of file storage, please see [the .NET guide for file storage](#).

Prerequisites

To use this guide, you must first [create an Azure storage account](#). You'll also need your storage access key for this account.

Create an F# Script and Start F# Interactive

The samples in this article can be used in either an F# application or an F# script. To create an F# script, create a file with the `.fsx` extension, for example `files.fsx`, in your F# development environment.

Next, use a [package manager](#) such as [Paket](#) or [NuGet](#) to install the `WindowsAzure.Storage` package and reference `WindowsAzure.Storage.dll` in your script using a `#r` directive.

Add namespace declarations

Add the following `open` statements to the top of the `files.fsx` file:

```
open System
open System.IO
open Microsoft.Azure // Namespace for CloudConfigurationManager
open Microsoft.WindowsAzure.Storage // Namespace for CloudStorageAccount
open Microsoft.WindowsAzure.Storage.File // Namespace for File storage types
```

Get your connection string

You'll need an Azure Storage connection string for this tutorial. For more information about connection strings, see [Configure Storage Connection Strings](#).

For the tutorial, you'll enter your connection string in your script, like this:

```
let storageConnString = "..." // fill this in from your storage account
```

However, this is **not recommended** for real projects. Your storage account key is similar to the root password for your storage account. Always be careful to protect your storage account key. Avoid distributing it to other users, hard-coding it, or saving it in a plain-text file that is accessible to others. You can regenerate your key using the Azure Portal if you believe it may have been compromised.

For real applications, the best way to maintain your storage connection string is in a configuration file. To fetch the connection string from a configuration file, you can do this:

```
// Parse the connection string and return a reference to the storage account.  
let storageConnString =  
    CloudConfigurationManager.GetSetting("StorageConnectionString")
```

Using Azure Configuration Manager is optional. You can also use an API such as the .NET Framework's `ConfigurationManager` type.

Parse the connection string

To parse the connection string, use:

```
// Parse the connection string and return a reference to the storage account.  
let storageAccount = CloudStorageAccount.Parse(storageConnString)
```

This will return a `CloudStorageAccount`.

Create the File service client

The `CloudFileClient` type enables you to programmatically use files stored in File storage. Here's one way to create the service client:

```
let fileClient = storageAccount.CreateCloudFileClient()
```

Now you are ready to write code that reads data from and writes data to File storage.

Create a file share

This example shows how to create a file share if it does not already exist:

```
let share = fileClient.GetShareReference("myfiles")  
share.CreateIfNotExists()
```

Create a root directory and a subdirectory

Here, you get the root directory and get a sub-directory of the root. You create both if they don't already exist.

```
let rootDir = share.GetRootDirectoryReference()  
let subDir = rootDir.GetDirectoryReference("myLogs")  
subDir.CreateIfNotExists()
```

Upload text as a file

This example shows how to upload text as a file.

```
let file = subDir.GetFileReference("log.txt")  
file.UploadText("This is the content of the log file")
```

Download a file to a local copy of the file

Here you download the file just created, appending the contents to a local file.

```
file.DownloadToFile("log.txt", FileMode.Append)
```

Set the maximum size for a file share

The example below shows how to check the current usage for a share and how to set the quota for the share.

`FetchAttributes` must be called to populate a share's `Properties`, and `SetProperties` to propagate local changes to Azure File storage.

```
// stats.Usage is current usage in GB
let stats = share.GetStats()
share.FetchAttributes()

// Set the quota to 10 GB plus current usage
share.Properties.Quota <- stats.Usage + 10 |> Nullable
share.SetProperties()

// Remove the quota
share.Properties.Quota <- Nullable()
share.SetProperties()
```

Generate a shared access signature for a file or file share

You can generate a shared access signature (SAS) for a file share or for an individual file. You can also create a shared access policy on a file share to manage shared access signatures. Creating a shared access policy is recommended, as it provides a means of revoking the SAS if it should be compromised.

Here, you create a shared access policy on a share, and then use that policy to provide the constraints for a SAS on a file in the share.

```
// Create a 24-hour read/write policy.
let policy =
    SharedAccessFilePolicy
    (SharedAccessExpiryTime = (DateTimeOffset.UtcNow.AddHours(24.) |> Nullable),
     Permissions = (SharedAccessFilePermissions.Read ||| SharedAccessFilePermissions.Write))

// Set the policy on the share.
let permissions = share.GetPermissions()
permissions.SharedAccessPolicies.Add("policyName", policy)
share.SetPermissions(permissions)

let sasToken = file.GetSharedAccessSignature(policy)
let sasUri = Uri(file.StorageUri.PrimaryUri.ToString() + sasToken)

let fileSas = CloudFile(sasUri)
fileSas.UploadText("This write operation is authenticated via SAS")
```

For more information about creating and using shared access signatures, see [Using Shared Access Signatures \(SAS\)](#) and [Create and use a SAS with Blob storage](#).

Copy files

You can copy a file to another file or to a blob, or a blob to a file. If you are copying a blob to a file, or a file to a blob, you *must* use a shared access signature (SAS) to authenticate the source object, even if you are copying within the same storage account.

Copy a file to another file

Here, you copy a file to another file in the same share. Because this copy operation copies between files in the same storage account, you can use Shared Key authentication to perform the copy.

```
let destFile = subDir.GetFileReference("log_copy.txt")
destFile.StartCopy(file)
```

Copy a file to a blob

Here, you create a file and copy it to a blob within the same storage account. You create a SAS for the source file, which the service uses to authenticate access to the source file during the copy operation.

```
// Get a reference to the blob to which the file will be copied.  
let blobClient = storageAccount.CreateCloudBlobClient()  
let container = blobClient.GetContainerReference("myContainer")  
container.CreateIfNotExists()  
let destBlob = container.GetBlockBlobReference("log_blob.txt")  
  
let filePolicy =  
    SharedAccessFilePolicy  
    (Permissions = SharedAccessFilePermissions.Read,  
     SharedAccessExpiryTime = (DateTimeOffset.UtcNow.AddHours(24.) |> Nullable))  
  
let fileSas2 = file.GetSharedAccessSignature(filePolicy)  
let sasUri2 = Uri(file.StorageUri.PrimaryUri.ToString() + fileSas2)  
destBlob.StartCopy(sasUri2)
```

You can copy a blob to a file in the same way. If the source object is a blob, then create a SAS to authenticate access to that blob during the copy operation.

Troubleshooting File storage using metrics

Azure Storage Analytics supports metrics for File storage. With metrics data, you can trace requests and diagnose issues.

You can enable metrics for File storage from the [Azure Portal](#), or you can do it from F# like this:

```
open Microsoft.WindowsAzure.Storage.File.Protocol  
open Microsoft.WindowsAzure.Storage.Shared.Protocol  
  
let props =  
    FileServiceProperties(  
        HourMetrics = MetricsProperties(  
            MetricsLevel = MetricsLevel.ServiceAndApi,  
            RetentionDays = (14 |> Nullable),  
            Version = "1.0"),  
        MinuteMetrics = MetricsProperties(  
            MetricsLevel = MetricsLevel.ServiceAndApi,  
            RetentionDays = (7 |> Nullable),  
            Version = "1.0"))  
  
fileClient.SetServiceProperties(props)
```

Get started with Azure Queue storage using F#

2/28/2019 • 6 minutes to read • [Edit Online](#)

Azure Queue storage provides cloud messaging between application components. In designing applications for scale, application components are often decoupled, so that they can scale independently. Queue storage delivers asynchronous messaging for communication between application components, whether they are running in the cloud, on the desktop, on an on-premises server, or on a mobile device. Queue storage also supports managing asynchronous tasks and building process work flows.

About this tutorial

This tutorial shows how to write F# code for some common tasks using Azure Queue storage. Tasks covered include creating and deleting queues and adding, reading, and deleting queue messages.

For a conceptual overview of queue storage, please see [the .NET guide for queue storage](#).

Prerequisites

To use this guide, you must first [create an Azure storage account](#). You'll also need your storage access key for this account.

Create an F# Script and Start F# Interactive

The samples in this article can be used in either an F# application or an F# script. To create an F# script, create a file with the `.fsx` extension, for example `queues.fsx`, in your F# development environment.

Next, use a [package manager](#) such as [Paket](#) or [NuGet](#) to install the `WindowsAzure.Storage` package and reference `WindowsAzure.Storage.dll` in your script using a `#r` directive.

Add namespace declarations

Add the following `open` statements to the top of the `queues.fsx` file:

```
open Microsoft.Azure // Namespace for CloudConfigurationManager
open Microsoft.WindowsAzure.Storage // Namespace for CloudStorageAccount
open Microsoft.WindowsAzure.Storage.Queue // Namespace for Queue storage types
```

Get your connection string

You'll need an Azure Storage connection string for this tutorial. For more information about connection strings, see [Configure Storage Connection Strings](#).

For the tutorial, you'll enter your connection string in your script, like this:

```
let storageConnString = "..." // fill this in from your storage account
```

However, this is **not recommended** for real projects. Your storage account key is similar to the root password for your storage account. Always be careful to protect your storage account key. Avoid distributing it to other users, hard-coding it, or saving it in a plain-text file that is accessible to others. You can regenerate your key using the Azure Portal if you believe it may have been compromised.

For real applications, the best way to maintain your storage connection string is in a configuration file. To fetch the connection string from a configuration file, you can do this:

```
// Parse the connection string and return a reference to the storage account.  
let storageConnString =  
    CloudConfigurationManager.GetSetting("StorageConnectionString")
```

Using Azure Configuration Manager is optional. You can also use an API such as the .NET Framework's `ConfigurationManager` type.

Parse the connection string

To parse the connection string, use:

```
// Parse the connection string and return a reference to the storage account.  
let storageAccount = CloudStorageAccount.Parse(storageConnString)
```

This will return a `CloudStorageAccount`.

Create the Queue service client

The `CloudQueueClient` class enables you to retrieve queues stored in Queue storage. Here's one way to create the service client:

```
let queueClient = storageAccount.CreateCloudQueueClient()
```

Now you are ready to write code that reads data from and writes data to Queue storage.

Create a queue

This example shows how to create a queue if it doesn't already exist:

```
// Retrieve a reference to a container.  
let queue = queueClient.GetQueueReference("myqueue")  
  
// Create the queue if it doesn't already exist  
queue.CreateIfNotExists()
```

Insert a message into a queue

To insert a message into an existing queue, first create a new `CloudQueueMessage`. Next, call the `AddMessage` method. A `CloudQueueMessage` can be created from either a string (in UTF-8 format) or a `byte` array, like this:

```
// Create a message and add it to the queue.  
let message = new CloudQueueMessage("Hello, World")  
queue.AddMessage(message)
```

Peek at the next message

You can peek at the message in the front of a queue, without removing it from the queue, by calling the `PeekMessage` method.

```
// Peek at the next message.  
let peekedMessage = queue.PeekMessage()  
let msgAsString = peekedMessage.AsString
```

Get the next message for processing

You can retrieve the message at the front of a queue for processing by calling the `GetMessage` method.

```
// Get the next message. Successful processing must be indicated via DeleteMessage later.  
let retrieved = queue.GetMessage()
```

You later indicate successful processing of the message by using `DeleteMessage`.

Change the contents of a queued message

You can change the contents of a retrieved message in-place in the queue. If the message represents a work task, you could use this feature to update the status of the work task. The following code updates the queue message with new contents, and sets the visibility timeout to extend another 60 seconds. This saves the state of work associated with the message, and gives the client another minute to continue working on the message. You could use this technique to track multi-step workflows on queue messages, without having to start over from the beginning if a processing step fails due to hardware or software failure. Typically, you would keep a retry count as well, and if the message is retried more than some number of times, you would delete it. This protects against a message that triggers an application error each time it is processed.

```
// Update the message contents and set a new timeout.  
retrieved.SetMessageContent("Updated contents.")  
queue.UpdateMessage(retrieved,  
    TimeSpan.FromSeconds(60.0),  
    MessageUpdateFields.Content ||| MessageUpdateFields.Visibility)
```

De-queue the next message

Your code de-queues a message from a queue in two steps. When you call `GetMessage`, you get the next message in a queue. A message returned from `GetMessage` becomes invisible to any other code reading messages from this queue. By default, this message stays invisible for 30 seconds. To finish removing the message from the queue, you must also call `DeleteMessage`. This two-step process of removing a message assures that if your code fails to process a message due to hardware or software failure, another instance of your code can get the same message and try again. Your code calls `DeleteMessage` right after the message has been processed.

```
// Process the message in less than 30 seconds, and then delete the message.  
queue.DeleteMessage(retrieved)
```

Use Async workflows with common Queue storage APIs

This example shows how to use an async workflow with common Queue storage APIs.

```
async {  
    let! exists = queue.CreateIfNotExistsAsync() |> Async.AwaitTask  
  
    let! retrieved = queue.GetMessageAsync() |> Async.AwaitTask  
  
    // ... process the message here ...  
  
    // Now indicate successful processing:  
    do! queue.DeleteMessageAsync(retrieved) |> Async.AwaitTask  
}
```

Additional options for de-queuing messages

There are two ways you can customize message retrieval from a queue. First, you can get a batch of messages (up to 32). Second, you can set a longer or shorter invisibility timeout, allowing your code more or less time to fully process each message. The following code example uses `GetMessages` to get 20 messages in one call and then processes each message. It also sets the invisibility timeout to five minutes for each message. Note that the 5 minutes starts for all messages at the same time, so after 5 minutes have passed since the call to `GetMessages`, any messages which have not been deleted will become visible again.

```
for msg in queue.GetMessages(20, Nullable(TimeSpan.FromMinutes(5.))) do
    // Process the message here.
    queue.DeleteMessage(msg)
```

Get the queue length

You can get an estimate of the number of messages in a queue. The `FetchAttributes` method asks the Queue service to retrieve the queue attributes, including the message count. The `ApproximateMessageCount` property returns the last value retrieved by the `FetchAttributes` method, without calling the Queue service.

```
queue.FetchAttributes()
let count = queue.ApproximateMessageCount.GetValueOrDefault()
```

Delete a queue

To delete a queue and all the messages contained in it, call the `Delete` method on the queue object.

```
// Delete the queue.
queue.Delete()
```

Next steps

Now that you've learned the basics of Queue storage, follow these links to learn about more complex storage tasks.

Get started with Azure Table storage and the Azure Cosmos DB Table API using F#

2/28/2019 • 9 minutes to read • [Edit Online](#)

Azure Table storage is a service that stores structured NoSQL data in the cloud. Table storage is a key/attribute store with a schemaless design. Because Table storage is schemaless, it's easy to adapt your data as the needs of your application evolve. Access to data is fast and cost-effective for all kinds of applications. Table storage is typically significantly lower in cost than traditional SQL for similar volumes of data.

You can use Table storage to store flexible datasets, such as user data for web applications, address books, device information, and any other type of metadata that your service requires. You can store any number of entities in a table, and a storage account may contain any number of tables, up to the capacity limit of the storage account.

Azure Cosmos DB provides the Table API for applications that are written for Azure Table storage and that require premium capabilities such as:

- Turnkey global distribution.
- Dedicated throughput worldwide.
- Single-digit millisecond latencies at the 99th percentile.
- Guaranteed high availability.
- Automatic secondary indexing.

Applications written for Azure Table storage can migrate to Azure Cosmos DB by using the Table API with no code changes and take advantage of premium capabilities. The Table API has client SDKs available for .NET, Java, Python, and Node.js.

For more information, see [Introduction to Azure Cosmos DB Table API](#).

About this tutorial

This tutorial shows how to write F# code to do some common tasks using Azure Table storage or the Azure Cosmos DB Table API, including creating and deleting a table and inserting, updating, deleting, and querying table data.

Prerequisites

To use this guide, you must first [create an Azure storage account](#) or [Azure Cosmos DB account](#).

Create an F# Script and Start F# Interactive

The samples in this article can be used in either an F# application or an F# script. To create an F# script, create a file with the `.fsx` extension, for example `tables.fsx`, in your F# development environment.

Next, use a [package manager](#) such as [Paket](#) or [NuGet](#) to install the `WindowsAzure.Storage` package and reference `WindowsAzure.Storage.dll` in your script using a `#r` directive. Do it again for `Microsoft.WindowsAzure.ConfigurationManager` in order to get the `Microsoft.Azure` namespace.

Add namespace declarations

Add the following `open` statements to the top of the `tables.fsx` file:

```
open System
open System.IO
open Microsoft.Azure // Namespace for CloudConfigurationManager
open Microsoft.WindowsAzure.Storage // Namespace for CloudStorageAccount
open Microsoft.WindowsAzure.Storage.Table // Namespace for Table storage types
```

Get your Azure Storage connection string

If you're connecting to Azure Storage Table service, you'll need your connection string for this tutorial. You can copy your connection string from the Azure portal. For more information about connection strings, see [Configure Storage Connection Strings](#).

Get your Azure Cosmos DB connection string

If you're connecting to Azure Cosmos DB, you'll need your connection string for this tutorial. You can copy your connection string from the Azure portal. In the Azure portal, in your Cosmos DB account, go to **Settings > Connection String**, and click the **Copy** button to copy your Primary Connection String.

For the tutorial, enter your connection string in your script, like the following example:

```
let storageConnString = "..." // fill this in from your storage account
```

However, this is **not recommended** for real projects. Your storage account key is similar to the root password for your storage account. Always be careful to protect your storage account key. Avoid distributing it to other users, hard-coding it, or saving it in a plain-text file that is accessible to others. You can regenerate your key using the Azure Portal if you believe it may have been compromised.

For real applications, the best way to maintain your storage connection string is in a configuration file. To fetch the connection string from a configuration file, you can do this:

```
// Parse the connection string and return a reference to the storage account.
let storageConnString =
    CloudConfigurationManager.GetSetting("StorageConnectionString")
```

Using Azure Configuration Manager is optional. You can also use an API such as the .NET Framework's `ConfigurationManager` type.

Parse the connection string

To parse the connection string, use:

```
// Parse the connection string and return a reference to the storage account.
let storageAccount = CloudStorageAccount.Parse(storageConnString)
```

This returns a `CloudStorageAccount`.

Create the Table service client

The `CloudTableClient` class enables you to retrieve tables and entities in Table storage. Here's one way to create the service client:

```
// Create the table client.
let tableClient = storageAccount.CreateCloudTableClient()
```

Now you are ready to write code that reads data from and writes data to Table storage.

Create a table

This example shows how to create a table if it does not already exist:

```
// Retrieve a reference to the table.  
let table = tableClient.GetTableReference("people")  
  
// Create the table if it doesn't exist.  
table.CreateIfNotExists()
```

Add an entity to a table

An entity has to have a type that inherits from `TableEntity`. You can extend `TableEntity` in any way you like, but your type *must* have a parameter-less constructor. Only properties that have both `get` and `set` are stored in your Azure Table.

An entity's partition and row key uniquely identify the entity in the table. Entities with the same partition key can be queried faster than those with different partition keys, but using diverse partition keys allows for greater scalability of parallel operations.

Here's an example of a `Customer` that uses the `lastName` as the partition key and the `firstName` as the row key.

```
type Customer(firstName, lastName, email: string, phone: string) =  
    inherit TableEntity(partitionKey=lastName, rowKey=firstName)  
    new() = Customer(null, null, null, null)  
    member val Email = email with get, set  
    member val PhoneNumber = phone with get, set  
  
let customer =  
    Customer("Walter", "Harp", "Walter@contoso.com", "425-555-0101")
```

Now add `Customer` to the table. To do so, create a `TableOperation` that executes on the table. In this case, you create an `Insert` operation.

```
let insertOp = TableOperation.Insert(customer)  
table.Execute(insertOp)
```

Insert a batch of entities

You can insert a batch of entities into a table using a single write operation. Batch operations allow you to combine operations into a single execution, but they have some restrictions:

- You can perform updates, deletes, and inserts in the same batch operation.
- A batch operation can include up to 100 entities.
- All entities in a batch operation must have the same partition key.
- While it is possible to perform a query in a batch operation, it must be the only operation in the batch.

Here's some code that combines two inserts into a batch operation:

```
let customer1 =  
    Customer("Jeff", "Smith", "Jeff@contoso.com", "425-555-0102")  
  
let customer2 =  
    Customer("Ben", "Smith", "Ben@contoso.com", "425-555-0103")  
  
let batchOp = TableBatchOperation()  
batchOp.Insert(customer1)  
batchOp.Insert(customer2)  
table.ExecuteBatch(batchOp)
```

Retrieve all entities in a partition

To query a table for all entities in a partition, use a `TableQuery` object. Here, you filter for entities where "Smith" is the partition key.

```
let query =
    TableQuery<Customer>().Where(
        TableQuery.GenerateFilterCondition(
            "PartitionKey", QueryComparisons.Equal, "Smith"))

let result = table.ExecuteQuery(query)
```

You now print the results:

```
for customer in result do
    printfn "customer: %A %A" customer.RowKey customer.PartitionKey
```

Retrieve a range of entities in a partition

If you don't want to query all the entities in a partition, you can specify a range by combining the partition key filter with a row key filter. Here, you use two filters to get all entities in the "Smith" partition where the row key (first name) starts with a letter earlier than "M" in the alphabet.

```
let range =
    TableQuery<Customer>().Where(
        TableQuery.CombineFilters(
            TableQuery.GenerateFilterCondition(
                "PartitionKey", QueryComparisons.Equal, "Smith"),
            TableOperators.And,
            TableQuery.GenerateFilterCondition(
                "RowKey", QueryComparisons.LessThan, "M")))

let rangeResult = table.ExecuteQuery(range)
```

You now print the results:

```
for customer in rangeResult do
    printfn "customer: %A %A" customer.RowKey customer.PartitionKey
```

Retrieve a single entity

You can write a query to retrieve a single, specific entity. Here, you use a `TableOperation` to specify the customer "Ben Smith". Instead of a collection, you get back a `Customer`. Specifying both the partition key and the row key in a query is the fastest way to retrieve a single entity from the Table service.

```
let retrieveOp = TableOperation.Retrieve<Customer>("Smith", "Ben")

let retrieveResult = table.Execute(retrieveOp)
```

You now print the results:

```
// Show the result
let retrieveCustomer = retrieveResult.Result :?> Customer
printfn "customer: %A %A" retrieveCustomer.RowKey retrieveCustomer.PartitionKey
```

Replace an entity

To update an entity, retrieve it from the Table service, modify the entity object, and then save the changes back to the Table service using a `Replace` operation. This causes the entity to be fully replaced on the server, unless the entity on the server has changed since it was retrieved, in which case the operation fails. This failure is to prevent your application from inadvertently overwriting changes from other sources.

```
try
    let customer = retrieveResult.Result :?> Customer
    customer.PhoneNumber <- "425-555-0103"
    let replaceOp = TableOperation.Replace(customer)
    table.Execute(replaceOp) |> ignore
    Console.WriteLine("Update succeeded")
with e ->
    Console.WriteLine("Update failed")
```

Insert-or-replace an entity

Sometimes, you don't know whether an entity exists in the table. And if it does, the current values stored in it are no longer needed. You can use `InsertOrReplace` to create the entity, or replace it if it exists, regardless of its state.

```
try
    let customer = retrieveResult.Result :?> Customer
    customer.PhoneNumber <- "425-555-0104"
    let replaceOp = TableOperation.InsertOrReplace(customer)
    table.Execute(replaceOp) |> ignore
    Console.WriteLine("Update succeeded")
with e ->
    Console.WriteLine("Update failed")
```

Query a subset of entity properties

A table query can retrieve just a few properties from an entity instead of all of them. This technique, called projection, can improve query performance, especially for large entities. Here, you return only email addresses using `DynamicTableEntity` and `EntityResolver`. Note that projection is not supported on the local storage emulator, so this code runs only when you're using an account on the Table service.

```
// Define the query, and select only the Email property.
let projectionQ = TableQuery<DynamicTableEntity>().Select [| "Email" |]

// Define an entity resolver to work with the entity after retrieval.
let resolver = EntityResolver<string>(fun pk rk ts props etag -
    if props.ContainsKey("Email") then
        props.[ "Email" ].StringValue
    else
        null
)

let resolvedResults = table.ExecuteQuery(projectionQ, resolver, null, null)
```

Retrieve entities in pages asynchronously

If you are reading a large number of entities, and you want to process them as they are retrieved rather than waiting for them all to return, you can use a segmented query. Here, you return results in pages by using an async workflow so that execution is not blocked while you're waiting for a large set of results to return.

```
let tableQ = TableQuery<Customer>()

let asyncQuery =
    let rec loop (cont: TableContinuationToken) = async {
        let! ct = Async.CancellationToken
        let! result = table.ExecuteQuerySegmentedAsync(tableQ, cont, ct) |> Async.AwaitTask

        // ...process the result here...

        // Continue to the next segment
        match result.ContinuationToken with
        | null -> ()
        | cont -> return! loop cont
    }
    loop null
```

You now execute this computation synchronously:

```
let asyncResults = asyncQuery |> Async.RunSynchronously
```

Delete an entity

You can delete an entity after you have retrieved it. As with updating an entity, this fails if the entity has changed since you retrieved it.

```
let deleteOp = TableOperation.Delete(customer)
table.Execute(deleteOp)
```

Delete a table

You can delete a table from a storage account. A table that has been deleted will be unavailable to be re-created for a period of time following the deletion.

```
table.DeleteIfExists()
```

Next steps

Now that you've learned the basics of Table storage, follow these links to learn about more complex storage tasks and the Azure Cosmos DB Table API.

Package Management for F# Azure Dependencies

5/4/2018 • 2 minutes to read • [Edit Online](#)

Obtaining packages for Azure development is easy when you use a package manager. The two options are [Paket](#) and [NuGet](#).

Using Paket

If you're using [Paket](#) as your dependency manager, you can use the `paket.exe` tool to add Azure dependencies. For example:

```
> paket add nuget WindowsAzure.Storage
```

Or, if you're using [Mono](#) for cross-platform .NET development:

```
> mono paket.exe add nuget WindowsAzure.Storage
```

This will add `WindowsAzure.Storage` to your set of package dependencies for the project in the current directory, modify the `paket.dependencies` file, and download the package. If you have previously set up dependencies, or are working with a project where dependencies have been set up by another developer, you can resolve and install dependencies locally like this:

```
> paket install
```

Or, for Mono development:

```
> mono paket.exe install
```

You can update all your package dependencies to the latest version like this:

```
> paket update
```

Or, for Mono development:

```
> mono paket.exe update
```

Using Nuget

If you're using [NuGet](#) as your dependency manager, you can use the `nuget.exe` tool to add Azure dependencies. For example:

```
> nuget install WindowsAzure.Storage -ExcludeVersion
```

Or, for Mono development:

```
> mono nuget.exe install WindowsAzure.Storage -ExcludeVersion
```

This will add `WindowsAzure.Storage` to your set of package dependencies for the project in the current directory, and download the package. If you have previously set up dependencies, or are working with a project where dependencies have been set up by another developer, you can resolve and install dependencies locally like this:

```
> nuget restore
```

Or, for Mono development:

```
> mono nuget.exe restore
```

You can update all your package dependencies to the latest version like this:

```
> nuget update
```

Or, for Mono development:

```
> mono nuget.exe update
```

Referencing Assemblies

In order to use your packages in your F# script, you need to reference the assemblies included in the packages using a `#r` directive. For example:

```
> #r "packages/WindowsAzure.Storage/lib/net40/Microsoft.WindowsAzure.Storage.dll"
```

As you can see, you'll need to specify the relative path to the DLL and the full DLL name, which may not be exactly the same as the package name. The path will include a framework version and possibly a package version number. To find all the installed assemblies, you can use something like this on a Windows command line:

```
> cd packages/WindowsAzure.Storage  
> dir /s/b *.dll
```

Or in a Unix shell, something like this:

```
> find packages/WindowsAzure.Storage -name "*.dll"
```

This will give you the paths to the installed assemblies. From there, you can select the correct path for your framework version.

Visual Basic Guide

10/24/2018 • 2 minutes to read • [Edit Online](#)

Visual Basic is engineered for productively building type-safe and object-oriented applications. Visual Basic enables developers to target Windows, Web, and mobile devices. As with all languages targeting the Microsoft .NET Framework, programs written in Visual Basic benefit from security and language interoperability.

This generation of Visual Basic continues the tradition of giving you a fast and easy way to create .NET Framework-based applications.

If you don't already have Visual Basic, you can acquire a version of Visual Studio that includes Visual Basic for free from the [Visual Studio](#) site.

In This Section

[Getting Started](#)

Helps you begin working by listing what is new and what is available in various editions of the product.

[Programming Concepts](#) Presents the language concepts that are most useful to Visual Basic programmers.

[Program Structure and Code Conventions](#)

Contains documentation on the basic structure and code conventions of Visual Basic such as naming conventions, comments in code, and limitations within Visual Basic.

[Visual Basic Language Features](#)

Provides links to topics that introduce and discuss important features of Visual Basic, including LINQ and XML literals.

[Visual Basic Reference](#)

Contains the Visual Basic language and compiler information.

[Developing Applications with Visual Basic](#)

Discusses various aspects of development in Visual Basic, such as security, exception handling, and using the .NET Framework class library.

[COM Interop](#)

Explains the interoperability issues associated with creating and using component object model (COM) objects with Visual Basic.

What's new for Visual Basic

1/23/2019 • 11 minutes to read • [Edit Online](#)

This topic lists key feature names for each version of Visual Basic, with detailed descriptions of the new and enhanced features in the latest versions of the language.

Current version

Visual Basic 15.8 / Visual Studio 2017 Version 15.8

For new features, see [Visual Basic 15.8](#)

Previous versions

Visual Basic 15.5 / Visual Studio 2017 Version 15.5

For new features, see [Visual Basic 15.5](#)

Visual Basic 15.3 / Visual Studio 2017 Version 15.3

For new features, see [Visual Basic 15.3](#)

Visual Basic 2017 / Visual Studio 2017

For new features, see [Visual Basic 2017](#)

Visual Basic / Visual Studio 2015

For new features, see [Visual Basic 14](#)

Visual Basic / Visual Studio 2013

Technology previews of the .NET Compiler Platform ("Roslyn")

Visual Basic / Visual Studio 2012

`Async` and `await` keywords, iterators, caller info attributes

Visual Basic, Visual Studio 2010

Auto-implemented properties, collection initializers, implicit line continuation, dynamic, generic co/contra variance, global namespace access

Visual Basic / Visual Studio 2008

Language Integrated Query (LINQ), XML literals, local type inference, object initializers, anonymous types, extension methods, local `var` type inference, lambda expressions, `if` operator, partial methods, nullable value types

Visual Basic / Visual Studio 2005

The `My` type and helper types (access to app, computer, files system, network)

Visual Basic / Visual Studio .NET 2003

Bit-shift operators, loop variable declaration

Visual Basic / Visual Studio .NET 2002

The first release of Visual Basic .NET

Visual Basic 15.8

Optimized floating-point to integer conversion

In previous versions of Visual Basic, conversion of `Double` and `Single` values to integers offered relatively poor

performance. Visual Basic 15.8 significantly enhances the performance of floating-point conversions to integers when you pass the value returned by any of the following methods to one of the [intrinsic Visual Basic integer conversion functions](#) (CByte, CShort, CInt, CLng, CSByte, CUShort, CUInt, CULng), or when the value returned by any of the following methods is implicitly cast to an integral type when [Option Strict](#) is set to [off](#):

- [Conversion.Fix\(Double\)](#)
- [Conversion.Fix\(Object\)](#)
- [Conversion.Fix\(Single\)](#)
- [Conversion.Int\(Double\)](#)
- [Conversion.Int\(Object\)](#)
- [Conversion.Int\(Single\)](#)
- [Math.Ceiling\(Double\)](#)
- [Math.Floor\(Double\)](#)
- [Math.Round\(Double\)](#)
- [Math.Truncate\(Double\)](#)

This optimization allows code to run faster -- up to twice as fast for code that does a large number of conversions to integer types. The following example illustrates some simple method calls that are affected by this optimization:

```
Dim s As Single = 173.7619
Dim d As Double = s

Dim i1 As Integer = CInt(Fix(s))           ' Result: 173
Dim b1 As Byte = CByte(Int(d))             ' Result: 173
Dim s1 AS Short = CShort(Math.Truncate(s)) ' Result: 173
Dim i2 As Integer = CInt(Math.Ceiling(d))   ' Result: 174
Dim i3 As Integer = CInt(Math.Round(s))     ' Result: 174
```

Note that this truncates rather than rounds floating-point values.

Visual Basic 15.5

Non-trailing named arguments

In Visual Basic 15.3 and earlier versions, when a method call included arguments both by position and by name, positional arguments had to precede named arguments. Starting with Visual Basic 15.5, positional and named arguments can appear in any order as long as all arguments up to the last positional argument are in the correct position. This is particularly useful when named arguments are used to make code more readable.

For example, the following method call has two positional arguments between a named argument. The named argument makes it clear that the value 19 represents an age.

```
StudentInfo.Display("Mary", age:=19, #9/21/1998#)
```

[Private Protected](#) member access modifier

This new keyword combination defines a member that is accessible by all members in its containing class as well as by types derived from the containing class, but only if they are also found in the containing assembly. Because structures cannot be inherited, [Private Protected](#) can only be applied to the members of a class.

Leading hex/binary/octal separator

Visual Basic 2017 added support for the underscore character (`_`) as a digit separator. Starting with Visual Basic 15.5, you can use the underscore character as a leading separator between the prefix and hexadecimal, binary, or

octal digits. The following example uses a leading digit separator to define 3,271,948,384 as a hexadecimal number:

```
Dim number As Integer = &H_C305_F860
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

Visual Basic 15.3

Named tuple inference

When you assign the value of tuple elements from variables, Visual Basic infers the name of tuple elements from the corresponding variable names; you do not have to explicitly name a tuple element. The following example uses inference to create a tuple with three named elements, `state`, `stateName`, and `capital`.

```
Dim state = "MI"
Dim stateName = "Michigan"
Dim capital = "Lansing"
Dim stateInfo = ( state, stateName, capital )
Console.WriteLine($"{stateInfo.stateName}: 2-letter code: {stateInfo.State}, Capital {stateInfo.capital}")
' The example displays the following output:
'     Michigan: 2-letter code: MI, Capital Lansing
```

Additional compiler switches

The Visual Basic command-line compiler now supports the **-refout** and **-refonly** compiler options to control the output of reference assemblies. **-refout** defines the output directory of the reference assembly, and **-refonly** specifies that only a reference assembly is to be output by compilation.

Visual Basic 2017

Tuples

Tuples are a lightweight data structure that most commonly is used to return multiple values from a single method call. Ordinarily, to return multiple values from a method, you have to do one of the following:

- Define a custom type (a `Class` or a `Structure`). This is a heavyweight solution.
- Define one or more `ByRef` parameters, in addition to returning a value from the method.

Visual Basic's support for tuples lets you quickly define a tuple, optionally assign semantic names to its values, and quickly retrieve its values. The following example wraps a call to the [TryParse](#) method and returns a tuple.

```
Imports System.Globalization

Public Module NumericLibrary
    Public Function ParseInteger(value As String) As (Success As Boolean, Number As Int32)
        Dim number As Integer
        Return (Int32.TryParse(value, NumberStyles.Any, CultureInfo.InvariantCulture, number), number)
    End Function
End Module
```

You can then call the method and handle the returned tuple with code like the following.

```
Dim numericString As String = "123,456"
Dim result = ParseInteger(numericString)
Console.WriteLine($"{If(result.Success, $"Success: {result.Number:N0}", "Failure")}")
Console.ReadLine()
'      Output: Success: 123,456
```

Binary literals and digit separators

You can define a binary literal by using the prefix `&B` or `&b`. In addition, you can use the underscore character, `_`, as a digit separator to enhance readability. The following example uses both features to assign a `Byte` value and to display it as a decimal, hexadecimal, and binary number.

```
Dim value As Byte = &B0110_1110
Console.WriteLine($"{nameof(value)} = {value} (hex: 0x{value:X2}) " +
    $"(binary: {Convert.ToString(value, 2)})")
' The example displays the following output:
'     value = 110 (hex: 0x6E) (binary: 1101110)
```

For more information, see the "Literal assignments" section of the [Byte](#), [Integer](#), [Long](#), [Short](#), [SByte](#), [UInteger](#), [ULong](#), and [UShort](#) data types.

Support for C# reference return values

Starting with C# 7.0, C# supports reference return values. That is, when the calling method receives a value returned by reference, it can change the value of the reference. Visual Basic does not allow you to author methods with reference return values, but it does allow you to consume and modify the reference return values.

For example, the following `Sentence` class written in C# includes a `FindNext` method that finds the next word in a sentence that begins with a specified substring. The string is returned as a reference return value, and a `Boolean` variable passed by reference to the method indicates whether the search was successful. This means that the caller can not only read the returned value; he or she can also modify it, and that modification is reflected in the `Sentence` class.

```

using System;

public class Sentence
{
    private string[] words;
    private int currentSearchPointer;

    public Sentence(string sentence)
    {
        words = sentence.Split(' ');
        currentSearchPointer = -1;
    }

    public ref string FindNext(string startWithString, ref bool found)
    {
        for (int count = currentSearchPointer + 1; count < words.Length; count++)
        {
            if (words[count].StartsWith(startWithString))
            {
                currentSearchPointer = count;
                found = true;
                return ref words[currentSearchPointer];
            }
        }
        currentSearchPointer = -1;
        found = false;
        return ref words[0];
    }

    public string GetSentence()
    {
        string stringToReturn = null;
        foreach (var word in words)
            stringToReturn += $"{word} ";

        return stringToReturn.Trim();
    }
}

```

In its simplest form, you can modify the word found in the sentence by using code like the following. Note that you are not assigning a value to the method, but rather to the expression that the method returns, which is the reference return value.

```

Dim sentence As New Sentence("A time to see the world is now.")
Dim found = False
sentence.FindNext("A", found) = "A good"
Console.WriteLine(sentence.GetSentence())
' The example displays the following output:
'     A good time to see the world is now.

```

A problem with this code, though, is that if a match is not found, the method returns the first word. Since the example does not examine the value of the `Boolean` argument to determine whether a match is found, it modifies the first word if there is no match. The following example corrects this by replacing the first word with itself if there is no match.

```

Dim sentence As New Sentence("A time to see the world is now.")
Dim found = False
sentence.FindNext("A", found) = IIf(found, "A good", sentence.FindNext("B", found))
Console.WriteLine(sentence.GetSentence())
' The example displays the following output:
'     A good time to see the world is now.

```

A better solution is to use a helper method to which the reference return value is passed by reference. The helper method can then modify the argument passed to it by reference. The following example does that.

```
Module Example
    Public Sub Main()
        Dim sentence As New Sentence("A time to see the world is now.")
        Dim found = False
        Dim returns = RefHelper(sentence.FindNext("A", found), "A good", found)
        Console.WriteLine(sentence.GetSentence())
    End Sub

    Private Function RefHelper(ByRef stringFound As String, replacement As String, success As Boolean) _
        As (originalString As String, found As Boolean)
        Dim originalString = stringFound
        If found Then stringFound = replacement
        Return (originalString, found)
    End Function
End Module
' The example displays the following output:
'     A good time to see the world is now.
```

For more information, see [Reference Return Values](#).

Visual Basic 14

Nameof

You can get the unqualified string name of a type or member for use in an error message without hard coding a string. This allows your code to remain correct when refactoring. This feature is also useful for hooking up model-view-controller MVC links and firing property changed events.

String interpolation

You can use string interpolation expressions to construct strings. An interpolated string expression looks like a template string that contains expressions. An interpolated string is easier to understand with respect to arguments than [Composite Formatting](#).

Null-conditional member access and indexing

You can test for null in a very light syntactic way before performing a member access (`?.`) or index (`?[]`) operation. These operators help you write less code to handle null checks, especially for descending into data structures. If the left operand or object reference is null, the operations returns null.

Multi-line string literals

String literals can contain newline sequences. You no longer need the old work around of using

```
<xml><![CDATA[...text with newlines...]]></xml>.Value
```

Comments

You can put comments after implicit line continuations, inside initializer expressions, and among LINQ expression terms.

Smarter fully-qualified name resolution

Given code such as `Threading.Thread.Sleep(1000)`, Visual Basic used to look up the namespace "Threading", discover it was ambiguous between System.Threading and System.Windows.Threading, and then report an error. Visual Basic now considers both possible namespaces together. If you show the completion list, the Visual Studio editor lists members from both types in the completion list.

Year-first date literals

You can have date literals in yyyy-mm-dd format, `#2015-03-17 16:10 PM#`.

Readonly interface properties

You can implement readonly interface properties using a readwrite property. The interface guarantees minimum functionality, and it does not stop an implementing class from allowing the property to be set.

TypeOf <expr> IsNot <type>

For more readability of your code, you can now use `TypeOf` with `IsNot`.

#Disable Warning <ID> and #Enable Warning <ID>

You can disable and enable specific warnings for regions within a source file.

XML doc comment improvements

When writing doc comments, you get smart editor and build support for validating parameter names, proper handling of `crefs` (generics, operators, etc.), colorizing, and refactoring.

Partial module and interface definitions

In addition to classes and structs, you can declare partial modules and interfaces.

#Region directives inside method bodies

You can put `#Region...#End Region` delimiters anywhere in a file, inside functions, and even spanning across function bodies.

Overrides definitions are implicitly overloads

If you add the `overrides` modifier to a definition, the compiler implicitly adds `Overloads` so that you can type less code in common cases.

CObj allowed in attributes arguments

The compiler used to give an error that `CObj(...)` was not a constant when used in attribute constructions.

Declaring and consuming ambiguous methods from different interfaces

Previously the following code yielded errors that prevented you from declaring `IMock` or from calling `GetDetails` (if these had been declared in C#):

```
Interface ICustomer
    Sub GetDetails(x As Integer)
End Interface

Interface ITime
    Sub GetDetails(x As String)
End Interface

Interface IMock : Inherits ICustomer, ITime
    Overloads Sub GetDetails(x As Char)
End Interface

Interface IMock2 : Inherits ICustomer, ITime
End Interface
```

Now the compiler will use normal overload resolution rules to choose the most appropriate `GetDetails` to call, and you can declare interface relationships in Visual Basic like those shown in the sample.

Accessing Application Web Services (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The `My.WebServices` object provides an instance of each Web service referenced by the current project. Each instance is instantiated on demand. You can access these Web services through the properties of the `My.WebServices` object. The name of the property is the same as the name of the Web service that the property accesses. Any class that inherits from `SoapHttpClientProtocol` is a Web service.

Tasks

The following table lists possible ways to access Web services referenced by an application.

TO	SEE
Call a Web service	My.WebServices Object
Call a Web service asynchronously and handle an event when it completes	How to: Call a Web Service Asynchronously

See also

- [My.WebServices Object](#)

How to: Call a Web Service Asynchronously (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

This example attaches a handler to a Web service's asynchronous handler event, so that it can retrieve the result of an asynchronous method call. This example used the DemoTemperatureService Web service at <http://www.xmethods.net>.

When you reference a Web service in your project in the Visual Studio Integrated Development Environment (IDE), it is added to the `My.WebServices` object, and the IDE generates a client proxy class to access a specified Web service.

The proxy class allows you to call the Web service methods synchronously, where your application waits for the function to complete. In addition, the proxy creates additional members to help call the method asynchronously. For each Web service function, `NameOfWebServiceFunction`, the proxy creates a `NameOfWebServiceFunction Async` subroutine, a `NameOfWebServiceFunction Completed` event, and a `NameOfWebServiceFunction CompletedEventArgs` class. This example demonstrates how to use the asynchronous members to access the `getTemp` function of the DemoTemperatureService Web service.

NOTE

This code does not work in Web applications, because ASP.NET does not support the `My.WebServices` object.

To call a Web service asynchronously

1. Reference the DemoTemperatureService Web service at <http://www.xmethods.net>. The address is

```
http://www.xmethods.net/sd/2001/DemoTemperatureService.wsdl
```

2. Add an event handler for the `getTempCompleted` event:

```
Private Sub getTempCompletedHandler(ByVal sender As Object,  
    ByVal e As net.xmethods.www.getTempCompletedEventArgs)  
  
    MsgBox("Temperature: " & e.Result)  
End Sub
```

NOTE

You cannot use the `Handles` statement to associate an event handler with the `My.WebServices` object's events.

3. Add a field to track if the event handler has been added to the `getTempCompleted` event:

```
Private handlerAttached As Boolean = False
```

4. Add a method to add the event handler to the `getTempCompleted` event, if necessary, and to call the `getTempAsync` method:

```
Sub CallGetTempAsync(ByVal zipCode As Integer)
    If Not handlerAttached Then
        AddHandler My.WebServices.
            TemperatureService.getTempCompleted,
            AddressOf Me.TS_getTempCompleted
        handlerAttached = True
    End If
    My.WebServices.TemperatureService.getTempAsync(zipCode)
End Sub
```

To call the `getTemp` Web method asynchronously, call the `CallGetTempAsync` method. When the Web method finishes, its return value is passed to the `getTempCompletedHandler` event handler.

Development with My (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Visual Basic provides new features for rapid application development that improve productivity and ease of use while delivering power. One of these features, called `My`, provides access to information and default object instances that are related to the application and its run-time environment. This information is organized in a format that is discoverable through IntelliSense and logically delineated according to use.

Top-level members of `My` are exposed as objects. Each object behaves similarly to a namespace or a class with `Shared` members, and it exposes a set of related members.

This table shows the top-level `My` objects and their relationship to each other.

In This Section

[Performing Tasks with My.Application, My.Computer, and My.User](#)

Describes the three central `My` objects, `My.Application`, `My.Computer`, and `My.User`, which provide access to information and functionality.

[Default Object Instances Provided by My.Forms and My.WebServices](#)

Describes the `My.Forms` and `My.WebServices` objects, which provide access to forms, data sources, and XML Web services used by your application.

[Rapid Application Development with My.Resources and My.Settings](#)

Describes the `My.Resources` and `My.Settings` objects, which provide access to an application's resources and settings.

[Overview of the Visual Basic Application Model](#)

Describes the Visual Basic Application Startup/Shutdown model.

[How My Depends on Project Type](#)

Gives details on which `My` features are available in different project types.

See also

- [ApplicationBase](#)

- [User](#)
- [My.Forms Object](#)
- [My.WebServices Object](#)

- How My Depends on Project Type

Performing Tasks with My.Application, My.Computer, and My.User (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

The three central `My` objects that provide access to information and commonly used functionality are `My.Application` (`ApplicationBase`), `My.Computer` (`Computer`), and `My.User` (`User`). You can use these objects to access information that is related to the current application, the computer that the application is installed on, or the current user of the application, respectively.

My.Application, My.Computer, and My.User

The following examples demonstrate how information can be retrieved using `My`.

```
' Displays a message box that shows the full command line for the
' application.
Dim args As String = ""
For Each arg As String In My.Application.CommandLineArgs
    args &= arg & " "
Next
MsgBox(args)
```

```
' Gets a list of subfolders in a folder
My.Computer.FileSystem.GetDirectories(
    My.Computer.FileSystem.SpecialDirectories.MyDocuments, True, "*Logs*")
```

In addition to retrieving information, the members exposed through these three objects also allow you to execute methods related to that object. For instance, you can access a variety of methods to manipulate files or update the registry through `My.Computer`.

File I/O is significantly easier and faster with `My`, which includes a variety of methods and properties for manipulating files, directories, and drives. The `TextFieldParser` object allows you to read from large structured files that have delimited or fixed-width fields. This example opens the `TextFieldParser` `reader` and uses it to read from `C:\TestFolder1\test1.txt`.

```
Dim reader =
    My.Computer.FileSystem.OpenTextFieldParser("C:\TestFolder1\test1.txt")
reader.TextFieldType = Microsoft.VisualBasic.FileIO.FieldType.Delimited
reader.Delimiters = New String() {","}
Dim currentRow As String()
While Not reader.EndOfData
    Try
        currentRow = reader.ReadFields()
        Dim currentField As String
        For Each currentField In currentRow
            MsgBox(currentField)
        Next
    Catch ex As Microsoft.VisualBasic.FileIO.MalformedLineException
        MsgBox("Line " & ex.Message &
            "is not valid and will be skipped.")
    End Try
End While
```

`My.Application` allows you to change the culture for your application. The following example demonstrates how this method can be called.

```
' Changes the current culture for the application to Jamaican English.  
My.Application.ChangeCulture("en-JM")
```

Default Object Instances Provided by My.Forms and My.WebServices (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

The [My.Forms](#) and [My.WebServices](#) objects provide access to forms, data sources, and XML Web services used by your application. They do this by providing collections of *default instances* of each of these objects.

Default Instances

A default instance is an instance of the class that is provided by the runtime and does not need to be declared and instantiated using the `Dim` and `New` statements. The following example demonstrates how you might have declared and instantiated an instance of a [Form](#) class called `Form1`, and how you are now able to get a default instance of this [Form](#) class through `My.Forms`.

```
' The old method of declaration and instantiation
Dim myForm As New Form1
myForm.show()
```

```
' With My.Forms, you can directly call methods on the default
' instance()
My.Forms.Form1.Show()
```

The `My.Forms` object returns a collection of default instances for every [Form](#) class that exists in your project. Similarly, `My.WebServices` provides a default instance of the proxy class for every Web service that you have created a reference to in your application.

Rapid Application Development with My.Resources and My.Settings (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

The `My.Resources` object provides access to the application's resources and allows you to dynamically retrieve resources for your application.

Retrieving Resources

A number of resources such as audio files, icons, images, and strings can be retrieved through the `My.Resources` object. For example, you can access the application's culture-specific resource files. The following example sets the icon of the form to the icon named `Form1Icon` stored in the application's resource file.

```
Sub SetFormIcon()
    Me.Icon = My.Resources.Form1Icon
End Sub
```

The `My.Resources` object exposes only global resources. It does not provide access to resource files associated with forms. You must access the form resources from the form.

Similarly, the `My.Settings` object provides access to the application's settings and allows you to dynamically store and retrieve property settings and other information for your application. For more information, see [My.Resources Object](#) and [My.Settings Object](#).

Overview of the Visual Basic Application Model

3/26/2019 • 3 minutes to read • [Edit Online](#)

Visual Basic provides a well-defined model for controlling the behavior of Windows Forms applications: the Visual Basic Application model. This model includes events for handling the application's startup and shutdown, as well as events for catching unhandled exceptions. It also provides support for developing single-instance applications. The application model is extensible, so developers that need more control can customize its overridable methods.

Uses for the Application Model

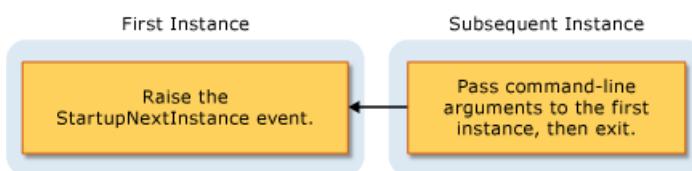

A typical application needs to perform tasks when it starts up and shuts down. For example, when it starts up, the application can display a splash screen, make database connections, load a saved state, and so on. When the application shuts down, it can close database connections, save the current state, and so on. In addition, the application can execute specific code when the application shuts down unexpectedly, such as during an unhandled exception.

The Visual Basic Application model makes it easy to create a *single-instance* application. A single-instance application differs from a normal application in that only one instance of the application can be running at a time. An attempt to launch another instance of a single-instance application results in the original instance being notified—by means of the `StartupNextInstance` event—that another launch attempt was made. The notification includes the subsequent instance's command-line arguments. The subsequent instance of the application is then closed before any initialization can occur.

A single-instance application starts and checks whether it is the first instance or a subsequent instance of the application:

- If it is the first instance, it starts as usual.
- Each subsequent attempt to start the application, while the first instance runs, results in very different behavior. The subsequent attempt notifies the first instance about the command-line arguments, and then immediately exits. The first instance handles the `StartupNextInstance` event to determine what the subsequent instance's command-line arguments were, and continues to run.

This diagram shows how a subsequent instance signals the first instance:

By handling the `StartupNextInstance` event, you can control how your single-instance application behaves. For example, Microsoft Outlook typically runs as a single-instance application; when Outlook is running and you attempt to start Outlook again, focus shifts to the original instance but another instance does not open.

Events in the Application Model

The following events are found in the application model:

- **Application startup.** The application raises the `Startup` event when it starts. By handling this event, you can add code that initializes the application before the main form is loaded. The `Startup` event also provides for canceling execution of the application during that phase of the startup process, if desired.

You can configure the application to show a splash screen while the application startup code runs. By default, the application model suppresses the splash screen when either the `/nosplash` or `-nosplash` command-line argument is used.

- **Single-instance applications.** The [StartupNextInstance](#) event is raised when a subsequent instance of a single-instance application starts. The event passes the command-line arguments of the subsequent instance.
- **Unhandled exceptions.** If the application encounters an unhandled exception, it raises the [UnhandledException](#) event. Your handler for that event can examine the exception and determine whether to continue execution.

The `UnhandledException` event is not raised in some circumstances. For more information, see [UnhandledException](#).

- **Network-connectivity changes.** If the computer's network availability changes, the application raises the [NetworkAvailabilityChanged](#) event.

The `NetworkAvailabilityChanged` event is not raised in some circumstances. For more information, see [NetworkAvailabilityChanged](#).

- **Application shut down.** The application provides the [Shutdown](#) event to signal when it is about to shut down. In that event handler, you can make sure that the operations your application needs to perform—closing and saving, for example—are completed. You can configure your application to shut down when the main form closes, or to shut down only when all forms close.

Availability

By default, the Visual Basic Application model is available for Windows Forms projects. If you configure the application to use a different startup object, or start the application code with a custom `Sub Main`, then that object or class may need to provide an implementation of the [WindowsFormsApplicationBase](#) class to use the application model. For information about changing the startup object, see [Application Page, Project Designer \(Visual Basic\)](#).

How My Depends on Project Type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

`My` exposes only those objects required by a particular project type. For example, the `My.Forms` object is available in a Windows Forms application but not available in a console application. This topic describes which `My` objects are available in different project types.

My in Windows Applications and Web Sites

`My` exposes only objects that are useful in the current project type; it suppresses objects that are not applicable. For example, the following image shows the `My` object model in a Windows Forms project.

In a Web site project, `My` exposes objects that are relevant to a Web developer (such as the `My.Request` and `My.Response` objects) while suppressing objects that are not relevant (such as the `My.Forms` object). The following image shows the `My` object model in a Web site project:

Project Details

The following table shows which `My` objects are enabled by default for eight project types: Windows application, class Library, console application, Windows control library, Web control library, Windows service, empty, and Web site.

There are three versions of the `My.Application` object, two versions of the `My.Computer` object, and two versions of `My.User` object; details about these versions are given in the footnotes after the table.

MY OBJECT	WINDOWS APPLICATION	CLASS LIBRARY	CONSOLE APPLICATION	WINDOWS CONTROL LIBRARY	WEB CONTROL LIBRARY	WINDOWS SERVICE	EMPTY	WEB SITE
<code>My.Application</code> <sup>1</sup>	<code>Yes</code> <sup>2</sup>	<code>Yes</code> <sup>2</sup>	<code>Yes</code> <sup>3</sup>	<code>Yes</code> <sup>2</sup>	No	<code>Yes</code> <sup>3</sup>	No	No
<code>My.Computer</code>	<code>Yes</code> <sup>4</sup>	<code>Yes</code> <sup>4</sup>	<code>Yes</code> <sup>4</sup>	<code>Yes</code> <sup>4</sup>	<code>Yes</code> <sup>5</sup>	<code>Yes</code> <sup>4</sup>	No	<code>Yes</code> <sup>5</sup>
<code>My.Forms</code>	<code>Yes</code>	No	No	<code>Yes</code>	No	No	No	No
<code>My.Log</code>	No	No	No	No	No	No	No	<code>Yes</code>
<code>My.Request</code>	No	No	No	No	No	No	No	<code>Yes</code>
<code>My.Resources</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	No	No
<code>My.Response</code>	No	No	No	No	No	No	No	<code>Yes</code>
<code>My.Settings</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	No	No
<code>My.User</code>	<code>Yes</code> <sup>6</sup>	<code>Yes</code> <sup>6</sup>	<code>Yes</code> <sup>6</sup>	<code>Yes</code> <sup>6</sup>	<code>Yes</code> <sup>7</sup>	<code>Yes</code> <sup>6</sup>	No	<code>Yes</code> <sup>7</sup>
<code>My.WebServices</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	<code>Yes</code>	No	No

<sup>1</sup> Windows Forms version of `My.Application`. Derives from the console version (see Note 3); adds support for interacting with the application's windows and provides the Visual Basic Application model.

<sup>2</sup> Library version of `My.Application`. Provides the basic functionality needed by an application: provides members for writing to the application log and accessing application information.

<sup>3</sup> Console version of `My.Application`. Derives from the library version (see Note 2), and adds additional members for accessing the application's command-line arguments and ClickOnce deployment information.

<sup>4</sup> Windows version of `My.Computer`. Derives from the Server version (see Note 5), and provides access to useful objects on a client machine, such as the keyboard, screen, and mouse.

<sup>5</sup> Server version of `My.Computer`. Provides basic information about the computer, such as the name, access to the clock, and so on.

<sup>6</sup> Windows version of `My.User`. This object is associated with the thread's current identity.

<sup>7</sup> Web version of `My.User`. This object is associated with the user identity of the application's current HTTP request.

Accessing data in Visual Basic applications

9/7/2018 • 2 minutes to read • [Edit Online](#)

Visual Basic includes several new features to assist in developing applications that access data. Data-bound forms for Windows applications are created by dragging items from the [Data Sources Window](#) onto the form. You bind controls to data by dragging items from the **Data Sources Window** onto existing controls.

Creating and Using Components in Visual Basic

1/23/2019 • 2 minutes to read • [Edit Online](#)

A *component* is a class that implements the [System.ComponentModel.IComponent](#) interface or that derives directly or indirectly from a class that implements [IComponent](#). A .NET Framework component is an object that is reusable, can interact with other objects, and provides control over external resources and design-time support.

An important feature of components is that they are designable, which means that a class that is a component can be used in the Visual Studio Integrated Development Environment. A component can be added to the Toolbox, dragged and dropped onto a form, and manipulated on a design surface. Notice that base design-time support for components is built into the .NET Framework; a component developer does not have to do any additional work to take advantage of the base design-time functionality.

A *control* is similar to a component, as both are designable. However, a control provides a user interface, while a component does not. A control must derive from one of the base control classes: [Control](#) or [Control](#).

When to Create a Component

If your class will be used on a design surface (such as the Windows Forms or Web Forms Designer) but has no user interface, it should be a component and implement [IComponent](#), or derive from a class that directly or indirectly implements [IComponent](#).

The [Component](#) and [MarshalByValueComponent](#) classes are base implementations of the [IComponent](#) interface. The main difference between these classes is that the [Component](#) class is marshaled by reference, while [IComponent](#) is marshaled by value. The following list provides broad guidelines for implementers.

- If your component needs to be marshaled by reference, derive from [Component](#).
- If your component needs to be marshaled by value, derive from [MarshalByValueComponent](#).
- If your component cannot derive from one of the base implementations due to single inheritance, implement [IComponent](#).

Component Classes

The [System.ComponentModel](#) namespace provides classes that are used to implement the run-time and design-time behavior of components and controls. This namespace includes the base classes and interfaces for implementing attributes and type converters, binding to data sources, and licensing components.

The core component classes are:

- [Component](#). A base implementation for the [IComponent](#) interface. This class enables object sharing between applications.
- [MarshalByValueComponent](#). A base implementation for the [IComponent](#) interface.
- [Container](#). The base implementation for the [.IContainer](#) interface. This class encapsulates zero or more components.

Some of the classes used for component licensing are:

- [License](#). The abstract base class for all licenses. A license is granted to a specific instance of a component.
- [LicenseManager](#). Provides properties and methods to add a license to a component and to manage a

[LicenseProvider](#).

- [LicenseProvider](#). The abstract base class for implementing a license provider.
- [LicenseProviderAttribute](#). Specifies the [LicenseProvider](#) class to use with a class.

Classes commonly used for describing and persisting components.

- [TypeDescriptor](#). Provides information about the characteristics for a component, such as its attributes, properties, and events.
- [EventDescriptor](#). Provides information about an event.
- [PropertyDescriptor](#). Provides information about a property.

Windows Forms Application Basics (Visual Basic)

2/28/2019 • 6 minutes to read • [Edit Online](#)

An important part of Visual Basic is the ability to create Windows Forms applications that run locally on users' computers. You can use Visual Studio to create the application and user interface using Windows Forms. A Windows Forms application is built on classes from the [System.Windows.Forms](#) namespace.

Designing Windows Forms Applications

You can create Windows Forms and Windows service applications with Visual Studio. For more information, see the following topics:

- [Getting Started with Windows Forms](#). Provides information on how to create and program Windows Forms.
- [Windows Forms Controls](#). Collection of topics detailing the use of Windows Forms controls.
- [Windows Service Applications](#). Lists topics that explain how to create Windows services.

Building Rich, Interactive User Interfaces

Windows Forms is the smart-client component of the .NET Framework, a set of managed libraries that enable common application tasks such as reading and writing to the file system. Using a development environment like Visual Studio, you can create Windows Forms applications that display information, request input from users, and communicate with remote computers over a network.

In Windows Forms, a form is a visual surface on which you display information to the user. You commonly build Windows Forms applications by placing controls on forms and developing responses to user actions, such as mouse clicks or key presses. A *control* is a discrete user interface (UI) element that displays data or accepts data input.

Events

When a user does something to your form or one of its controls, it generates an event. Your application reacts to these events by using code, and processes the events when they occur. For more information, see [Creating Event Handlers in Windows Forms](#).

Controls

Windows Forms contains a variety of controls that you can place on forms: controls that display text boxes, buttons, drop-down boxes, radio buttons, and even Web pages. For a list of all the controls you can use on a form, see [Controls to Use on Windows Forms](#). If an existing control does not meet your needs, Windows Forms also supports creating your own custom controls using the [UserControl](#) class.

Windows Forms has rich UI controls that emulate features in high-end applications like Microsoft Office. Using the [ToolStrip](#) and [MenuStrip](#) control, you can create toolbars and menus that contain text and images, display submenus, and host other controls such as text boxes and combo boxes.

With the Visual Studio drag-and-drop forms designer, you can easily create Windows Forms applications: just select the controls with your cursor and place them where you want on the form. The designer provides tools such as grid lines and "snap lines" to take the hassle out of aligning controls. And whether you use Visual Studio or compile at the command line, you can use the [FlowLayoutPanel](#), [TableLayoutPanel](#) and [SplitContainer](#) controls to create advanced form layouts with minimal time and effort.

Custom UI Elements

Finally, if you must create your own custom UI elements, the [System.Drawing](#) namespace contains all of the classes you need to render lines, circles, and other shapes directly on a form.

For step-by-step information about using these features, see the following Help topics.

TO	SEE
Create a new Windows Forms application with Visual Studio	Tutorial 1: Create a picture viewer
Use controls on forms	How to: Add Controls to Windows Forms
Create graphics with System.Drawing	Getting Started with Graphics Programming
Create custom controls	How to: Inherit from the UserControl Class

Displaying and Manipulating Data

Many applications must display data from a database, XML file, XML Web service, or other data source. Windows Forms provides a flexible control called the [DataGridView](#) control for rendering such tabular data in a traditional row and column format, so that every piece of data occupies its own cell. Using [DataGridView](#) you can customize the appearance of individual cells, lock arbitrary rows and columns in place, and display complex controls inside cells, among other features.

Connecting to data sources over a network is a simple task with Windows Forms smart clients. The [BindingSource](#) component, new with Windows Forms in Visual Studio 2005 and the .NET Framework 2.0, represents a connection to a data source, and exposes methods for binding data to controls, navigating to the previous and next records, editing records, and saving changes back to the original source. The [BindingNavigator](#) control provides a simple interface over the [BindingSource](#) component for users to navigate between records.

Data-Bound Controls

You can create data-bound controls easily using the Data Sources window, which displays data sources such as databases, Web services, and objects in your project. You can create data-bound controls by dragging items from this window onto forms in your project. You can also data-bind existing controls to data by dragging objects from the Data Sources window onto existing controls.

Settings

Another type of data binding you can manage in Windows Forms is settings. Most smart-client applications must retain some information about their run-time state, such as the last-known size of forms, and retain user-preference data, such as default locations for saved files. The application-settings feature addresses these requirements by providing an easy way to store both types of settings on the client computer. Once defined using either Visual Studio or a code editor, these settings are persisted as XML and automatically read back into memory at run time.

For step-by-step information about using these features, see the following Help topics.

Deploying Applications to Client Computers

Once you have written your application, you must send it to your users so that they can install and run it on their own client computers. Using the ClickOnce technology, you can deploy your applications from within Visual Studio by using just a few clicks and provide users with a URL pointing to your application on the Web. ClickOnce manages all of the elements and dependencies in your application and ensures that the application is properly installed on the client computer.

ClickOnce applications can be configured to run only when the user is connected to the network, or to run both online and offline. When you specify that an application should support offline operation, ClickOnce adds a link to your application in the user's **Start** menu, so that the user can open it without using the URL.

When you update your application, you publish a new deployment manifest and a new copy of your application to your Web server. ClickOnce detects that there is an update available and upgrades the user's installation; no custom programming is required to update old assemblies.

For a full introduction to ClickOnce, see [ClickOnce Security and Deployment](#). For step-by-step information about using these features, see the following Help topics:

Deploy an application with ClickOnce	How to: Publish a ClickOnce Application using the Publish Wizard Walkthrough: Manually Deploying a ClickOnce Application
Update a ClickOnce deployment	How to: Manage Updates for a ClickOnce Application
Manage security with ClickOnce	How to: Enable ClickOnce Security Settings

Other Controls and Features

There are many other features in Windows Forms that make implementing common tasks fast and easy, such as support for creating dialog boxes, printing, adding Help and documentation, and localizing your application to multiple languages. In addition, Windows Forms relies on the robust security system of the .NET Framework, enabling you to release more secure applications to your customers.

For step-by-step information about using these features, see the following Help topics:

Extending the My Namespace in Visual Basic

3/5/2019 • 8 minutes to read • [Edit Online](#)

The `My` namespace in Visual Basic exposes properties and methods that enable you to easily take advantage of the power of the .NET Framework. The `My` namespace simplifies common programming problems, often reducing a difficult task to a single line of code. Additionally, the `My` namespace is fully extensible so that you can customize the behavior of `My` and add new services to its hierarchy to adapt to specific application needs. This topic discusses both how to customize existing members of the `My` namespace and how to add your own custom classes to the `My` namespace.

Topic Contents

- [Customizing Existing My Namespace Members](#)
- [Adding Members to My Objects](#)
- [Adding Custom Objects to the My Namespace](#)
- [Adding Members to the My Namespace](#)
- [Adding Events to Custom My Objects](#)
- [Design Guidelines](#)
- [Designing Class Libraries for My](#)
- [Packaging and Deploying Extensions](#)

Customizing Existing My Namespace Members

The `My` namespace in Visual Basic exposes frequently used information about your application, your computer, and more. For a complete list of the objects in the `My` namespace, see [My Reference](#). You may have to customize existing members of the `My` namespace so that they better match the needs of your application. Any property of an object in the `My` namespace that is not read-only can be set to a custom value.

For example, assume that you frequently use the `My.User` object to access the current security context for the user running your application. However, your company uses a custom user object to expose additional information and capabilities for users within the company. In this scenario, you can replace the default value of the `My.User.CurrentPrincipal` property with an instance of your own custom principal object, as shown in the following example.

```
My.User.CurrentPrincipal = CustomPrincipal
```

Setting the `CurrentPrincipal` property on the `My.User` object changes the identity under which the application runs. The `My.User` object, in turn, returns information about the newly specified user.

Adding Members to My Objects

The types returned from `My.Application` and `My.Computer` are defined as `Partial` classes. Therefore, you can extend the `My.Application` and `My.Computer` objects by creating a `Partial` class named `MyApplication` or `MyComputer`. The class cannot be a `Private` class. If you specify the class as part of the `My` namespace, you can add properties and methods that will be included with the `My.Application` or `My.Computer` objects.

For example, the following example adds a property named `DnsServerIPAddresses` to the `My.Computer` object.

```
Imports System.Net.NetworkInformation

Namespace My

    Partial Class MyComputer
        Friend ReadOnly Property DnsServerIPAddresses() As IPAddressCollection
            Get
                Dim dnsAddressList As IPAddressCollection = Nothing

                For Each adapter In System.Net.NetworkInformation.
                    NetworkInterface.GetAllNetworkInterfaces()

                        Dim adapterProperties = adapter.GetIPProperties()
                        Dim dnsServers As IPAddressCollection = adapterProperties.DnsAddresses
                        If dnsAddressList Is Nothing Then
                            dnsAddressList = dnsServers
                        Else
                            dnsAddressList.Union(dnsServers)
                        End If
                    Next adapter

                Return dnsAddressList
            End Get
        End Property
    End Class

End Namespace
```

Adding Custom Objects to the My Namespace

Although the `My` namespace provides solutions for many common programming tasks, you may encounter tasks that the `My` namespace does not address. For example, your application might access custom directory services for user data, or your application might use assemblies that are not installed by default with Visual Basic. You can extend the `My` namespace to include custom solutions to common tasks that are specific to your environment. The `My` namespace can easily be extended to add new members to meet growing application needs. Additionally, you can deploy your `My` namespace extensions to other developers as a Visual Basic template.

Adding Members to the My Namespace

Because `My` is a namespace like any other namespace, you can add top-level properties to it by just adding a module and specifying a `Namespace` of `My`. Annotate the module with the `HideModuleName` attribute as shown in the following example. The `HideModuleName` attribute ensures that IntelliSense will not display the module name when it displays the members of the `My` namespace.

```
Namespace My
    <HideModuleName()>
    Module MyCustomModule

    End Module
End Namespace
```

To add members to the `My` namespace, add properties as needed to the module. For each property added to the `My` namespace, add a private field of type `ThreadSafeObjectProvider<of T>`, where the type is the type returned by your custom property. This field is used to create thread-safe object instances to be returned by the property by calling the `GetInstance` method. As a result, each thread that is accessing the extended property receives its own instance of the returned type. The following example adds a property named `SampleExtension` that is of type `SampleExtension` to the `My` namespace:

```
Namespace My
<HideModuleName()>
Module MyCustomExtensions
    Private _extension As New ThreadSafeObjectProvider(Of SampleExtension)
    Friend ReadOnly Property SampleExtension() As SampleExtension
        Get
            Return _extension.GetInstance()
        End Get
    End Property
End Module
End Namespace
```

Adding Events to Custom My Objects

You can use the `My.Application` object to expose events for your custom `My` objects by extending the `MyApplication` partial class in the `My` namespace. For Windows-based projects, you can double-click the **My Project** node in for your project in **Solution Explorer**. In the Visual Basic **Project Designer**, click the `Application` tab and then click the `View Application Events` button. A new file that is named `ApplicationEvents.vb` will be created. It contains the following code for extending the `MyApplication` class.

```
Namespace My
    Partial Friend Class MyApplication
    End Class
End Namespace
```

You can add event handlers for your custom `My` objects by adding custom event handlers to the `MyApplication` class. Custom events enable you to add code that will execute when an event handler is added, removed, or the event is raised. Note that the `AddHandler` code for a custom event runs only if code is added by a user to handle the event. For example, consider that the `SampleExtension` object from the previous section has a `Load` event that you want to add a custom event handler for. The following code example shows a custom event handler named `SampleExtensionLoad` that will be invoked when the `My.SampleExtension.Load` event occurs. When code is added to handle the new `My.SampleExtensionLoad` event, the `AddHandler` part of this custom event code is executed. The `MyApplication_SampleExtensionLoad` method is included in the code example to show an example of an event handler that handles the `My.SampleExtensionLoad` event. Note that the `SampleExtensionLoad` event will be available when you select the **My Application Events** option in the left drop-down list above the Code Editor when you are editing the `ApplicationEvents.vb` file.

```
Namespace My
```

```
Partial Friend Class MyApplication

    ' Custom event handler for Load event.
    Private _sampleExtensionHandlers As EventHandler

    Public Custom Event SampleExtensionLoad As EventHandler
        AddHandler(ByVal value As EventHandler)
            ' Warning: This code is not thread-safe. Do not call
            ' this code from multiple concurrent threads.
            If _sampleExtensionHandlers Is Nothing Then
                AddHandler My.SampleExtension.Load, AddressOf OnSampleExtensionLoad
            End If
            _sampleExtensionHandlers =
                System.Delegate.Combine(_sampleExtensionHandlers, value)
        End AddHandler
        RemoveHandler(ByVal value As EventHandler)
            _sampleExtensionHandlers =
                System.Delegate.Remove(_sampleExtensionHandlers, value)
        End RemoveHandler
        RaiseEvent(ByVal sender As Object, ByVal e As EventArgs)
            If _sampleExtensionHandlers IsNot Nothing Then
                _sampleExtensionHandlers.Invoke(sender, e)
            End If
        End RaiseEvent
    End Event

    ' Method called by custom event handler to raise user-defined
    ' event handlers.
    <Global.System.ComponentModel.EditorBrowsable(
        Global.System.ComponentModel.EditorBrowsableState.Advanced)>
    Protected Overridable Sub OnSampleExtensionLoad(
        ByVal sender As Object, ByVal e As EventArgs)
        RaiseEvent SampleExtensionLoad(sender, e)
    End Sub

    ' Event handler to call My.SampleExtensionLoad event.
    Private Sub MyApplication_SampleExtensionLoad(
        ByVal sender As Object, ByVal e As System.EventArgs
    ) Handles Me.SampleExtensionLoad

    End Sub
End Class
End Namespace
```

Design Guidelines

When you develop extensions to the `My` namespace, use the following guidelines to help minimize the maintenance costs of your extension components.

- **Include only the extension logic.** The logic included in the `My` namespace extension should include only the code that is needed to expose the required functionality in the `My` namespace. Because your extension will reside in user projects as source code, updating the extension component incurs a high maintenance cost and should be avoided if possible.
- **Minimize project assumptions.** When you create your extensions of the `My` namespace, do not assume a set of references, project-level imports, or specific compiler settings (for example, `Option Strict` off). Instead, minimize dependencies and fully qualify all type references by using the `Global` keyword. Also, ensure that the extension compiles with `Option Strict` on to minimize errors in the extension.
- **Isolate the extension code.** Placing the code in a single file makes your extension easily deployable as a

Visual Studio item template. For more information, see "Packaging and Deploying Extensions" later in this topic. Placing all the `My` namespace extension code in a single file or a separate folder in a project will also help users locate the `My` namespace extension.

Designing Class Libraries for My

As is the case with most object models, some design patterns work well in the `My` namespace and others do not. When designing an extension to the `My` namespace, consider the following principles:

- **Stateless methods.** Methods in the `My` namespace should provide a complete solution to a specific task. Ensure that the parameter values that are passed to the method provide all the input required to complete the particular task. Avoid creating methods that rely on prior state, such as open connections to resources.
- **Global instances.** The only state that is maintained in the `My` namespace is global to the project. For example, `My.Application.Info` encapsulates state that is shared throughout the application.
- **Simple parameter types.** Keep things simple by avoiding complex parameter types. Instead, create methods that either take no parameter input or that take simple input types such as strings, primitive types, and so on.
- **Factory methods.** Some types are necessarily difficult to instantiate. Providing factory methods as extensions to the `My` namespace enables you to more easily discover and consume types that fall into this category. An example of a factory method that works well is `My.Computer.FileSystem.OpenTextFileReader`. There are several stream types available in the .NET Framework. By specifying text files specifically, the `OpenTextFileReader` helps the user understand which stream to use.

These guidelines do not preclude general design principles for class libraries. Rather, they are recommendations that are optimized for developers who are using Visual Basic and the `My` namespace. For general design principles for creating class libraries, see [Framework Design Guidelines](#).

Packaging and Deploying Extensions

You can include `My` namespace extensions in a Visual Studio project template, or you can package your extensions and deploy them as a Visual Studio item template. When you package your `My` namespace extensions as a Visual Studio item template, you can take advantage of additional capabilities provided by Visual Basic. These capabilities enable you to include an extension when a project references a particular assembly, or enable users to explicitly add your `My` namespace extension by using the **My Extensions** page of the Visual Basic Project Designer.

For details about how to deploy `My` namespace extensions, see [Packaging and Deploying Custom My Extensions](#).

Package and deploy custom My extensions (Visual Basic)

8/19/2018 • 4 minutes to read • [Edit Online](#)

Visual Basic provides an easy way for you to deploy your custom `My` namespace extensions by using Visual Studio templates. If you are creating a project template for which your `My` extensions are an integral part of the new project type, you can just include your custom `My` extension code with the project when you export the template. For more information about exporting project templates, see [How to: Create Project Templates](#).

If your custom `My` extension is in a single code file, you can export the file as an item template that users can add to any type of Visual Basic project. You can then customize the item template to enable additional capabilities and behavior for your custom `My` extension in a Visual Basic project. Those capabilities include the following:

- Allowing users to manage your custom `My` extension from the **My Extensions** page of the Visual Basic Project Designer.
- Automatically adding your custom `My` extension when a reference to a specified assembly is added to a project.
- Hiding the `My` extension item template in the **Add Item** dialog box so that it is not included in the list of project items.

This topic discusses how to package a custom `My` extension as a hidden item template that can be managed from the **My Extensions** page of the Visual Basic Project Designer. The custom `My` extension can also be added automatically when a reference to a specified assembly is added to a project.

Create a My namespace extension

The first step in creating a deployment package for a custom `My` extension is to create the extension as a single code file. For details and guidance about how to create a custom `My` extension, see [Extending the My Namespace in Visual Basic](#).

Export a My namespace extension as an item template

After you have a code file that includes your `My` namespace extension, you can export the code file as a Visual Studio item template. For instructions on how to export a file as a Visual Studio item template, see [How to: Create Item Templates](#).

NOTE

If your `My` namespace extension has a dependency on a particular assembly, you can customize your item template to automatically install your `My` namespace extension when a reference to that assembly is added. As a result, you will want to exclude that assembly reference when you export the code file as a Visual Studio item template.

Customize the item template

You can enable your item template to be managed from the **My Extensions** page of the Visual Basic Project Designer. You can also enable the item template to be added automatically when a reference to a specified assembly is added to a project. To enable these customizations, you will add a new file, called the `CustomData` file,

to your template, and then add a new element to the XML in your .vstemplate file.

Add the CustomData file

The CustomData file is a text file that has a file name extension of .CustomData (the file name can be set to any value meaningful to your template) and that contains XML. The XML in the CustomData file instructs Visual Basic to include your `My` extension when users use the **My Extensions** page of the Visual Basic Project Designer. You can optionally add the `<AssemblyFullName>` attribute to your CustomData file XML. This instructs Visual Basic to automatically install your custom `My` extension when a reference to a particular assembly is added to the project. You can use any text editor or XML editor to create the CustomData file, and then add it to your item template's compressed folder (.zip file).

For example, the following XML shows the contents of a CustomData file that will add the template item to the My Extensions folder of a Visual Basic project when a reference to the Microsoft.VisualBasic.PowerPacks.Vs.dll assembly is added to the project.

```
<VBMyExtensionTemplate  
ID="Microsoft.VisualBasic.Samples.MyExtensions.MyPrinterInfo"  
Version="1.0.0.0"  
AssemblyFullName="Microsoft.VisualBasic.PowerPacks-vs"  
/>
```

The CustomData file contains a `<VBMyExtensionTemplate>` element that has attributes as listed in the following table.

ATTRIBUTE	DESCRIPTION
<code>ID</code>	Required. A unique identifier for the extension. If the extension that has this ID has already been added to the project, the user will not be prompted to add it again.
<code>Version</code>	Required. A version number for the item template.
<code>AssemblyFullName</code>	Optional. An assembly name. When a reference to this assembly is added to the project, the user will be prompted to add the <code>My</code> extension from this item template.

Add the `<CustomDataSignature>` element to the .vstemplate file

To identify your Visual Studio item template as a `My` namespace extension, you must also modify the .vstemplate file for your item template. You must add a `<CustomDataSignature>` element to the `<TemplateData>` element. The `<CustomDataSignature>` element must contain the text `Microsoft.VisualBasic.MyExtension`, as shown in the following example.

```
<CustomDataSignature>Microsoft.VisualBasic.MyExtension</CustomDataSignature>
```

You cannot modify files in a compressed folder (.zip file) directly. You must copy the .vstemplate file from the compressed folder, modify it, and then replace the .vstemplate file in the compressed folder with your updated copy.

The following example shows the contents of a .vstemplate file that has the `<CustomDataSignature>` element added.

```
<VSTemplate Version="2.0.0" xmlns="http://schemas.microsoft.com/developer/vstemplate/2005" Type="Item">
<TemplateData>
  <DefaultName>MyCustomExtensionModule.vb</DefaultName>
  <Name>MyPrinterInfo</Name>
  <Description>Custom My Extensions Item Template</Description>
  <ProjectType>VisualBasic</ProjectType>
  <SortOrder>10</SortOrder>
  <Icon>_TemplateIcon.ico</Icon>
  <CustomDataSignature>Microsoft.VisualBasic.MyExtension</CustomDataSignature>
</TemplateData>
<TemplateContent>
  <References />
  <ProjectItem SubType="Code"
    TargetFileName="$fileinputname$.vb"
    ReplaceParameters="true"
    >MyCustomExtensionModule.vb</ProjectItem>
</TemplateContent>
</VSTemplate>
```

Install the template

To install the template, you can copy the compressed folder (.zip file) to the Visual Basic item templates folder. By default, user item templates are located in %USERPROFILE%\Documents\Visual Studio <Version>\Templates\ItemTemplates\Visual Basic. Alternatively, you can publish the template as a Visual Studio Installer (.vsi) file.

Extending the Visual Basic Application Model

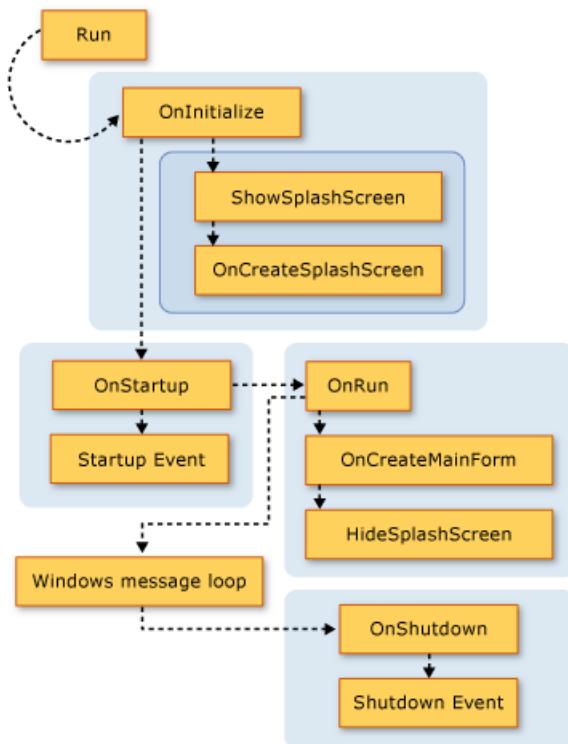

1/23/2019 • 4 minutes to read • [Edit Online](#)

You can add functionality to the application model by overriding the `Overridable` members of the `WindowsFormsApplicationBase` class. This technique allows you to customize the behavior of the application model and add calls to your own methods as the application starts up and shuts down.

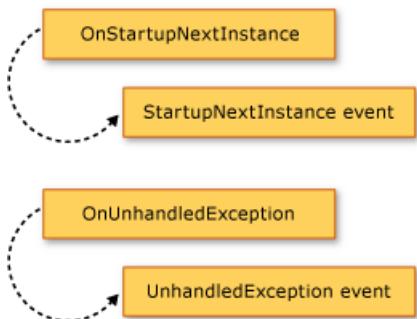

Visual Overview of the Application Model

This section visually presents the sequence of function calls in the Visual Basic Application Model. The next section describes the purpose of each function in detail.

The following graphic shows the application model call sequence in a normal Visual Basic Windows Forms application. The sequence starts when the `Sub Main` procedure calls the `Run` method.

The Visual Basic Application Model also provides the `StartupNextInstance` and `UnhandledException` events. The following graphics show the mechanism for raising these events.

Overriding the Base Methods

The `Run` method defines the order in which the `Application` methods run. By default, the `Sub Main` procedure for

a Windows Forms application calls the [Run](#) method.

If the application is a normal application (multiple-instance application), or the first instance of a single-instance application, the [Run](#) method executes the [Overridable](#) methods in the following order:

1. [OnInitialize](#). By default, this method sets the visual styles, text display styles, and current principal for the main application thread (if the application uses Windows authentication), and calls [ShowSplashScreen](#) if neither `/nosplash` nor `-nosplash` is used as a command-line argument.

The application startup sequence is canceled if this function returns `False`. This can be useful if there are circumstances in which the application should not run.

The [OnInitialize](#) method calls the following methods:

- a. [ShowSplashScreen](#). Determines if the application has a splash screen defined and if it does, displays the splash screen on a separate thread.

The [ShowSplashScreen](#) method contains the code that displays the splash screen for at least the number of milliseconds specified by the [MinimumSplashScreenDisplayTime](#) property. To use this functionality, you must add the splash screen to your application using the **Project Designer** (which sets the `My.Application.MinimumSplashScreenDisplayTime` property to two seconds), or set the `My.Application.MinimumSplashScreenDisplayTime` property in a method that overrides the [OnInitialize](#) or [OnCreateSplashScreen](#) method. For more information, see [MinimumSplashScreenDisplayTime](#).

- b. [OnCreateSplashScreen](#). Allows a designer to emit code that initializes the splash screen.

By default, this method does nothing. If you select a splash screen for your application in the Visual Basic **Project Designer**, the designer overrides the [OnCreateSplashScreen](#) method with a method that sets the [SplashScreen](#) property to a new instance of the splash-screen form.

2. [OnStartup](#). Provides an extensibility point for raising the [Startup](#) event. The application startup sequence stops if this function returns `False`.

By default, this method raises the [Startup](#) event. If the event handler sets the [Cancel](#) property of the event argument to `True`, the method returns `False` to cancel the application startup.

3. [OnRun](#). Provides the starting point for when the main application is ready to start running, after the initialization is done.

By default, before it enters the Windows Forms message loop, this method calls the [OnCreateMainForm](#) (to create the application's main form) and [HideSplashScreen](#) (to close the splash screen) methods:

- a. [OnCreateMainForm](#). Provides a way for a designer to emit code that initializes the main form.

By default, this method does nothing. However, when you select a main form for your application in the Visual Basic **Project Designer**, the designer overrides the [OnCreateMainForm](#) method with a method that sets the [MainForm](#) property to a new instance of the main form.

- b. [HideSplashScreen](#). If application has a splash screen defined and it is open, this method closes the splash screen.

By default, this method closes the splash screen.

4. [OnStartupNextInstance](#). Provides a way to customize how a single-instance application behaves when another instance of the application starts.

By default, this method raises the [StartupNextInstance](#) event.

5. [OnShutdown](#). Provides an extensibility point for raising the [Shutdown](#) event. This method does not run if an unhandled exception occurs in the main application.

By default, this method raises the [Shutdown](#) event.

6. [OnUnhandledException](#). Executed if an unhandled exception occurs in any of the above listed methods.

By default, this method raises the [UnhandledException](#) event as long as a debugger is not attached and the application is handling the [UnhandledException](#) event.

If the application is a single-instance application, and the application is already running, the subsequent instance of the application calls the [OnStartupNextInstance](#) method on the original instance of the application, and then exits.

The [OnStartupNextInstance\(StartupNextInstanceEventArgs\)](#) constructor calls the [UseCompatibleTextRendering](#) property to determine which text rendering engine to use for the application's forms. By default, the [UseCompatibleTextRendering](#) property returns `False`, indicating that the GDI text rendering engine be used, which is the default in Visual Basic 2005. You can override the [UseCompatibleTextRendering](#) property to return `True`, which indicates that the GDI+ text rendering engine be used, which is the default in Visual Basic .NET 2002 and Visual Basic .NET 2003.

Configuring the Application

As a part of the Visual Basic Application model, the [UseCompatibleTextRendering](#) class provides protected properties that configure the application. These properties should be set in the constructor of the implementing class.

In a default Windows Forms project, the **Project Designer** creates code to set the properties with the designer settings. The properties are used only when the application is starting; setting them after the application starts has no effect.

PROPERTY	DETERMINES	SETTING IN THE APPLICATION PANE OF THE PROJECT DESIGNER
IsSingleInstance	Whether the application runs as a single-instance or multiple-instance application.	Make single instance application check box
EnableVisualStyles	If the application will use visual styles that match Windows XP.	Enable XP visual styles check box
SaveMySettingsOnExit	If application automatically saves application's user-settings changes when the application exits.	Save My.Settings on Shutdown check box
ShutdownStyle	What causes the application to terminate, such as when the startup form closes or when the last form closes.	Shutdown mode list

Customizing Which Objects are Available in My (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic describes how you can control which `My` objects are enabled by setting your project's `_MYTYPE` conditional-compilation constant. The Visual Studio Integrated Development Environment (IDE) keeps the `_MYTYPE` conditional-compilation constant for a project in sync with the project's type.

Predefined `_MYTYPE` Values

You must use the `/define` compiler option to set the `_MYTYPE` conditional-compilation constant. When specifying your own value for the `_MYTYPE` constant, you must enclose the string value in backslash/quotation mark (\") sequences. For example, you could use:

```
/define:_MYTYPE=\"WindowsForms\"
```

This table shows what the `_MYTYPE` conditional-compilation constant is set to for several project types.

PROJECT TYPE	_MYTYPE VALUE
Class Library	"Windows"
Console Application	"Console"
Web	"Web"
Web Control Library	"WebControl"
Windows Application	"WindowsForms"
Windows Application, when starting with custom <code>Sub Main</code>	"WindowsFormsWithCustomSubMain"
Windows Control Library	"Windows"
Windows Service	"Console"
Empty	"Empty"

NOTE

All conditional-compilation string comparisons are case-sensitive, regardless of how the `Option Compare` statement is set.

Dependent `_MY` Compilation Constants

The `_MYTYPE` conditional-compilation constant, in turn, controls the values of several other `_MY` compilation constants:

<code>_MYTYPE</code>	<code>_MYAPPLICATIONTYPE</code>	<code>_MYCOMPUTERTYPE</code>	<code>_MYFORMS</code>	<code>_MYUSERTYPE</code>	<code>_MYWEBSERVICES</code>
"Console"	"Console"	"Windows"	Undefined	"Windows"	TRUE
"Custom"	Undefined	Undefined	Undefined	Undefined	Undefined
"Empty"	Undefined	Undefined	Undefined	Undefined	Undefined
"Web"	Undefined	"Web"	FALSE	"Web"	FALSE
"WebControl"	Undefined	"Web"	FALSE	"Web"	TRUE
"Windows" or ""	"Windows"	"Windows"	Undefined	"Windows"	TRUE
"WindowsForms"	"WindowsForms"	"Windows"	TRUE	"Windows"	TRUE
"WindowsForms WithCustomSub Main"	"Console"	"Windows"	TRUE	"Windows"	TRUE

By default, undefined conditional-compilation constants resolve to `FALSE`. You can specify values for the undefined constants when compiling your project to override the default behavior.

NOTE

When `_MYTYPE` is set to "Custom", the project contains the `My` namespace, but it contains no objects. However, setting `_MYTYPE` to "Empty" prevents the compiler from adding the `My` namespace and its objects.

This table describes the effects of the predefined values of the `_MY` compilation constants.

CONSTANT	MEANING
<code>_MYAPPLICATIONTYPE</code>	<p>Enables <code>My.Application</code>, if the constant is "Console," "Windows," or "WindowsForms":</p> <ul style="list-style-type: none"> - The "Console" version derives from <code>ConsoleApplicationBase</code>, and has fewer members than the "Windows" version. - The "Windows" version derives from <code>ApplicationBase</code>, and has fewer members than the "WindowsForms" version. - The "WindowsForms" version of <code>My.Application</code> derives from <code>WindowsFormsApplicationBase</code>. If the <code>TARGET</code> constant is defined to be "winexe", then the class includes a <code>Sub Main</code> method.
<code>_MYCOMPUTERTYPE</code>	<p>Enables <code>My.Computer</code>, if the constant is "Web" or "Windows":</p> <ul style="list-style-type: none"> - The "Web" version derives from <code>ServerComputer</code>, and has fewer members than the "Windows" version. - The "Windows" version of <code>My.Computer</code> derives from <code>Computer</code>.
<code>_MYFORMS</code>	Enables <code>My.Forms</code> , if the constant is <code>TRUE</code> .

CONSTANT	MEANING
_MYUSERTYPE	Enables <code>My.User</code> , if the constant is "Web" or "Windows": - The "Web" version of <code>My.User</code> is associated with the user identity of the current HTTP request. - The "Windows" version of <code>My.User</code> is associated with the thread's current principal.
_MYWEBSERVICES	Enables <code>My.WebServices</code> , if the constant is <code>TRUE</code> .
_MYTYPE	Enables <code>My.Log</code> , <code>My.Request</code> , and <code>My.Response</code> , if the constant is "Web".

Programming Concepts (Visual Basic)

3/8/2019 • 2 minutes to read • [Edit Online](#)

This section explains programming concepts in the Visual Basic language.

In this section

TITLE	DESCRIPTION
Asynchronous Programming with Async and Await (Visual Basic)	Describes how to write asynchronous solutions by using <code>Async</code> and <code>Await</code> keywords. Includes a walkthrough.
Attributes overview (Visual Basic)	Discusses how to provide additional information about programming elements such as types, fields, methods, and properties by using attributes.
Caller Information (Visual Basic)	Describes how to obtain information about the caller of a method. This information includes the file path and the line number of the source code and the member name of the caller.
Collections (Visual Basic)	Describes some of the types of collections provided by the .NET Framework. Demonstrates how to use simple collections and collections of key/value pairs.
Covariance and Contravariance (Visual Basic)	Shows how to enable implicit conversion of generic type parameters in interfaces and delegates.
Expression Trees (Visual Basic)	Explains how you can use expression trees to enable dynamic modification of executable code.
Iterators (Visual Basic)	Describes iterators, which are used to step through collections and return elements one at a time.
Language-Integrated Query (LINQ) (Visual Basic)	Discusses the powerful query capabilities in the language syntax of Visual Basic, and the model for querying relational databases, XML documents, datasets, and in-memory collections.
Object-Oriented Programming (Visual Basic)	Describes common object-oriented concepts, including encapsulation, inheritance, and polymorphism.
Reflection (Visual Basic)	Explains how to use reflection to dynamically create an instance of a type, bind the type to an existing object, or get the type from an existing object and invoke its methods or access its fields and properties.
Serialization (Visual Basic)	Describes key concepts in binary, XML, and SOAP serialization.

Performance Tips	Discusses several basic rules that may help you increase the performance of your application.

Asynchronous Programming with Async and Await (Visual Basic)

3/16/2019 • 16 minutes to read • [Edit Online](#)

You can avoid performance bottlenecks and enhance the overall responsiveness of your application by using asynchronous programming. However, traditional techniques for writing asynchronous applications can be complicated, making them difficult to write, debug, and maintain.

Visual Studio 2012 introduced a simplified approach, `async` programming, that leverages asynchronous support in the .NET Framework 4.5 and higher as well as in the Windows Runtime. The compiler does the difficult work that the developer used to do, and your application retains a logical structure that resembles synchronous code. As a result, you get all the advantages of asynchronous programming with a fraction of the effort.

This topic provides an overview of when and how to use `async` programming and includes links to support topics that contain details and examples.

Async Improves Responsiveness

Asynchrony is essential for activities that are potentially blocking, such as when your application accesses the web. Access to a web resource sometimes is slow or delayed. If such an activity is blocked within a synchronous process, the entire application must wait. In an asynchronous process, the application can continue with other work that doesn't depend on the web resource until the potentially blocking task finishes.

The following table shows typical areas where asynchronous programming improves responsiveness. The listed APIs from the .NET Framework 4.5 and the Windows Runtime contain methods that support `async` programming.

APPLICATION AREA	SUPPORTING APIs THAT CONTAIN ASYNC METHODS
Web access	HttpClient , SyndicationClient
Working with files	StorageFile , StreamWriter , StreamReader , XmlReader
Working with images	MediaCapture , BitmapEncoder , BitmapDecoder
WCF programming	Synchronous and Asynchronous Operations

Asynchrony proves especially valuable for applications that access the UI thread because all UI-related activity usually shares one thread. If any process is blocked in a synchronous application, all are blocked. Your application stops responding, and you might conclude that it has failed when instead it's just waiting.

When you use asynchronous methods, the application continues to respond to the UI. You can resize or minimize a window, for example, or you can close the application if you don't want to wait for it to finish.

The `async`-based approach adds the equivalent of an automatic transmission to the list of options that you can choose from when designing asynchronous operations. That is, you get all the benefits of traditional asynchronous programming but with much less effort from the developer.

Async Methods Are Easier to Write

The `Async` and `Await` keywords in Visual Basic are the heart of async programming. By using those two keywords, you can use resources in the .NET Framework or the Windows Runtime to create an asynchronous method almost as easily as you create a synchronous method. Asynchronous methods that you define by using `Async` and `Await` are referred to as `async` methods.

The following example shows an `async` method. Almost everything in the code should look completely familiar to you. The comments call out the features that you add to create the `asynchrony`.

You can find a complete Windows Presentation Foundation (WPF) example file at the end of this topic, and you can download the sample from [Async Sample: Example from "Asynchronous Programming with Async and Await"](#).

```
' Three things to note in the signature:  
' - The method has an Async modifier.  
' - The return type is Task or Task(Of T). (See "Return Types" section.)  
' - Here, it is Task(Of Integer) because the return statement returns an integer.  
' - The method name ends in "Async."  
Async Function AccessTheWebAsync() As Task(Of Integer)  
  
    ' You need to add a reference to System.Net.Http to declare client.  
    Dim client As HttpClient = New HttpClient()  
  
    ' GetStringAsync returns a Task(Of String). That means that when you await the  
    ' task you'll get a string (urlContents).  
    Dim getStringTask As Task(Of String) = client.GetStringAsync("https://msdn.microsoft.com")  
  
    ' You can do work here that doesn't rely on the string from GetStringAsync.  
    DoIndependentWork()  
  
    ' The Await operator suspends AccessTheWebAsync.  
    ' - AccessTheWebAsync can't continue until getStringTask is complete.  
    ' - Meanwhile, control returns to the caller of AccessTheWebAsync.  
    ' - Control resumes here when getStringTask is complete.  
    ' - The Await operator then retrieves the string result from getStringTask.  
    Dim urlContents As String = Await getStringTask  
  
    ' The return statement specifies an integer result.  
    ' Any methods that are awaiting AccessTheWebAsync retrieve the length value.  
    Return urlContents.Length  
End Function
```

If `AccessTheWebAsync` doesn't have any work that it can do between calling `GetStringAsync` and awaiting its completion, you can simplify your code by calling and awaiting in the following single statement.

```
Dim urlContents As String = Await client.GetStringAsync()
```

The following characteristics summarize what makes the previous example an `async` method.

- The method signature includes an `Async` modifier.
- The name of an `async` method, by convention, ends with an "Async" suffix.
- The return type is one of the following types:
 - `Task<TResult>` if your method has a return statement in which the operand has type `TResult`.
 - `Task` if your method has no return statement or has a return statement with no operand.
 - `Sub` if you're writing an `async` event handler.

For more information, see "Return Types and Parameters" later in this topic.

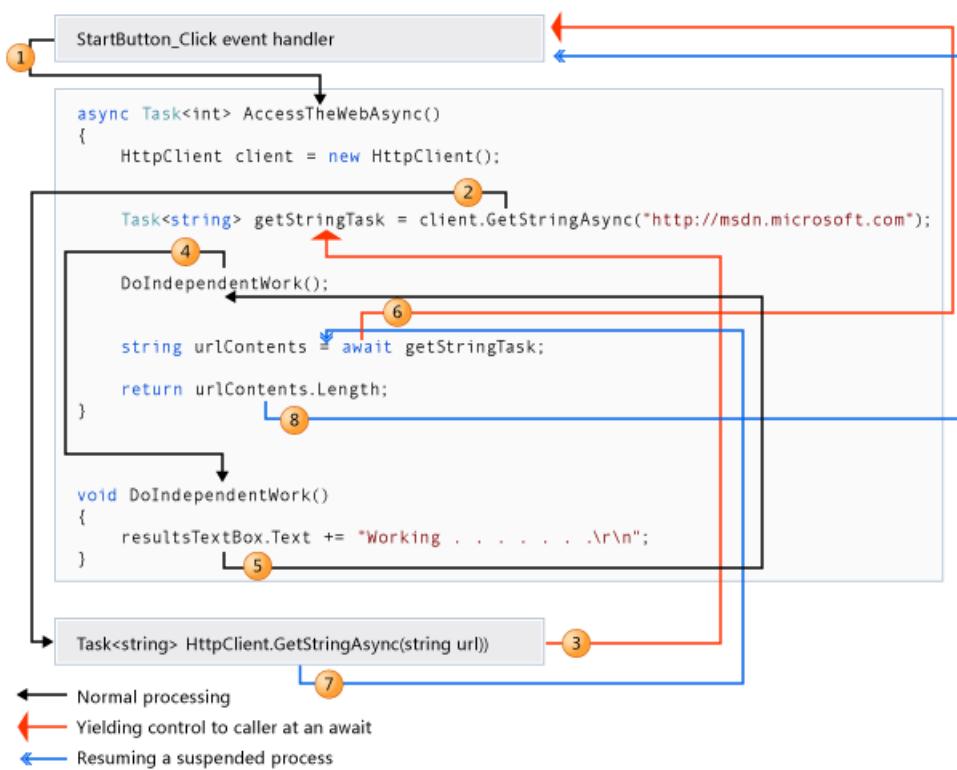

- The method usually includes at least one await expression, which marks a point where the method can't continue until the awaited asynchronous operation is complete. In the meantime, the method is suspended, and control returns to the method's caller. The next section of this topic illustrates what happens at the suspension point.

In async methods, you use the provided keywords and types to indicate what you want to do, and the compiler does the rest, including keeping track of what must happen when control returns to an await point in a suspended method. Some routine processes, such as loops and exception handling, can be difficult to handle in traditional asynchronous code. In an async method, you write these elements much as you would in a synchronous solution, and the problem is solved.

For more information about asynchrony in previous versions of the .NET Framework, see [TPL and Traditional .NET Framework Asynchronous Programming](#).

What Happens in an Async Method

The most important thing to understand in asynchronous programming is how the control flow moves from method to method. The following diagram leads you through the process.

The numbers in the diagram correspond to the following steps.

- An event handler calls and awaits the `AccessTheWebAsync` async method.
- `AccessTheWebAsync` creates an `HttpClient` instance and calls the `GetStringAsync` asynchronous method to download the contents of a website as a string.
- Something happens in `GetStringAsync` that suspends its progress. Perhaps it must wait for a website to download or some other blocking activity. To avoid blocking resources, `GetStringAsync` yields control to its caller, `AccessTheWebAsync`.

`GetStringAsync` returns a `Task<TResult>` where `TResult` is a string, and `AccessTheWebAsync` assigns the task to the `getStringTask` variable. The task represents the ongoing process for the call to `GetStringAsync`, with a commitment to produce an actual string value when the work is complete.

4. Because `getStringTask` hasn't been awaited yet, `AccessTheWebAsync` can continue with other work that doesn't depend on the final result from `GetStringAsync`. That work is represented by a call to the synchronous method `DoIndependentWork`.
5. `DoIndependentWork` is a synchronous method that does its work and returns to its caller.
6. `AccessTheWebAsync` has run out of work that it can do without a result from `getStringTask`. `AccessTheWebAsync` next wants to calculate and return the length of the downloaded string, but the method can't calculate that value until the method has the string.

Therefore, `AccessTheWebAsync` uses an await operator to suspend its progress and to yield control to the method that called `AccessTheWebAsync`. `AccessTheWebAsync` returns a `Task<int>` (`Task(Of Integer)` in Visual Basic) to the caller. The task represents a promise to produce an integer result that's the length of the downloaded string.

NOTE

If `GetStringAsync` (and therefore `getStringTask`) is complete before `AccessTheWebAsync` awaits it, control remains in `AccessTheWebAsync`. The expense of suspending and then returning to `AccessTheWebAsync` would be wasted if the called asynchronous process (`getStringTask`) has already completed and `AccessTheWebSync` doesn't have to wait for the final result.

- Inside the caller (the event handler in this example), the processing pattern continues. The caller might do other work that doesn't depend on the result from `AccessTheWebAsync` before awaiting that result, or the caller might await immediately. The event handler is waiting for `AccessTheWebAsync`, and `AccessTheWebAsync` is waiting for `GetStringAsync`.
7. `GetStringAsync` completes and produces a string result. The string result isn't returned by the call to `GetStringAsync` in the way that you might expect. (Remember that the method already returned a task in step 3.) Instead, the string result is stored in the task that represents the completion of the method, `getStringTask`. The await operator retrieves the result from `getStringTask`. The assignment statement assigns the retrieved result to `urlContents`.

8. When `AccessTheWebAsync` has the string result, the method can calculate the length of the string. Then the work of `AccessTheWebAsync` is also complete, and the waiting event handler can resume. In the full example at the end of the topic, you can confirm that the event handler retrieves and prints the value of the length result.

If you are new to asynchronous programming, take a minute to consider the difference between synchronous and asynchronous behavior. A synchronous method returns when its work is complete (step 5), but an async method returns a task value when its work is suspended (steps 3 and 6). When the async method eventually completes its work, the task is marked as completed and the result, if any, is stored in the task.

For more information about control flow, see [Control Flow in Async Programs \(Visual Basic\)](#).

API Async Methods

You might be wondering where to find methods such as `GetStringAsync` that support async programming. The .NET Framework 4.5 or higher contains many members that work with `Async` and `Await`. You can recognize these members by the "Async" suffix that's attached to the member name and a return type of `Task` or `Task<TResult>`. For example, the `System.IO.Stream` class contains methods such as `CopyToAsync`, `ReadAsync`, and `WriteAsync` alongside the synchronous methods `CopyTo`, `Read`, and `Write`.

The Windows Runtime also contains many methods that you can use with `Async` and `Await` in Windows apps. For more information and example methods, see [Call asynchronous APIs in C# or Visual Basic, Asynchronous](#)

programming (Windows Runtime apps), and [WhenAny: Bridging between the .NET Framework and the Windows Runtime](#).

Threads

Async methods are intended to be non-blocking operations. An `Await` expression in an async method doesn't block the current thread while the awaited task is running. Instead, the expression signs up the rest of the method as a continuation and returns control to the caller of the async method.

The `Async` and `Await` keywords don't cause additional threads to be created. Async methods don't require multithreading because an async method doesn't run on its own thread. The method runs on the current synchronization context and uses time on the thread only when the method is active. You can use `Task.Run` to move CPU-bound work to a background thread, but a background thread doesn't help with a process that's just waiting for results to become available.

The async-based approach to asynchronous programming is preferable to existing approaches in almost every case. In particular, this approach is better than `BackgroundWorker` for I/O-bound operations because the code is simpler and you don't have to guard against race conditions. In combination with `Task.Run`, async programming is better than `BackgroundWorker` for CPU-bound operations because async programming separates the coordination details of running your code from the work that `Task.Run` transfers to the threadpool.

Async and Await

If you specify that a method is an async method by using an `Async` modifier, you enable the following two capabilities.

- The marked async method can use `Await` to designate suspension points. The await operator tells the compiler that the async method can't continue past that point until the awaited asynchronous process is complete. In the meantime, control returns to the caller of the async method.

The suspension of an async method at an `Await` expression doesn't constitute an exit from the method, and `Finally` blocks don't run.

- The marked async method can itself be awaited by methods that call it.

An async method typically contains one or more occurrences of an `Await` operator, but the absence of `Await` expressions doesn't cause a compiler error. If an async method doesn't use an `Await` operator to mark a suspension point, the method executes as a synchronous method does, despite the `Async` modifier. The compiler issues a warning for such methods.

`Async` and `Await` are contextual keywords. For more information and examples, see the following topics:

- [Async](#)
- [Await Operator](#)

Return Types and Parameters

In .NET Framework programming, an async method typically returns a `Task` or a `Task<TResult>`. Inside an async method, an `Await` operator is applied to a task that's returned from a call to another async method.

You specify `Task<TResult>` as the return type if the method contains a `Return` statement that specifies an operand of type `TResult`.

You use `Task` as the return type if the method has no return statement or has a return statement that doesn't return an operand.

The following example shows how you declare and call a method that returns a `Task<TResult>` or a `Task`.

```
' Signature specifies Task(Of Integer)
Async Function TaskOfTResult_MethodAsync() As Task(Of Integer)

    Dim hours As Integer
    ' ...
    ' Return statement specifies an integer result.
    Return hours
End Function

' Calls to TaskOfTResult_MethodAsync
Dim returnedTaskTResult As Task(Of Integer) = TaskOfTResult_MethodAsync()
Dim intResult As Integer = Await returnedTaskTResult
' or, in a single statement
Dim intResult As Integer = Await TaskOfTResult_MethodAsync()

' Signature specifies Task
Async Function Task_MethodAsync() As Task

    ' ...
    ' The method has no return statement.
End Function

' Calls to Task_MethodAsync
Task returnedTask = Task_MethodAsync()
Await returnedTask
' or, in a single statement
Await Task_MethodAsync()
```

Each returned task represents ongoing work. A task encapsulates information about the state of the asynchronous process and, eventually, either the final result from the process or the exception that the process raises if it doesn't succeed.

An `async` method can also be a `Sub` method. This return type is used primarily to define event handlers, where a return type is required. `Async` event handlers often serve as the starting point for `async` programs.

An `async` method that's a `Sub` procedure can't be awaited, and the caller can't catch any exceptions that the method throws.

An `async` method can't declare `ByRef` parameters, but the method can call methods that have such parameters.

For more information and examples, see [Async Return Types \(Visual Basic\)](#). For more information about how to catch exceptions in `async` methods, see [Try...Catch...Finally Statement](#).

Asynchronous APIs in Windows Runtime programming have one of the following return types, which are similar to tasks:

- `IAsyncOperation<TResult>`, which corresponds to `Task<TResult>`
- `IAsyncAction`, which corresponds to `Task`
- `IAsyncActionWithProgress<TProgress>`
- `IAsyncOperationWithProgress<TResult, TProgress>`

For more information and an example, see [Call asynchronous APIs in C# or Visual Basic](#).

Naming Convention

By convention, you append "Async" to the names of methods that have an `Async` modifier.

You can ignore the convention where an event, base class, or interface contract suggests a different name. For

example, you shouldn't rename common event handlers, such as `Button1_Click`.

Complete Example

The following code is the `MainWindow.xaml.vb` file from the Windows Presentation Foundation (WPF) application that this topic discusses. You can download the sample from [Async Sample: Example from "Asynchronous Programming with Async and Await"](#).

```

' Add an Imports statement and a reference for System.Net.Http
Imports System.Net.Http

Class MainWindow

    ' Mark the event handler with async so you can use Await in it.
    Private Async Sub StartButton_Click(sender As Object, e As RoutedEventArgs)

        ' Call and await separately.
        'Task<int> getLengthTask = AccessTheWebAsync();
        '' You can do independent work here.
        'int contentLength = await getLengthTask;

        Dim contentLength As Integer = Await AccessTheWebAsync()

        ResultsTextBox.Text &=
            String.Format(vbCrLf & "Length of the downloaded string: {0}." & vbCrLf, contentLength)
    End Sub

    ' Three things to note in the signature:
    ' - The method has an Async modifier.
    ' - The return type is Task or Task(Of T). (See "Return Types" section.)
    ' - Here, it is Task(Of Integer) because the return statement returns an integer.
    ' - The method name ends in "Async."
    Async Function AccessTheWebAsync() As Task(Of Integer)

        ' You need to add a reference to System.Net.Http to declare client.
        Dim client As HttpClient = New HttpClient()

        ' GetStringAsync returns a Task(Of String). That means that when you await the
        ' task you'll get a string (urlContents).
        Dim getStringTask As Task(Of String) = client.GetStringAsync("https://msdn.microsoft.com")

        ' You can do work here that doesn't rely on the string from GetStringAsync.
        DoIndependentWork()

        ' The Await operator suspends AccessTheWebAsync.
        ' - AccessTheWebAsync can't continue until getStringTask is complete.
        ' - Meanwhile, control returns to the caller of AccessTheWebAsync.
        ' - Control resumes here when getStringTask is complete.
        ' - The Await operator then retrieves the string result from getStringTask.
        Dim urlContents As String = Await getStringTask

        ' The return statement specifies an integer result.
        ' Any methods that are awaiting AccessTheWebAsync retrieve the length value.
        Return urlContents.Length
    End Function

    Sub DoIndependentWork()
        ResultsTextBox.Text &= "Working . . . . ."
    End Sub
End Class

' Sample Output:

' Working . . . . .

' Length of the downloaded string: 41763.

Attributes overview (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

Attributes provide a powerful method of associating metadata, or declarative information, with code (assemblies, types, methods, properties, and so forth). After an attribute is associated with a program entity, the attribute can be queried at run time by using a technique called *reflection*. For more information, see [Reflection \(Visual Basic\)](#).

Attributes have the following properties:

- Attributes add metadata to your program. *Metadata* is information about the types defined in a program. All .NET assemblies contain a specified set of metadata that describes the types and type members defined in the assembly. You can add custom attributes to specify any additional information that is required. For more information, see [Creating Custom Attributes \(Visual Basic\)](#).
- You can apply one or more attributes to entire assemblies, modules, or smaller program elements such as classes and properties.
- Attributes can accept arguments in the same way as methods and properties.
- Your program can examine its own metadata or the metadata in other programs by using reflection. For more information, see [Accessing Attributes by Using Reflection \(Visual Basic\)](#).

Using Attributes

Attributes can be placed on most any declaration, though a specific attribute might restrict the types of declarations on which it is valid. In Visual Basic, an attribute is enclosed in angle brackets (< >). It must appear immediately before the element to which it is applied, on the same line.

In this example, the [SerializableAttribute](#) attribute is used to apply a specific characteristic to a class:

```
<System.Serializable()> Public Class SampleClass  
    ' Objects of this type can be serialized.  
End Class
```

A method with the attribute [DllImportAttribute](#) is declared like this:

```
Imports System.Runtime.InteropServices  
  
<System.Runtime.InteropServicesDllImport("user32.dll")>  
Sub SampleMethod()  
End Sub
```

More than one attribute can be placed on a declaration:

```
Imports System.Runtime.InteropServices
```

```
Sub MethodA(<[In](), Out()> ByVal x As Double)
End Sub
Sub MethodB(<Out(), [In]()> ByVal x As Double)
End Sub
```

Some attributes can be specified more than once for a given entity. An example of such a multiuse attribute is [ConditionalAttribute](#):

```
<Conditional("DEBUG"), Conditional("TEST1")>
Sub TraceMethod()
End Sub
```

NOTE

By convention, all attribute names end with the word "Attribute" to distinguish them from other items in the .NET Framework. However, you do not need to specify the attribute suffix when using attributes in code. For example, `[DllImport]` is equivalent to `[DllImportAttribute]`, but `DllImportAttribute` is the attribute's actual name in the .NET Framework.

Attribute Parameters

Many attributes have parameters, which can be positional, unnamed, or named. Any positional parameters must be specified in a certain order and cannot be omitted; named parameters are optional and can be specified in any order. Positional parameters are specified first. For example, these three attributes are equivalent:

```
<DllImport("user32.dll")>
<DllImport("user32.dll", SetLastError:=False, ExactSpelling:=False)>
<DllImport("user32.dll", ExactSpelling:=False, SetLastError:=False)>
```

The first parameter, the DLL name, is positional and always comes first; the others are named. In this case, both named parameters default to false, so they can be omitted. Refer to the individual attribute's documentation for information on default parameter values.

Attribute Targets

The *target* of an attribute is the entity to which the attribute applies. For example, an attribute may apply to a class, a particular method, or an entire assembly. By default, an attribute applies to the element that it precedes. But you can also explicitly identify, for example, whether an attribute is applied to a method, or to its parameter, or to its return value.

To explicitly identify an attribute target, use the following syntax:

```
<target : attribute-list>
```

The list of possible `target` values is shown in the following table.

TARGET VALUE	APPLIES TO
<code>assembly</code>	Entire assembly
<code>module</code>	Current assembly module (which is different from a Visual Basic Module)

The following example shows how to apply attributes to assemblies and modules. For more information, see

Common Attributes (Visual Basic).

```
Imports System.Reflection  
<Assembly: AssemblyTitleAttribute("Production assembly 4"),  
Module: CLSCompliant(True)>
```

Common Uses for Attributes

The following list includes a few of the common uses of attributes in code:

- Marking methods using the `WebMethod` attribute in Web services to indicate that the method should be callable over the SOAP protocol. For more information, see [WebMethodAttribute](#).
- Describing how to marshal method parameters when interoperating with native code. For more information, see [MarshalAsAttribute](#).
- Describing the COM properties for classes, methods, and interfaces.
- Calling unmanaged code using the `DllImportAttribute` class.
- Describing your assembly in terms of title, version, description, or trademark.
- Describing which members of a class to serialize for persistence.
- Describing how to map between class members and XML nodes for XML serialization.
- Describing the security requirements for methods.
- Specifying characteristics used to enforce security.
- Controlling optimizations by the just-in-time (JIT) compiler so the code remains easy to debug.
- Obtaining information about the caller to a method.

Caller Information (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

By using Caller Info attributes, you can obtain information about the caller to a method. You can obtain file path of the source code, the line number in the source code, and the member name of the caller. This information is helpful for tracing, debugging, and creating diagnostic tools.

To obtain this information, you use attributes that are applied to optional parameters, each of which has a default value. The following table lists the Caller Info attributes that are defined in the [System.Runtime.CompilerServices](#) namespace:

ATTRIBUTE	DESCRIPTION	TYPE
CallerFilePathAttribute	Full path of the source file that contains the caller. This is the file path at compile time.	String
CallerLineNumberAttribute	Line number in the source file at which the method is called.	Integer
CallerMemberNameAttribute	Method or property name of the caller. See Member Names later in this topic.	String

Example

The following example shows how to use Caller Info attributes. On each call to the `TraceMessage` method, the caller information is substituted as arguments to the optional parameters.

```
Private Sub DoProcessing()
    TraceMessage("Something happened.")
End Sub

Public Sub TraceMessage(message As String,
    <System.Runtime.CompilerServices.CallerMemberName> Optional memberName As String = Nothing,
    <System.Runtime.CompilerServices.CallerFilePath> Optional sourcefilePath As String = Nothing,
    <System.Runtime.CompilerServices.CallerLineNumber()> Optional sourceLineNumber As Integer = 0)

    System.Diagnostics.Trace.WriteLine("message: " & message)
    System.Diagnostics.Trace.WriteLine("member name: " & memberName)
    System.Diagnostics.Trace.WriteLine("source file path: " & sourcefilePath)
    System.Diagnostics.Trace.WriteLine("source line number: " & sourceLineNumber)
End Sub

' Sample output:
'   message: Something happened.
'   member name: DoProcessing
'   source file path: C:\Users\username\Documents\Visual Studio
'   source line number: 15
```

Remarks

You must specify an explicit default value for each optional parameter. You can't apply Caller Info attributes to parameters that aren't specified as optional.

The Caller Info attributes don't make a parameter optional. Instead, they affect the default value that's passed in when the argument is omitted.

Caller Info values are emitted as literals into the Intermediate Language (IL) at compile time. Unlike the results of the [StackTrace](#) property for exceptions, the results aren't affected by obfuscation.

You can explicitly supply the optional arguments to control the caller information or to hide caller information.

Member Names

You can use the `CallerMemberName` attribute to avoid specifying the member name as a `String` argument to the called method. By using this technique, you avoid the problem that **Rename Refactoring** doesn't change the `String` values. This benefit is especially useful for the following tasks:

- Using tracing and diagnostic routines.
- Implementing the [INotifyPropertyChanged](#) interface when binding data. This interface allows the property of an object to notify a bound control that the property has changed, so that the control can display the updated information. Without the `CallerMemberName` attribute, you must specify the property name as a literal.

The following chart shows the member names that are returned when you use the `CallerMemberName` attribute.

CALLS OCCURS WITHIN	MEMBER NAME RESULT
Method, property, or event	The name of the method, property, or event from which the call originated.
Constructor	The string ".ctor"
Static constructor	The string ".cctor"
Destructor	The string "Finalize"
User-defined operators or conversions	The generated name for the member, for example, "op_Addition".
Attribute constructor	The name of the member to which the attribute is applied. If the attribute is any element within a member (such as a parameter, a return value, or a generic type parameter), this result is the name of the member that's associated with that element.
No containing member (for example, assembly-level or attributes that are applied to types)	The default value of the optional parameter.

Collections (Visual Basic)

3/5/2019 • 14 minutes to read • [Edit Online](#)

For many applications, you want to create and manage groups of related objects. There are two ways to group objects: by creating arrays of objects, and by creating collections of objects.

Arrays are most useful for creating and working with a fixed number of strongly-typed objects. For information about arrays, see [Arrays](#).

Collections provide a more flexible way to work with groups of objects. Unlike arrays, the group of objects you work with can grow and shrink dynamically as the needs of the application change. For some collections, you can assign a key to any object that you put into the collection so that you can quickly retrieve the object by using the key.

A collection is a class, so you must declare an instance of the class before you can add elements to that collection.

If your collection contains elements of only one data type, you can use one of the classes in the [System.Collections.Generic](#) namespace. A generic collection enforces type safety so that no other data type can be added to it. When you retrieve an element from a generic collection, you do not have to determine its data type or convert it.

NOTE

For the examples in this topic, include [Imports](#) statements for the `System.Collections.Generic` and `System.Linq` namespaces.

In this topic

- [Using a Simple Collection](#)
- [Kinds of Collections](#)
 - [System.Collections.Generic Classes](#)
 - [System.Collections.Concurrent Classes](#)
 - [System.Collections Classes](#)
 - [Visual Basic Collection Class](#)
- [Implementing a Collection of Key/Value Pairs](#)
- [Using LINQ to Access a Collection](#)
- [Sorting a Collection](#)
- [Defining a Custom Collection](#)
- [Iterators](#)

Using a Simple Collection

The examples in this section use the generic `List<T>` class, which enables you to work with a strongly typed list of objects.

The following example creates a list of strings and then iterates through the strings by using a [For Each...Next](#) statement.

```
' Create a list of strings.  
Dim salmons As New List(Of String)  
salmons.Add("chinook")  
salmons.Add("coho")  
salmons.Add("pink")  
salmons.Add("sockeye")  
  
' Iterate through the list.  
For Each salmon As String In salmons  
    Console.WriteLine(salmon & " ")  
Next  
'Output: chinook coho pink sockeye
```

If the contents of a collection are known in advance, you can use a *collection initializer* to initialize the collection. For more information, see [Collection Initializers](#).

The following example is the same as the previous example, except a collection initializer is used to add elements to the collection.

```
' Create a list of strings by using a  
' collection initializer.  
Dim salmons As New List(Of String) From  
    {"chinook", "coho", "pink", "sockeye"}  
  
For Each salmon As String In salmons  
    Console.WriteLine(salmon & " ")  
Next  
'Output: chinook coho pink sockeye
```

You can use a [For...Next](#) statement instead of a [For Each](#) statement to iterate through a collection. You accomplish this by accessing the collection elements by the index position. The index of the elements starts at 0 and ends at the element count minus 1.

The following example iterates through the elements of a collection by using [For...Next](#) instead of [For Each](#).

```
Dim salmons As New List(Of String) From  
    {"chinook", "coho", "pink", "sockeye"}  
  
For index = 0 To salmons.Count - 1  
    Console.WriteLine(salmons(index) & " ")  
Next  
'Output: chinook coho pink sockeye
```

The following example removes an element from the collection by specifying the object to remove.

```

' Create a list of strings by using a
' collection initializer.
Dim salmons As New List(Of String) From
 {"chinook", "coho", "pink", "sockeye"}

' Remove an element in the list by specifying
' the object.
salmons.Remove("coho")

For Each salmon As String In salmons
    Console.WriteLine(salmon & " ")
Next
'Output: chinook pink sockeye

```

The following example removes elements from a generic list. Instead of a `For Each` statement, a `For...Next` statement that iterates in descending order is used. This is because the `RemoveAt` method causes elements after a removed element to have a lower index value.

```

Dim numbers As New List(Of Integer) From
 {0, 1, 2, 3, 4, 5, 6, 7, 8, 9}

' Remove odd numbers.
For index As Integer = numbers.Count - 1 To 0 Step -1
    If numbers(index) Mod 2 = 1 Then
        ' Remove the element by specifying
        ' the zero-based index in the list.
        numbers.RemoveAt(index)
    End If
Next

' Iterate through the list.
' A lambda expression is placed in the ForEach method
' of the List(T) object.
numbers.ForEach(
    Sub(number) Console.WriteLine(number & " "))
' Output: 0 2 4 6 8

```

For the type of elements in the `List<T>`, you can also define your own class. In the following example, the `Galaxy` class that is used by the `List<T>` is defined in the code.

```

Private Sub IterateThroughList()
    Dim theGalaxies As New List(Of Galaxy) From
    {
        New Galaxy With {.Name = "Tadpole", .MegaLightYears = 400},
        New Galaxy With {.Name = "Pinwheel", .MegaLightYears = 25},
        New Galaxy With {.Name = "Milky Way", .MegaLightYears = 0},
        New Galaxy With {.Name = "Andromeda", .MegaLightYears = 3}
    }

    For Each theGalaxy In theGalaxies
        With theGalaxy
            Console.WriteLine(.Name & " " & .MegaLightYears)
        End With
    Next

    ' Output:
    ' Tadpole 400
    ' Pinwheel 25
    ' Milky Way 0
    ' Andromeda 3
End Sub

Public Class Galaxy
    Public Property Name As String
    Public Property MegaLightYears As Integer
End Class

```

Kinds of Collections

Many common collections are provided by the .NET Framework. Each type of collection is designed for a specific purpose.

Some of the common collection classes are described in this section:

- [System.Collections.Generic](#) classes
- [System.Collections.Concurrent](#) classes
- [System.Collections](#) classes
- Visual Basic `Collection` class

System.Collections.Generic Classes

You can create a generic collection by using one of the classes in the [System.Collections.Generic](#) namespace. A generic collection is useful when every item in the collection has the same data type. A generic collection enforces strong typing by allowing only the desired data type to be added.

The following table lists some of the frequently used classes of the [System.Collections.Generic](#) namespace:

CLASS	DESCRIPTION
Dictionary< TKey, TValue >	Represents a collection of key/value pairs that are organized based on the key.
List< T >	Represents a list of objects that can be accessed by index. Provides methods to search, sort, and modify lists.
Queue< T >	Represents a first in, first out (FIFO) collection of objects.

CLASS	DESCRIPTION
SortedList<TKey,TValue>	Represents a collection of key/value pairs that are sorted by key based on the associated IComparer<T> implementation.
Stack<T>	Represents a last in, first out (LIFO) collection of objects.

For additional information, see [Commonly Used Collection Types](#), [Selecting a Collection Class](#), and [System.Collections.Generic](#).

System.Collections.Concurrent Classes

In the .NET Framework 4 or newer, the collections in the [System.Collections.Concurrent](#) namespace provide efficient thread-safe operations for accessing collection items from multiple threads.

The classes in the [System.Collections.Concurrent](#) namespace should be used instead of the corresponding types in the [System.Collections.Generic](#) and [System.Collections](#) namespaces whenever multiple threads are accessing the collection concurrently. For more information, see [Thread-Safe Collections](#) and [System.Collections.Concurrent](#).

Some classes included in the [System.Collections.Concurrent](#) namespace are [BlockingCollection<T>](#), [ConcurrentDictionary<TKey,TValue>](#), [ConcurrentQueue<T>](#), and [ConcurrentStack<T>](#).

System.Collections Classes

The classes in the [System.Collections](#) namespace do not store elements as specifically typed objects, but as objects of type [Object](#).

Whenever possible, you should use the generic collections in the [System.Collections.Generic](#) namespace or the [System.Collections.Concurrent](#) namespace instead of the legacy types in the [System.Collections](#) namespace.

The following table lists some of the frequently used classes in the [System.Collections](#) namespace:

CLASS	DESCRIPTION
ArrayList	Represents an array of objects whose size is dynamically increased as required.
Hashtable	Represents a collection of key/value pairs that are organized based on the hash code of the key.
Queue	Represents a first in, first out (FIFO) collection of objects.
Stack	Represents a last in, first out (LIFO) collection of objects.

The [System.Collections.Specialized](#) namespace provides specialized and strongly typed collection classes, such as string-only collections and linked-list and hybrid dictionaries.

Visual Basic Collection Class

You can use the Visual Basic [Collection](#) class to access a collection item by using either a numeric index or a [String](#) key. You can add items to a collection object either with or without specifying a key. If you add an item without a key, you must use its numeric index to access it.

The Visual Basic [Collection](#) class stores all its elements as type [Object](#), so you can add an item of any data type. There is no safeguard against inappropriate data types being added.

When you use the Visual Basic [Collection](#) class, the first item in a collection has an index of 1. This differs from the .NET Framework collection classes, for which the starting index is 0.

Whenever possible, you should use the generic collections in the [System.Collections.Generic](#) namespace or the [System.Collections.Concurrent](#) namespace instead of the Visual Basic `Collection` class.

For more information, see [Collection](#).

Implementing a Collection of Key/Value Pairs

The [Dictionary<TKey,TValue>](#) generic collection enables you to access to elements in a collection by using the key of each element. Each addition to the dictionary consists of a value and its associated key. Retrieving a value by using its key is fast because the `Dictionary` class is implemented as a hash table.

The following example creates a `Dictionary` collection and iterates through the dictionary by using a `For Each` statement.

```
Private Sub IterateThroughDictionary()
    Dim elements As Dictionary(Of String, Element) = BuildDictionary()

    For Each kvp As KeyValuePair(Of String, Element) In elements
        Dim theElement As Element = kvp.Value

        Console.WriteLine("key: " & kvp.Key)
        With theElement
            Console.WriteLine("values: " & .Symbol & " " &
                .Name & " " & .AtomicNumber)
        End With
    Next
End Sub

Private Function BuildDictionary() As Dictionary(Of String, Element)
    Dim elements As New Dictionary(Of String, Element)

    AddToDictionary(elements, "K", "Potassium", 19)
    AddToDictionary(elements, "Ca", "Calcium", 20)
    AddToDictionary(elements, "Sc", "Scandium", 21)
    AddToDictionary(elements, "Ti", "Titanium", 22)

    Return elements
End Function

Private Sub AddToDictionary(ByVal elements As Dictionary(Of String, Element),
    ByVal symbol As String, ByVal name As String, ByVal atomicNumber As Integer)
    Dim theElement As New Element

    theElement.Symbol = symbol
    theElement.Name = name
    theElement.AtomicNumber = atomicNumber

    elements.Add(Key:=theElement.Symbol, value:=theElement)
End Sub

Public Class Element
    Public Property Symbol As String
    Public Property Name As String
    Public Property AtomicNumber As Integer
End Class
```

To instead use a collection initializer to build the `Dictionary` collection, you can replace the `BuildDictionary` and `AddToDictionary` methods with the following method.

```

Private Function BuildDictionary2() As Dictionary(Of String, Element)
    Return New Dictionary(Of String, Element) From
    {
        {"K", New Element With
            {.Symbol = "K", .Name = "Potassium", .AtomicNumber = 19}},
        {"Ca", New Element With
            {.Symbol = "Ca", .Name = "Calcium", .AtomicNumber = 20}},
        {"Sc", New Element With
            {.Symbol = "Sc", .Name = "Scandium", .AtomicNumber = 21}},
        {"Ti", New Element With
            {.Symbol = "Ti", .Name = "Titanium", .AtomicNumber = 22}}
    }
End Function

```

The following example uses the [ContainsKey](#) method and the [Item\[TKey\]](#) property of `Dictionary` to quickly find an item by key. The `Item` property enables you to access an item in the `elements` collection by using the `elements(symbol)` code in Visual Basic.

```

Private Sub FindInDictionary(ByVal symbol As String)
    Dim elements As Dictionary(Of String, Element) = BuildDictionary()

    If elements.ContainsKey(symbol) = False Then
        Console.WriteLine(symbol & " not found")
    Else
        Dim theElement = elements(symbol)
        Console.WriteLine("found: " & theElement.Name)
    End If
End Sub

```

The following example instead uses the [TryGetValue](#) method quickly find an item by key.

```

Private Sub FindInDictionary2(ByVal symbol As String)
    Dim elements As Dictionary(Of String, Element) = BuildDictionary()

    Dim theElement As Element = Nothing
    If elements.TryGetValue(symbol, theElement) = False Then
        Console.WriteLine(symbol & " not found")
    Else
        Console.WriteLine("found: " & theElement.Name)
    End If
End Sub

```

Using LINQ to Access a Collection

LINQ (Language-Integrated Query) can be used to access collections. LINQ queries provide filtering, ordering, and grouping capabilities. For more information, see [Getting Started with LINQ in Visual Basic](#).

The following example runs a LINQ query against a generic `List`. The LINQ query returns a different collection that contains the results.

```

Private Sub ShowLINQ()
    Dim elements As List(Of Element) = BuildList()

    ' LINQ Query.
    Dim subset = From theElement In elements
                 Where theElement.AtomicNumber < 22
                 Order By theElement.Name

    For Each theElement In subset
        Console.WriteLine(theElement.Name & " " & theElement.AtomicNumber)
    Next

    ' Output:
    ' Calcium 20
    ' Potassium 19
    ' Scandium 21
End Sub

Private Function BuildList() As List(Of Element)
    Return New List(Of Element) From
    {
        {New Element With
            {.Symbol = "K", .Name = "Potassium", .AtomicNumber = 19}},
        {New Element With
            {.Symbol = "Ca", .Name = "Calcium", .AtomicNumber = 20}},
        {New Element With
            {.Symbol = "Sc", .Name = "Scandium", .AtomicNumber = 21}},
        {New Element With
            {.Symbol = "Ti", .Name = "Titanium", .AtomicNumber = 22}}
    }
End Function

Public Class Element
    Public Property Symbol As String
    Public Property Name As String
    Public Property AtomicNumber As Integer
End Class

```

Sorting a Collection

The following example illustrates a procedure for sorting a collection. The example sorts instances of the `Car` class that are stored in a `List<T>`. The `Car` class implements the `IComparable<T>` interface, which requires that the `CompareTo` method be implemented.

Each call to the `CompareTo` method makes a single comparison that is used for sorting. User-written code in the `CompareTo` method returns a value for each comparison of the current object with another object. The value returned is less than zero if the current object is less than the other object, greater than zero if the current object is greater than the other object, and zero if they are equal. This enables you to define in code the criteria for greater than, less than, and equal.

In the `ListCars` method, the `cars.Sort()` statement sorts the list. This call to the `Sort` method of the `List<T>` causes the `CompareTo` method to be called automatically for the `Car` objects in the `List`.

```

Public Sub ListCars()

    ' Create some new cars.
    Dim cars As New List(Of Car) From
    {
        New Car With {.Name = "car1", .Color = "blue", .Speed = 20},
        New Car With {.Name = "car2", .Color = "red", .Speed = 50},
        New Car With {.Name = "car3", .Color = "green", .Speed = 10},
        New Car With {.Name = "car4", .Color = "blue", .Speed = 50},
        New Car With {.Name = "car5", .Color = "blue", .Speed = 20}
    }

```

```

        New Car With {.Name = "car5", .Color = "blue", .Speed = 30},
        New Car With {.Name = "car6", .Color = "red", .Speed = 60},
        New Car With {.Name = "car7", .Color = "green", .Speed = 50}
    }

    ' Sort the cars by color alphabetically, and then by speed
    ' in descending order.
    cars.Sort()

    ' View all of the cars.
    For Each thisCar As Car In cars
        Console.WriteLine(thisCar.Color.PadRight(5) & " ")
        Console.WriteLine(thisCar.Speed.ToString & " ")
        Console.WriteLine(thisCar.Name)
        Console.WriteLine()
    Next

    ' Output:
    ' blue 50 car4
    ' blue 30 car5
    ' blue 20 car1
    ' green 50 car7
    ' green 10 car3
    ' red 60 car6
    ' red 50 car2
End Sub

Public Class Car
    Implements IComparable(Of Car)

    Public Property Name As String
    Public Property Speed As Integer
    Public Property Color As String

    Public Function CompareTo(ByVal other As Car) As Integer _
        Implements System.IComparable(Of Car).CompareTo
        ' A call to this method makes a single comparison that is
        ' used for sorting.

        ' Determine the relative order of the objects being compared.
        ' Sort by color alphabetically, and then by speed in
        ' descending order.

        ' Compare the colors.
        Dim compare As Integer
        compare = String.Compare(Me.Color, other.Color, True)

        ' If the colors are the same, compare the speeds.
        If compare = 0 Then
            compare = Me.Speed.CompareTo(other.Speed)

            ' Use descending order for speed.
            compare = -compare
        End If

        Return compare
    End Function
End Class

```

Defining a Custom Collection

You can define a collection by implementing the [IEnumerable<T>](#) or [IEnumerable](#) interface. For additional information, see [Enumerating a Collection](#).

Although you can define a custom collection, it is usually better to instead use the collections that are included in the .NET Framework, which are described in [Kinds of Collections](#) earlier in this topic.

The following example defines a custom collection class named `AllColors`. This class implements the `IEnumerable` interface, which requires that the `GetEnumerator` method be implemented.

The `GetEnumerator` method returns an instance of the `ColorEnumerator` class. `ColorEnumerator` implements the `IEnumerator` interface, which requires that the `Current` property, `MoveNext` method, and `Reset` method be implemented.

```

Public Sub ListColors()
    Dim colors As New AllColors()

    For Each theColor As Color In colors
        Console.WriteLine(theColor.Name & " ")
    Next
    Console.WriteLine()
    ' Output: red blue green
End Sub

' Collection class.
Public Class AllColors
    Implements System.Collections.IEnumerable

    Private _colors() As Color =
    {
        New Color With {.Name = "red"},
        New Color With {.Name = "blue"},
        New Color With {.Name = "green"}
    }

    Public Function GetEnumerator() As System.Collections.IEnumerator _
        Implements System.Collections.IEnumerable.GetEnumerator

        Return New ColorEnumerator(_colors)

        ' Instead of creating a custom enumerator, you could
        ' use the GetEnumerator of the array.
        'Return _colors.GetEnumerator
    End Function

    ' Custom enumerator.
    Private Class ColorEnumerator
        Implements System.Collections.IEnumerator

        Private _colors() As Color
        Private _position As Integer = -1

        Public Sub New(ByVal colors() As Color)
            _colors = colors
        End Sub

        Public ReadOnly Property Current() As Object _
            Implements System.Collections.IEnumerator.Current
            Get
                Return _colors(_position)
            End Get
        End Property

        Public Function MoveNext() As Boolean _
            Implements System.Collections.IEnumerator.MoveNext
            _position += 1
            Return (_position < _colors.Length)
        End Function

        Public Sub Reset() Implements System.Collections.IEnumerator.Reset
            _position = -1
        End Sub
    End Class
End Class

' Element class.
Public Class Color
    Public Property Name As String
End Class

```

Iterators

An *iterator* is used to perform a custom iteration over a collection. An iterator can be a method or a `get` accessor. An iterator uses a `Yield` statement to return each element of the collection one at a time.

You call an iterator by using a `For Each...Next` statement. Each iteration of the `For Each` loop calls the iterator. When a `Yield` statement is reached in the iterator, an expression is returned, and the current location in code is retained. Execution is restarted from that location the next time that the iterator is called.

For more information, see [Iterators \(Visual Basic\)](#).

The following example uses an iterator method. The iterator method has a `yield` statement that is inside a `For...Next` loop. In the `ListEvenNumbers` method, each iteration of the `For Each` statement body creates a call to the iterator method, which proceeds to the next `Yield` statement.

```
Public Sub ListEvenNumbers()
    For Each number As Integer In EvenSequence(5, 18)
        Console.WriteLine(number & " ")
    Next
    Console.WriteLine()
    ' Output: 6 8 10 12 14 16 18
End Sub

Private Iterator Function EvenSequence(
    ByVal firstNumber As Integer, ByVal lastNumber As Integer) _
    As IEnumerable(Of Integer)

    ' Yield even numbers in the range.
    For number = firstNumber To lastNumber
        If number Mod 2 = 0 Then
            Yield number
        End If
    Next
End Function
```

Covariance and Contravariance (Visual Basic)

10/4/2018 • 3 minutes to read • [Edit Online](#)

In Visual Basic, covariance and contravariance enable implicit reference conversion for array types, delegate types, and generic type arguments. Covariance preserves assignment compatibility and contravariance reverses it.

The following code demonstrates the difference between assignment compatibility, covariance, and contravariance.

```
' Assignment compatibility.  
Dim str As String = "test"  
' An object of a more derived type is assigned to an object of a less derived type.  
Dim obj As Object = str  
  
' Covariance.  
Dim strings As IEnumerable(Of String) = New List(Of String)()  
' An object that is instantiated with a more derived type argument  
' is assigned to an object instantiated with a less derived type argument.  
' Assignment compatibility is preserved.  
Dim objects As IEnumerable(Of Object) = strings  
  
' Contravariance.  
' Assume that there is the following method in the class:  
' Shared Sub SetObject(ByVal o As Object)  
' End Sub  
Dim actObject As Action(Of Object) = AddressOf SetObject  
  
' An object that is instantiated with a less derived type argument  
' is assigned to an object instantiated with a more derived type argument.  
' Assignment compatibility is reversed.  
Dim actString As Action(Of String) = actObject
```

Covariance for arrays enables implicit conversion of an array of a more derived type to an array of a less derived type. But this operation is not type safe, as shown in the following code example.

```
Dim array() As Object = New String(10) {}  
' The following statement produces a run-time exception.  
' array(0) = 10
```

Covariance and contravariance support for method groups allows for matching method signatures with delegate types. This enables you to assign to delegates not only methods that have matching signatures, but also methods that return more derived types (covariance) or that accept parameters that have less derived types (contravariance) than that specified by the delegate type. For more information, see [Variance in Delegates \(Visual Basic\)](#) and [Using Variance in Delegates \(Visual Basic\)](#).

The following code example shows covariance and contravariance support for method groups.

```

Shared Function GetObject() As Object
    Return Nothing
End Function

Shared Sub SetObject(ByVal obj As Object)
End Sub

Shared Function GetString() As String
    Return ""
End Function

Shared Sub SetString(ByVal str As String)

End Sub

Shared Sub Test()
    ' Covariance. A delegate specifies a return type as object,
    ' but you can assign a method that returns a string.
    Dim del As Func(Of Object) = AddressOf GetString

    ' Contravariance. A delegate specifies a parameter type as string,
    ' but you can assign a method that takes an object.
    Dim del2 As Action(Of String) = AddressOf SetObject
End Sub

```

In .NET Framework 4 or later, Visual Basic supports covariance and contravariance in generic interfaces and delegates and allows for implicit conversion of generic type parameters. For more information, see [Variance in Generic Interfaces \(Visual Basic\)](#) and [Variance in Delegates \(Visual Basic\)](#).

The following code example shows implicit reference conversion for generic interfaces.

```

Dim strings As IEnumerable(Of String) = New List(Of String)
Dim objects As IEnumerable(Of Object) = strings

```

A generic interface or delegate is called *variant* if its generic parameters are declared covariant or contravariant. Visual Basic enables you to create your own variant interfaces and delegates. For more information, see [Creating Variant Generic Interfaces \(Visual Basic\)](#) and [Variance in Delegates \(Visual Basic\)](#).

Expression Trees (Visual Basic)

3/8/2019 • 4 minutes to read • [Edit Online](#)

Expression trees represent code in a tree-like data structure, where each node is an expression, for example, a method call or a binary operation such as `x < y`.

You can compile and run code represented by expression trees. This enables dynamic modification of executable code, the execution of LINQ queries in various databases, and the creation of dynamic queries. For more information about expression trees in LINQ, see [How to: Use Expression Trees to Build Dynamic Queries \(Visual Basic\)](#).

Expression trees are also used in the dynamic language runtime (DLR) to provide interoperability between dynamic languages and the .NET Framework and to enable compiler writers to emit expression trees instead of Microsoft intermediate language (MSIL). For more information about the DLR, see [Dynamic Language Runtime Overview](#).

You can have the C# or Visual Basic compiler create an expression tree for you based on an anonymous lambda expression, or you can create expression trees manually by using the [System.Linq.Expressions](#) namespace.

Creating Expression Trees from Lambda Expressions

When a lambda expression is assigned to a variable of type [Expression<TDelegate>](#), the compiler emits code to build an expression tree that represents the lambda expression.

The Visual Basic compiler can generate expression trees only from expression lambdas (or single-line lambdas). It cannot parse statement lambdas (or multi-line lambdas). For more information about lambda expressions in Visual Basic, see [Lambda Expressions](#).

The following code examples demonstrate how to have the Visual Basic compiler create an expression tree that represents the lambda expression `Function(num) num < 5`.

```
Dim lambda As Expression(Of Func(Of Integer, Boolean)) =
    Function(num) num < 5
```

Creating Expression Trees by Using the API

To create expression trees by using the API, use the [Expression](#) class. This class contains static factory methods that create expression tree nodes of specific types, for example, [ParameterExpression](#), which represents a variable or parameter, or [MethodCallExpression](#), which represents a method call. [ParameterExpression](#), [MethodCallExpression](#), and the other expression-specific types are also defined in the [System.Linq.Expressions](#) namespace. These types derive from the abstract type [Expression](#).

The following code example demonstrates how to create an expression tree that represents the lambda expression `Function(num) num < 5` by using the API.

```

' Import the following namespace to your project: System.Linq.Expressions

' Manually build the expression tree for the lambda expression num => num < 5.
Dim numParam As ParameterExpression = Expression.Parameter(GetType(Integer), "num")
Dim five As ConstantExpression = Expression.Constant(5, GetType(Integer))
Dim numLessThanFive As BinaryExpression = Expression.LessThan(numParam, five)
Dim lambda1 As Expression(Of Func(Of Integer, Boolean)) =
    Expression.Lambda(Of Func(Of Integer, Boolean))(
        numLessThanFive,
        New ParameterExpression() {numParam})

```

In .NET Framework 4 or later, the expression trees API also supports assignments and control flow expressions such as loops, conditional blocks, and `try-catch` blocks. By using the API, you can create expression trees that are more complex than those that can be created from lambda expressions by the Visual Basic compiler. The following example demonstrates how to create an expression tree that calculates the factorial of a number.

```

' Creating a parameter expression.
Dim value As ParameterExpression =
    Expression.Parameter(GetType(Integer), "value")

' Creating an expression to hold a local variable.
Dim result As ParameterExpression =
    Expression.Parameter(GetType(Integer), "result")

' Creating a label to jump to from a loop.
Dim label As LabelTarget = Expression.Label(GetType(Integer))

' Creating a method body.
Dim block As BlockExpression = Expression.Block(
    New ParameterExpression() {result},
    Expression.Assign(result, Expression.Constant(1)),
    Expression.Loop(
        Expression.IfThenElse(
            Expression.GreaterThan(value, Expression.Constant(1)),
            Expression.MultiplyAssign(result,
                Expression.PostDecrementAssign(value)),
            Expression.Break(label, result)
        ),
        label
    )
)

' Compile an expression tree and return a delegate.
Dim factorial As Integer =
    Expression.Lambda(Of Func(Of Integer, Integer))(block, value).Compile()(5)

Console.WriteLine(factorial)
' Prints 120.

```

For more information, see [Generating Dynamic Methods with Expression Trees in Visual Studio 2010](#), which also applies to later versions of Visual Studio.

Parsing Expression Trees

The following code example demonstrates how the expression tree that represents the lambda expression `Function(num) num < 5` can be decomposed into its parts.

```

' Import the following namespace to your project: System.Linq.Expressions

' Create an expression tree.
Dim exprTree As Expression(Of Func(Of Integer, Boolean)) = Function(num) num < 5

' Decompose the expression tree.
Dim param As ParameterExpression = exprTree.Parameters(0)
Dim operation As BinaryExpression = exprTree.Body
Dim left As ParameterExpression = operation.Left
Dim right As ConstantExpression = operation.Right

Console.WriteLine(String.Format("Decomposed expression: {0} => {1} {2} {3}",
    param.Name, left.Name, operation.NodeType, right.Value))

' This code produces the following output:
'

' Decomposed expression: num => num LessThan 5

```

Immutability of Expression Trees

Expression trees should be immutable. This means that if you want to modify an expression tree, you must construct a new expression tree by copying the existing one and replacing nodes in it. You can use an expression tree visitor to traverse the existing expression tree. For more information, see [How to: Modify Expression Trees \(Visual Basic\)](#).

Compiling Expression Trees

The [Expression<TDelegate>](#) type provides the [Compile](#) method that compiles the code represented by an expression tree into an executable delegate.

The following code example demonstrates how to compile an expression tree and run the resulting code.

```

' Creating an expression tree.
Dim expr As Expression(Of Func(Of Integer, Boolean)) =
    Function(num) num < 5

' Compiling the expression tree into a delegate.
Dim result As Func(Of Integer, Boolean) = expr.Compile()

' Invoking the delegate and writing the result to the console.
Console.WriteLine(result(4))

' Prints True.

' You can also use simplified syntax
' to compile and run an expression tree.
' The following line can replace two previous statements.
Console.WriteLine(expr.Compile()(4))

' Also prints True.

```

For more information, see [How to: Execute Expression Trees \(Visual Basic\)](#).

Iterators (Visual Basic)

3/5/2019 • 10 minutes to read • [Edit Online](#)

An *iterator* can be used to step through collections such as lists and arrays.

An iterator method or `get` accessor performs a custom iteration over a collection. An iterator method uses the `Yield` statement to return each element one at a time. When a `Yield` statement is reached, the current location in code is remembered. Execution is restarted from that location the next time the iterator function is called.

You consume an iterator from client code by using a `For Each...Next` statement, or by using a LINQ query.

In the following example, the first iteration of the `For Each` loop causes execution to proceed in the `SomeNumbers` iterator method until the first `Yield` statement is reached. This iteration returns a value of 3, and the current location in the iterator method is retained. On the next iteration of the loop, execution in the iterator method continues from where it left off, again stopping when it reaches a `Yield` statement. This iteration returns a value of 5, and the current location in the iterator method is again retained. The loop completes when the end of the iterator method is reached.

```
Sub Main()
    For Each number As Integer In SomeNumbers()
        Console.WriteLine(number & " ")
    Next
    ' Output: 3 5 8
    Console.ReadKey()
End Sub

Private Iterator Function SomeNumbers() As System.Collections.IEnumerable
    Yield 3
    Yield 5
    Yield 8
End Function
```

The return type of an iterator method or `get` accessor can be `IEnumerable`, `IEnumerable<T>`, `IEnumerator`, or `IEnumerator<T>`.

You can use an `Exit Function` or `Return` statement to end the iteration.

A Visual Basic iterator function or `get` accessor declaration includes an `Iterator` modifier.

Iterators were introduced in Visual Basic in Visual Studio 2012.

- [Simple Iterator](#)
- [Creating a Collection Class](#)
- [Try Blocks](#)
- [Anonymous Methods](#)
- [Using Iterators with a Generic List](#)
- [Syntax Information](#)
- [Technical Implementation](#)

- Use of Iterators

NOTE

For all examples in the topic except the Simple Iterator example, include **Imports** statements for the `System.Collections` and `System.Collections.Generic` namespaces.

Simple Iterator

The following example has a single `Yield` statement that is inside a `For...Next` loop. In `Main`, each iteration of the `For Each` statement body creates a call to the iterator function, which proceeds to the next `Yield` statement.

```
Sub Main()
    For Each number As Integer In EvenSequence(5, 18)
        Console.WriteLine(number & " ")
    Next
    ' Output: 6 8 10 12 14 16 18
    Console.ReadKey()
End Sub

Private Iterator Function EvenSequence(
    ByVal firstNumber As Integer, ByVal lastNumber As Integer) _
As System.Collections.Generic.IEnumerable(Of Integer)

    ' Yield even numbers in the range.
    For number As Integer = firstNumber To lastNumber
        If number Mod 2 = 0 Then
            Yield number
        End If
    Next
End Function
```

Creating a Collection Class

In the following example, the `DaysOfTheWeek` class implements the **IEnumerable** interface, which requires a **GetEnumerator** method. The compiler implicitly calls the `GetEnumerator` method, which returns an **IEnumerator**.

The `GetEnumerator` method returns each string one at a time by using the `yield` statement, and an `Iterator` modifier is in the function declaration.

```

Sub Main()
    Dim days As New DaysOfTheWeek()
    For Each day As String In days
        Console.WriteLine(day & " ")
    Next
    ' Output: Sun Mon Tue Wed Thu Fri Sat
    Console.ReadKey()
End Sub

Private Class DaysOfTheWeek
    Implements IEnumerable

    Public days =
        New String() {"Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat"}

    Public Iterator Function GetEnumerator() As IEnumerator _
        Implements IEnumerable.GetEnumerator

        ' Yield each day of the week.
        For i As Integer = 0 To days.Length - 1
            Yield days(i)
        Next
    End Function
End Class

```

The following example creates a `Zoo` class that contains a collection of animals.

The `For Each` statement that refers to the class instance (`theZoo`) implicitly calls the `GetEnumerator` method. The `For Each` statements that refer to the `Birds` and `Mammals` properties use the `AnimalsForType` named iterator method.

```

Sub Main()
    Dim theZoo As New Zoo()

    theZoo.AddMammal("Whale")
    theZoo.AddMammal("Rhinoceros")
    theZoo.AddBird("Penguin")
    theZoo.AddBird("Warbler")

    For Each name As String In theZoo
        Console.WriteLine(name & " ")
    Next
    Console.WriteLine()
    ' Output: Whale Rhinoceros Penguin Warbler

    For Each name As String In theZoo.Birds
        Console.WriteLine(name & " ")
    Next
    Console.WriteLine()
    ' Output: Penguin Warbler

    For Each name As String In theZoo.Mammals
        Console.WriteLine(name & " ")
    Next
    Console.WriteLine()
    ' Output: Whale Rhinoceros

    Console.ReadKey()
End Sub

Public Class Zoo
    Implements IEnumerable

    ' Private members.
    Private animals As New List(Of Animal)

```

```

' Public methods.
Public Sub AddMammal(ByVal name As String)
    animals.Add(New Animal With {.Name = name, .Type = Animal.TypeEnum.Mammal})
End Sub

Public Sub AddBird(ByVal name As String)
    animals.Add(New Animal With {.Name = name, .Type = Animal.TypeEnum.Bird})
End Sub

Public Iterator Function GetEnumerator() As IEnumerable _
    Implements IEnumerable.GetEnumerator

    For Each theAnimal As Animal In animals
        Yield theAnimal.Name
    Next
End Function

' Public members.
Public ReadOnly Property Mammals As IEnumerable
    Get
        Return AnimalsForType(Animal.TypeEnum.Mammal)
    End Get
End Property

Public ReadOnly Property Birds As IEnumerable
    Get
        Return AnimalsForType(Animal.TypeEnum.Bird)
    End Get
End Property

' Private methods.
Private Iterator Function AnimalsForType( _
    ByVal type As Animal.TypeEnum) As IEnumerable
    For Each theAnimal As Animal In animals
        If (theAnimal.Type = type) Then
            Yield theAnimal.Name
        End If
    Next
End Function

' Private class.
Private Class Animal
    Public Enum TypeEnum
        Bird
        Mammal
    End Enum

    Public Property Name As String
    Public Property Type As TypeEnum
    End Class
End Class

```

Try Blocks

Visual Basic allows a `Yield` statement in the `Try` block of a [Try...Catch...Finally Statement](#). A `Try` block that has a `Yield` statement can have `Catch` blocks, and can have a `Finally` block.

The following example includes `Try`, `Catch`, and `Finally` blocks in an iterator function. The `Finally` block in the iterator function executes before the `For Each` iteration finishes.

```

Sub Main()
    For Each number As Integer In Test()
        Console.WriteLine(number)
    Next
    Console.WriteLine("For Each is done.")

    ' Output:
    ' 3
    ' 4
    ' Something happened. Yields are done.
    ' Finally is called.
    ' For Each is done.
    Console.ReadKey()
End Sub

Private Iterator Function Test() As IEnumerable(Of Integer)
    Try
        Yield 3
        Yield 4
        Throw New Exception("Something happened. Yields are done.")
        Yield 5
        Yield 6
    Catch ex As Exception
        Console.WriteLine(ex.Message)
    Finally
        Console.WriteLine("Finally is called.")
    End Try
End Function

```

A `Yield` statement cannot be inside a `Catch` block or a `Finally` block.

If the `For Each` body (instead of the iterator method) throws an exception, a `Catch` block in the iterator function is not executed, but a `Finally` block in the iterator function is executed. A `catch` block inside an iterator function catches only exceptions that occur inside the iterator function.

Anonymous Methods

In Visual Basic, an anonymous function can be an iterator function. The following example illustrates this.

```

Dim iterateSequence = Iterator Function() _
    As IEnumerable(Of Integer)
    Yield 1
    Yield 2
End Function

For Each number As Integer In iterateSequence()
    Console.Write(number & " ")
Next
' Output: 1 2
Console.ReadKey()

```

The following example has a non-iterator method that validates the arguments. The method returns the result of an anonymous iterator that describes the collection elements.

```

Sub Main()
    For Each number As Integer In GetSequence(5, 10)
        Console.WriteLine(number & " ")
    Next
    ' Output: 5 6 7 8 9 10
    Console.ReadKey()
End Sub

Public Function GetSequence(ByVal low As Integer, ByVal high As Integer) _
As IEnumerable
    ' Validate the arguments.
    If low < 1 Then
        Throw New ArgumentException("low is too low")
    End If
    If high > 140 Then
        Throw New ArgumentException("high is too high")
    End If

    ' Return an anonymous iterator function.
    Dim iterateSequence = Iterator Function() As IEnumerable
        For index = low To high
            Yield index
        Next
    End Function

    Return iterateSequence()
End Function

```

If validation is instead inside the iterator function, the validation cannot be performed until the start of the first iteration of the `For Each` body.

Using Iterators with a Generic List

In the following example, the `Stack(of T)` generic class implements the `IEnumerable<T>` generic interface. The `Push` method assigns values to an array of type `T`. The `GetEnumerator` method returns the array values by using the `Yield` statement.

In addition to the generic `GetEnumerator` method, the non-generic `GetEnumerator` method must also be implemented. This is because `IEnumerable<T>` inherits from `IEnumerable`. The non-generic implementation defers to the generic implementation.

The example uses named iterators to support various ways of iterating through the same collection of data. These named iterators are the `TopToBottom` and `BottomToTop` properties, and the `TopN` method.

The `BottomToTop` property declaration includes the `Iterator` keyword.

```

Sub Main()
    Dim theStack As New Stack(Of Integer)

    ' Add items to the stack.
    For number As Integer = 0 To 9
        theStack.Push(number)
    Next

    ' Retrieve items from the stack.
    ' For Each is allowed because theStack implements
    ' IEnumerable(Of Integer).
    For Each number As Integer In theStack
        Console.WriteLine("{0} ", number)
    Next
    Console.WriteLine()
    ' Output: 9 8 7 6 5 4 3 2 1 0

    ' For Each is allowed, because theStack.TopToBottom

```

```

    ' Each is allowed, because the stack implements IEnumerable(Of Integer).
For Each number As Integer In theStack.TopToBottom
    Console.WriteLine("{0} ", number)
Next
Console.WriteLine()
' Output: 9 8 7 6 5 4 3 2 1 0

For Each number As Integer In theStack.BottomToTop
    Console.WriteLine("{0} ", number)
Next
Console.WriteLine()
' Output: 0 1 2 3 4 5 6 7 8 9

For Each number As Integer In theStack.TopN(7)
    Console.WriteLine("{0} ", number)
Next
Console.WriteLine()
' Output: 9 8 7 6 5 4 3

Console.ReadKey()
End Sub

Public Class Stack(Of T)
    Implements IEnumerable(Of T)

    Private values As T() = New T(99) {}
    Private top As Integer = 0

    Public Sub Push(ByVal t As T)
        values(top) = t
        top = top + 1
    End Sub

    Public Function Pop() As T
        top = top - 1
        Return values(top)
    End Function

    ' This function implements the GetEnumerator method. It allows
    ' an instance of the class to be used in a For Each statement.
    Public Iterator Function GetEnumerator() As IEnumerator(Of T) _
        Implements IEnumerable(Of T).GetEnumerator

        For index As Integer = top - 1 To 0 Step -1
            Yield values(index)
        Next
    End Function

    Public Iterator Function GetEnumerator1() As IEnumerator _
        Implements IEnumerable.GetEnumerator

        Yield GetEnumerator()
    End Function

    Public ReadOnly Property TopToBottom() As IEnumerable(Of T)
        Get
            Return Me
        End Get
    End Property

    Public ReadOnly Iterator Property BottomToTop As IEnumerable(Of T)
        Get
            For index As Integer = 0 To top - 1
                Yield values(index)
            Next
        End Get
    End Property

    Public Iterator Function TopN(ByVal n As Integer) As IEnumerable

```

```

    Public Iterator Function TopN(ByVal itemsFromTop As Integer) _
        As IEnumerable(Of T)

        ' Return less than itemsFromTop if necessary.
        Dim startIndex As Integer =
            If(itemsFromTop >= top, 0, top - itemsFromTop)

        For index As Integer = top - 1 To startIndex Step -1
            Yield values(index)
        Next
    End Function
End Class

```

Syntax Information

An iterator can occur as a method or `get` accessor. An iterator cannot occur in an event, instance constructor, static constructor, or static destructor.

An implicit conversion must exist from the expression type in the `Yield` statement to the return type of the iterator.

In Visual Basic, an iterator method cannot have any `ByRef` parameters.

In Visual Basic, "Yield" is not a reserved word and has special meaning only when it is used in an `Iterator` method or `get` accessor.

Technical Implementation

Although you write an iterator as a method, the compiler translates it into a nested class that is, in effect, a state machine. This class keeps track of the position of the iterator as long the `For Each...Next` loop in the client code continues.

To see what the compiler does, you can use the `Ildasm.exe` tool to view the Microsoft intermediate language code that is generated for an iterator method.

When you create an iterator for a `class` or `struct`, you do not have to implement the whole `IEnumerator` interface. When the compiler detects the iterator, it automatically generates the `Current`, `MoveNext`, and `Dispose` methods of the `IEnumerator` or `IEnumerator<T>` interface.

On each successive iteration of the `For Each...Next` loop (or the direct call to `IEnumerator.MoveNext`), the next iterator code body resumes after the previous `Yield` statement. It then continues to the next `Yield` statement until the end of the iterator body is reached, or until an `Exit Function` or `Return` statement is encountered.

Iterators do not support the `IEnumerator.Reset` method. To re-iterate from the start, you must obtain a new iterator.

For additional information, see the [Visual Basic Language Specification](#).

Use of Iterators

Iterators enable you to maintain the simplicity of a `For Each` loop when you need to use complex code to populate a list sequence. This can be useful when you want to do the following:

- Modify the list sequence after the first `For Each` loop iteration.
- Avoid fully loading a large list before the first iteration of a `For Each` loop. An example is a paged fetch to load a batch of table rows. Another example is the `EnumerateFiles` method, which implements iterators within the .NET Framework.

- Encapsulate building the list in the iterator. In the iterator method, you can build the list and then yield each result in a loop.

Language-Integrated Query (LINQ) (Visual Basic)

5/4/2018 • 2 minutes to read • [Edit Online](#)

LINQ is a set of features that extends powerful query capabilities to the language syntax of Visual Basic. LINQ introduces standard, easily-learned patterns for querying and updating data, and the technology can be extended to support potentially any kind of data store. The .NET Framework includes LINQ provider assemblies that enable the use of LINQ with .NET Framework collections, SQL Server databases, ADO.NET Datasets, and XML documents.

In This Section

[Introduction to LINQ \(Visual Basic\)](#)

Provides a general introduction to the kinds of applications that you can write and the kinds of problems that you can solve with LINQ queries.

[Getting Started with LINQ in Visual Basic](#)

Describes the basic facts you should know in order to understand the Visual Basic documentation and samples.

[Visual Studio IDE and Tools Support for LINQ \(Visual Basic\)](#)

Describes Visual Studio's Object Relational Designer, debugger support for queries, and other IDE features related to LINQ.

[Standard Query Operators Overview \(Visual Basic\)](#)

Provides an introduction to the standard query operators. It also provides links to topics that have more information about each type of query operation.

[LINQ to Objects \(Visual Basic\)](#)

Includes links to topics that explain how to use LINQ to Objects to access in-memory data structures,

[LINQ to XML \(Visual Basic\)](#)

Includes links to topics that explain how to use LINQ to XML, which provides the in-memory document modification capabilities of the Document Object Model (DOM), and supports LINQ query expressions.

[LINQ to ADO.NET \(Portal Page\)](#)

Provides an entry point for documentation about LINQ to DataSet, LINQ to SQL, and LINQ to Entities. LINQ to DataSet enables you to build richer query capabilities into [DataSet](#) by using the same query functionality that is available for other data sources. LINQ to SQL provides a run-time infrastructure for managing relational data as objects. LINQ to Entities enables developers to write queries against the Entity Framework conceptual model by using C#.

[Enabling a Data Source for LINQ Querying](#)

Provides an introduction to custom LINQ providers, LINQ expression trees, and other ways to extend LINQ.

Object-oriented programming (Visual Basic)

11/16/2018 • 10 minutes to read • [Edit Online](#)

Visual Basic provides full support for object-oriented programming including encapsulation, inheritance, and polymorphism.

Encapsulation means that a group of related properties, methods, and other members are treated as a single unit or object.

Inheritance describes the ability to create new classes based on an existing class.

Polymorphism means that you can have multiple classes that can be used interchangeably, even though each class implements the same properties or methods in different ways.

This section describes the following concepts:

- [Classes and objects](#)
 - [Class members](#)
 - [Properties and fields](#)
 - [Methods](#)
 - [Constructors](#)
 - [Destructors](#)
 - [Events](#)
 - [Nested classes](#)
 - [Access modifiers and access levels](#)
 - [Instantiating classes](#)
 - [Shared classes and members](#)
 - [Anonymous types](#)
- [Inheritance](#)
 - [Overriding members](#)
- [Interfaces](#)
- [Generics](#)
- [Delegates](#)

Classes and objects

The terms *class* and *object* are sometimes used interchangeably, but in fact, classes describe the *type* of objects, while objects are usable *instances* of classes. So, the act of creating an object is called *instantiation*. Using the blueprint analogy, a class is a blueprint, and an object is a building made from that blueprint.

To define a class:

```
Class SampleClass  
End Class
```

Visual Basic also provides a light version of classes called *structures* that are useful when you need to create large array of objects and do not want to consume too much memory for that.

To define a structure:

```
Structure SampleStructure  
End Structure
```

For more information, see:

- [Class Statement](#)
- [Structure Statement](#)

Class members

Each class can have different *class members* that include properties that describe class data, methods that define class behavior, and events that provide communication between different classes and objects.

Properties and fields

Fields and properties represent information that an object contains. Fields are like variables because they can be read or set directly.

To define a field:

```
Class SampleClass  
    Public SampleField As String  
End Class
```

Properties have get and set procedures, which provide more control on how values are set or returned.

Visual Basic allows you either to create a private field for storing the property value or use so-called auto-implemented properties that create this field automatically behind the scenes and provide the basic logic for the property procedures.

To define an auto-implemented property:

```
Class SampleClass  
    Public Property SampleProperty as String  
End Class
```

If you need to perform some additional operations for reading and writing the property value, define a field for storing the property value and provide the basic logic for storing and retrieving it:

```
Class SampleClass  
    Private m_Sample As String  
    Public Property Sample() As String  
        Get  
            ' Return the value stored in the field.  
            Return m_Sample  
        End Get  
        Set(ByVal Value As String)  
            ' Store the value in the field.  
            m_Sample = Value  
        End Set  
    End Property  
End Class
```

Most properties have methods or procedures to both set and get the property value. However, you can create read-only or write-only properties to restrict them from being modified or read. In Visual Basic you can use `ReadOnly` and `WriteOnly` keywords. However, auto-implemented properties cannot be read-only or write-only.

For more information, see:

- [Property Statement](#)
- [Get Statement](#)
- [Set Statement](#)
- [ReadOnly](#)
- [WriteOnly](#)

Methods

A *method* is an action that an object can perform.

NOTE

In Visual Basic, there are two ways to create a method: the `Sub` statement is used if the method does not return a value; the `Function` statement is used if a method returns a value.

To define a method of a class:

```
Class SampleClass
    Public Function SampleFunc(ByVal SampleParam As String)
        ' Add code here
    End Function
End Class
```

A class can have several implementations, or *overloads*, of the same method that differ in the number of parameters or parameter types.

To overload a method:

```
Overloads Sub Display(ByVal theChar As Char)
    ' Add code that displays Char data.
End Sub
Overloads Sub Display(ByVal theInteger As Integer)
    ' Add code that displays Integer data.
End Sub
```

In most cases you declare a method within a class definition. However, Visual Basic also supports *extension methods* that allow you to add methods to an existing class outside the actual definition of the class.

For more information, see:

- [Function Statement](#)
- [Sub Statement](#)
- [Overloads](#)
- [Extension Methods](#)

Constructors

Constructors are class methods that are executed automatically when an object of a given type is created.

Constructors usually initialize the data members of the new object. A constructor can run only once when a class is created. Furthermore, the code in the constructor always runs before any other code in a class. However, you can create multiple constructor overloads in the same way as for any other method.

To define a constructor for a class:

```

Class SampleClass
    Sub New(ByVal s As String)
        // Add code here.
    End Sub
End Class

```

For more information, see: [Object Lifetime: How Objects Are Created and Destroyed](#).

Destructors

Destructors are used to destruct instances of classes. In the .NET Framework, the garbage collector automatically manages the allocation and release of memory for the managed objects in your application. However, you may still need destructors to clean up any unmanaged resources that your application creates. There can be only one destructor for a class.

For more information about destructors and garbage collection in the .NET Framework, see [Garbage Collection](#).

Events

Events enable a class or object to notify other classes or objects when something of interest occurs. The class that sends (or raises) the event is called the *publisher* and the classes that receive (or handle) the event are called *subscribers*. For more information about events, how they are raised and handled, see [Events](#).

- To declare events, use the [Event Statement](#).
- To raise events, use the [RaiseEvent Statement](#).
- To specify event handlers using a declarative way, use the [WithEvents](#) statement and the [Handles](#) clause.
- To be able to dynamically add, remove, and change the event handler associated with an event, use the [AddHandler Statement](#) and [RemoveHandler Statement](#) together with the [AddressOf Operator](#).

Nested classes

A class defined within another class is called *nested*. By default, the nested class is private.

```

Class Container
    Class Nested
        ' Add code here.
    End Class
End Class

```

To create an instance of the nested class, use the name of the container class followed by the dot and then followed by the name of the nested class:

```
Dim nestedInstance As Container.Nested = New Container.Nested()
```

Access modifiers and access levels

All classes and class members can specify what access level they provide to other classes by using *access modifiers*.

The following access modifiers are available:

VISUAL BASIC MODIFIER	DEFINITION
Public	The type or member can be accessed by any other code in the same assembly or another assembly that references it.

VISUAL BASIC MODIFIER	DEFINITION
Private	The type or member can only be accessed by code in the same class.
Protected	The type or member can only be accessed by code in the same class or in a derived class.
Friend	The type or member can be accessed by any code in the same assembly, but not from another assembly.
Protected Friend	The type or member can be accessed by any code in the same assembly, or by any derived class in another assembly.

For more information, see [Access levels in Visual Basic](#).

Instantiating classes

To create an object, you need to instantiate a class, or create a class instance.

```
Dim sampleObject as New SampleClass()
```

After instantiating a class, you can assign values to the instance's properties and fields and invoke class methods.

```
' Set a property value.
sampleObject.SampleProperty = "Sample String"
' Call a method.
sampleObject.SampleMethod()
```

To assign values to properties during the class instantiation process, use object initializers:

```
Dim sampleObject = New SampleClass With
    {.FirstProperty = "A", .SecondProperty = "B"}
```

For more information, see:

- [New Operator](#)
- [Object Initializers: Named and Anonymous Types](#)

Shared classes and members

A shared member of the class is a property, procedure, or field that is shared by all instances of a class.

To define a shared member:

```
Class SampleClass
    Public Shared SampleString As String = "Sample String"
End Class
```

To access the shared member, use the name of the class without creating an object of this class:

```
MsgBox(SampleClass.SampleString)
```

Shared modules in Visual Basic have shared members only and cannot be instantiated. Shared members also cannot access non-shared properties, fields or methods

For more information, see:

- [Shared](#)
- [Module Statement](#)

Anonymous types

Anonymous types enable you to create objects without writing a class definition for the data type. Instead, the compiler generates a class for you. The class has no usable name and contains the properties you specify in declaring the object.

To create an instance of an anonymous type:

```
' sampleObject is an instance of a simple anonymous type.  
Dim sampleObject =  
    New With {Key .FirstProperty = "A", .SecondProperty = "B"}
```

For more information, see: [Anonymous Types](#).

Inheritance

Inheritance enables you to create a new class that reuses, extends, and modifies the behavior that is defined in another class. The class whose members are inherited is called the *base class*, and the class that inherits those members is called the *derived class*. However, all classes in Visual Basic implicitly inherit from the [Object](#) class that supports .NET class hierarchy and provides low-level services to all classes.

NOTE

Visual Basic doesn't support multiple inheritance. That is, you can specify only one base class for a derived class.

To inherit from a base class:

```
Class DerivedClass  
    Inherits BaseClass  
End Class
```

By default all classes can be inherited. However, you can specify whether a class must not be used as a base class, or create a class that can be used as a base class only.

To specify that a class cannot be used as a base class:

```
NotInheritable Class SampleClass  
End Class
```

To specify that a class can be used as a base class only and cannot be instantiated:

```
MustInherit Class BaseClass  
End Class
```

For more information, see:

- [Inherits Statement](#)
- [NotInheritable](#)
- [MustInherit](#)

Overriding members

By default, a derived class inherits all members from its base class. If you want to change the behavior of the inherited member, you need to override it. That is, you can define a new implementation of the method, property or event in the derived class.

The following modifiers are used to control how properties and methods are overridden:

VISUAL BASIC MODIFIER	DEFINITION
Overridable	Allows a class member to be overridden in a derived class.
Overrides	Overrides a virtual (overridable) member defined in the base class.
NotOverridable	Prevents a member from being overridden in an inheriting class.
MustOverride	Requires that a class member to be overridden in the derived class.
Shadows	Hides a member inherited from a base class

Interfaces

Interfaces, like classes, define a set of properties, methods, and events. But unlike classes, interfaces do not provide implementation. They are implemented by classes, and defined as separate entities from classes. An interface represents a contract, in that a class that implements an interface must implement every aspect of that interface exactly as it is defined.

To define an interface:

```
Public Interface ISampleInterface
    Sub DoSomething()
End Interface
```

To implement an interface in a class:

```
Class SampleClass
    Implements ISampleInterface
    Sub DoSomething
        ' Method implementation.
    End Sub
End Class
```

For more information, see:

- [Interfaces](#)
- [Interface Statement](#)
- [Implements Statement](#)

Generics

Classes, structures, interfaces and methods in .NET can include *type parameters* that define types of objects that they can store or use. The most common example of generics is a collection, where you can specify the type of objects to be stored in a collection.

To define a generic class:

```
Class SampleGeneric(Of T)
    Public Field As T
End Class
```

To create an instance of a generic class:

```
Dim sampleObject As New SampleGeneric(Of String)
sampleObject.Field = "Sample string"
```

For more information, see:

- [Generics](#)
- [Generic Types in Visual Basic](#)

Delegates

A *delegate* is a type that defines a method signature, and can provide a reference to any method with a compatible signature. You can invoke (or call) the method through the delegate. Delegates are used to pass methods as arguments to other methods.

NOTE

Event handlers are nothing more than methods that are invoked through delegates. For more information about using delegates in event handling, see [Events](#).

To create a delegate:

```
Delegate Sub SampleDelegate(ByVal str As String)
```

To create a reference to a method that matches the signature specified by the delegate:

```
Class SampleClass
    ' Method that matches the SampleDelegate signature.
    Sub SampleSub(ByVal str As String)
        ' Add code here.
    End Sub
    ' Method that instantiates the delegate.
    Sub SampleDelegateSub()
        Dim sd As SampleDelegate = AddressOf SampleSub
        sd("Sample string")
    End Sub
End Class
```

For more information, see:

- [Delegates](#)
- [Delegate Statement](#)
- [AddressOf Operator](#)

Reflection (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Reflection provides objects (of type [Type](#)) that describe assemblies, modules and types. You can use reflection to dynamically create an instance of a type, bind the type to an existing object, or get the type from an existing object and invoke its methods or access its fields and properties. If you are using attributes in your code, reflection enables you to access them. For more information, see [Attributes](#).

Here's a simple example of reflection using the static method `GetType` - inherited by all types from the `Object` base class - to obtain the type of a variable:

```
' Using GetType to obtain type information:  
Dim i As Integer = 42  
Dim type As System.Type = i.GetType()  
System.Console.WriteLine(type)
```

The output is:

```
System.Int32
```

The following example uses reflection to obtain the full name of the loaded assembly.

```
' Using Reflection to get information from an Assembly:  
Dim info As System.Reflection.Assembly = GetType(System.Int32).Assembly  
System.Console.WriteLine(info)
```

The output is:

```
mscorlib, Version=2.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089
```

Reflection Overview

Reflection is useful in the following situations:

- When you have to access attributes in your program's metadata. For more information, see [Retrieving Information Stored in Attributes](#).
- For examining and instantiating types in an assembly.
- For building new types at runtime. Use classes in [System.Reflection.Emit](#).
- For performing late binding, accessing methods on types created at run time. See the topic [Dynamically Loading and Using Types](#).

Serialization (Visual Basic)

3/25/2019 • 3 minutes to read • [Edit Online](#)

Serialization is the process of converting an object into a stream of bytes in order to store the object or transmit it to memory, a database, or a file. Its main purpose is to save the state of an object in order to be able to recreate it when needed. The reverse process is called deserialization.

How Serialization Works

This illustration shows the overall process of serialization.

The object is serialized to a stream, which carries not just the data, but information about the object's type, such as its version, culture, and assembly name. From that stream, it can be stored in a database, a file, or memory.

Uses for Serialization

Serialization allows the developer to save the state of an object and recreate it as needed, providing storage of objects as well as data exchange. Through serialization, a developer can perform actions like sending the object to a remote application by means of a Web Service, passing an object from one domain to another, passing an object through a firewall as an XML string, or maintaining security or user-specific information across applications.

Making an Object Serializable

To serialize an object, you need the object to be serialized, a stream to contain the serialized object, and a **Formatter**. `System.Runtime.Serialization` contains the classes necessary for serializing and deserializing objects.

Apply the `SerializableAttribute` attribute to a type to indicate that instances of this type can be serialized. A `SerializationException` exception is thrown if you attempt to serialize but the type does not have the `SerializableAttribute` attribute.

If you do not want a field within your class to be serializable, apply the `NonSerializedAttribute` attribute. If a field of a serializable type contains a pointer, a handle, or some other data structure that is specific to a particular environment, and the field cannot be meaningfully reconstituted in a different environment, then you may want to make it nonserializable.

If a serialized class contains references to objects of other classes that are marked `SerializableAttribute`, those objects will also be serialized.

Binary and XML Serialization

Either binary or XML serialization can be used. In binary serialization, all members, even those that are read-only, are serialized, and performance is enhanced. XML serialization provides more readable code, as well as greater flexibility of object sharing and usage for interoperability purposes.

Binary Serialization

Binary serialization uses binary encoding to produce compact serialization for uses such as storage or socket-based network streams.

XML Serialization

XML serialization serializes the public fields and properties of an object, or the parameters and return values of methods, into an XML stream that conforms to a specific XML Schema definition language (XSD) document. XML serialization results in strongly typed classes with public properties and fields that are converted to XML.

[System.Xml.Serialization](#) contains the classes necessary for serializing and deserializing XML.

You can apply attributes to classes and class members in order to control the way the [XmlSerializer](#) serializes or deserializes an instance of the class.

Basic and Custom Serialization

Serialization can be performed in two ways, basic and custom. Basic serialization uses the .NET Framework to automatically serialize the object.

Basic Serialization

The only requirement in basic serialization is that the object has the [SerializableAttribute](#) attribute applied. The [NonSerializedAttribute](#) can be used to keep specific fields from being serialized.

When you use basic serialization, the versioning of objects may create problems, in which case custom serialization may be preferable. Basic serialization is the easiest way to perform serialization, but it does not provide much control over the process.

Custom Serialization

In custom serialization, you can specify exactly which objects will be serialized and how it will be done. The class must be marked [SerializableAttribute](#) and implement the [ISerializable](#) interface.

If you want your object to be deserialized in a custom manner as well, you must use a custom constructor.

Designer Serialization

Designer serialization is a special form of serialization that involves the kind of object persistence usually associated with development tools. Designer serialization is the process of converting an object graph into a source file that can later be used to recover the object graph. A source file can contain code, markup, or even SQL table information.

Program Structure and Code Conventions (Visual Basic)

5/4/2018 • 2 minutes to read • [Edit Online](#)

This section introduces the typical Visual Basic program structure, provides a simple Visual Basic program, "Hello, World", and discusses Visual Basic code conventions. Code conventions are suggestions that focus not on a program's logic but on its physical structure and appearance. Following them makes your code easier to read, understand, and maintain. Code conventions can include, among others:

- Standardized formats for labeling and commenting code.
- Guidelines for spacing, formatting, and indenting code.
- Naming conventions for objects, variables, and procedures.

The following topics present a set of programming guidelines for Visual Basic programs, along with examples of good usage.

In This Section

[Structure of a Visual Basic Program](#)

Provides an overview of the elements that make up a Visual Basic program.

[Main Procedure in Visual Basic](#)

Discusses the procedure that serves as the starting point and overall control for your application.

[References and the Imports Statement](#)

Discusses how to reference objects in other assemblies.

[Namespaces in Visual Basic](#)

Describes how namespaces organize objects within assemblies.

[Visual Basic Naming Conventions](#)

Includes general guidelines for naming procedures, constants, variables, arguments, and objects.

[Visual Basic Coding Conventions](#)

Reviews the guidelines used in developing the samples in this documentation.

[Conditional Compilation](#)

Describes how to compile particular blocks of code selectively while directing the compiler to ignore others.

[How to: Break and Combine Statements in Code](#)

Shows how to divide long statements into multiple lines and combine short statements on one line.

[How to: Collapse and Hide Sections of Code](#)

Shows how to collapse and hide sections of code in the Visual Basic code editor.

[How to: Label Statements](#)

Shows how to mark a line of code to identify it for use with statements such as `On Error Goto`.

[Special Characters in Code](#)

Shows how and where to use non-numeric and non-alphabetic characters.

[Comments in Code](#)

Discusses how to add descriptive comments to your code.

[Keywords as Element Names in Code](#)

Describes how to use brackets ([]) to delimit variable names that are also Visual Basic keywords.

[Me, My, MyBase, and MyClass](#)

Describes various ways to refer to elements of a Visual Basic program.

[Visual Basic Limitations](#)

Discusses the removal of known coding limits within Visual Basic.

Related Sections

[Typographic and Code Conventions](#)

Provides standard coding conventions for Visual Basic.

[Writing Code](#)

Describes features that make it easier for you to write and manage your code.

Structure of a Visual Basic Program

2/23/2019 • 3 minutes to read • [Edit Online](#)

A Visual Basic program is built up from standard building blocks. A *solution* comprises one or more projects. A *project* in turn can contain one or more assemblies. Each *assembly* is compiled from one or more source files. A *source file* provides the definition and implementation of classes, structures, modules, and interfaces, which ultimately contain all your code.

For more information about these building blocks of a Visual Basic program, see [Solutions and Projects](#) and [Assemblies in .NET](#).

File-Level Programming Elements

When you start a project or file and open the code editor, you see some code already in place and in the correct order. Any code that you write should follow the following sequence:

1. `Option` statements
2. `Imports` statements
3. `Namespace` statements and namespace-level elements

If you enter statements in a different order, compilation errors can result.

A program can also contain conditional compilation statements. You can intersperse these in the source file among the statements of the preceding sequence.

Option Statements

`Option` statements establish ground rules for subsequent code, helping prevent syntax and logic errors. The [Option Explicit Statement](#) ensures that all variables are declared and spelled correctly, which reduces debugging time. The [Option Strict Statement](#) helps to minimize logic errors and data loss that can occur when you work between variables of different data types. The [Option Compare Statement](#) specifies the way strings are compared to each other, based on either their `Binary` or `Text` values.

Imports Statements

You can include an [Imports Statement \(.NET Namespace and Type\)](#) to import names defined outside your project. An `Imports` statement allows your code to refer to classes and other types defined within the imported namespace, without having to qualify them. You can use as many `Imports` statements as appropriate. For more information, see [References and the Imports Statement](#).

Namespace Statements

Namespaces help you organize and classify your programming elements for ease of grouping and accessing. You use the [Namespace Statement](#) to classify the following statements within a particular namespace. For more information, see [Namespaces in Visual Basic](#).

Conditional Compilation Statements

Conditional compilation statements can appear almost anywhere in your source file. They cause parts of your code to be included or excluded at compile time depending on certain conditions. You can also use them for debugging your application, because conditional code runs in debugging mode only. For more information, see [Conditional Compilation](#).

Namespace-Level Programming Elements

Classes, structures, and modules contain all the code in your source file. They are *namespace-level* elements, which can appear within a namespace or at the source file level. They hold the declarations of all other programming elements. Interfaces, which define element signatures but provide no implementation, also appear at module level. For more information on the module-level elements, see the following:

- [Class Statement](#)
- [Structure Statement](#)
- [Module Statement](#)
- [Interface Statement](#)

Data elements at namespace level are enumerations and delegates.

Module-Level Programming Elements

Procedures, operators, properties, and events are the only programming elements that can hold executable code (statements that perform actions at run time). They are the *module-level* elements of your program. For more information on the procedure-level elements, see the following:

- [Function Statement](#)
- [Sub Statement](#)
- [Declare Statement](#)
- [Operator Statement](#)
- [Property Statement](#)
- [Event Statement](#)

Data elements at module level are variables, constants, enumerations, and delegates.

Procedure-Level Programming Elements

Most of the contents of *procedure-level* elements are executable statements, which constitute the run-time code of your program. All executable code must be in some procedure (`Function`, `Sub`, `Operator`, `Get`, `Set`, `AddHandler`, `RemoveHandler`, `RaiseEvent`). For more information, see [Statements](#).

Data elements at procedure level are limited to local variables and constants.

The Main Procedure

The `Main` procedure is the first code to run when your application has been loaded. `Main` serves as the starting point and overall control for your application. There are four varieties of `Main`:

- `Sub Main()`
- `Sub Main(ByVal cmdArgs() As String)`
- `Function Main() As Integer`
- `Function Main(ByVal cmdArgs() As String) As Integer`

The most common variety of this procedure is `Sub Main()`. For more information, see [Main Procedure in Visual Basic](#).

- [Visual Basic Limitations](#)

Main Procedure in Visual Basic

1/23/2019 • 3 minutes to read • [Edit Online](#)

Every Visual Basic application must contain a procedure called `Main`. This procedure serves as the starting point and overall control for your application. The .NET Framework calls your `Main` procedure when it has loaded your application and is ready to pass control to it. Unless you are creating a Windows Forms application, you must write the `Main` procedure for applications that run on their own.

`Main` contains the code that runs first. In `Main`, you can determine which form is to be loaded first when the program starts, find out if a copy of your application is already running on the system, establish a set of variables for your application, or open a database that the application requires.

Requirements for the Main Procedure

A file that runs on its own (usually with extension .exe) must contain a `Main` procedure. A library (for example with extension .dll) does not run on its own and does not require a `Main` procedure. The requirements for the different types of projects you can create are as follows:

- Console applications run on their own, and you must supply at least one `Main` procedure..
- Windows Forms applications run on their own. However, the Visual Basic compiler automatically generates a `Main` procedure in such an application, and you do not need to write one.
- Class libraries do not require a `Main` procedure. These include Windows Control Libraries and Web Control Libraries. Web applications are deployed as class libraries.

Declaring the Main Procedure

There are four ways to declare the `Main` procedure. It can take arguments or not, and it can return a value or not.

NOTE

If you declare `Main` in a class, you must use the `Shared` keyword. In a module, `Main` does not need to be `Shared`.

- The simplest way is to declare a `Sub` procedure that does not take arguments or return a value.

```
Module mainModule
    Sub Main()
        MsgBox("The Main procedure is starting the application.")
        ' Insert call to appropriate starting place in your code.
        MsgBox("The application is terminating.")
    End Sub
End Module
```

- `Main` can also return an `Integer` value, which the operating system uses as the exit code for your program. Other programs can test this code by examining the Windows ERRORLEVEL value. To return an exit code, you must declare `Main` as a `Function` procedure instead of a `Sub` procedure.

```

Module mainModule
    Function Main() As Integer
        MsgBox("The Main procedure is starting the application.")
        Dim returnValue As Integer = 0
        ' Insert call to appropriate starting place in your code.
        ' On return, assign appropriate value to returnValue.
        ' 0 usually means successful completion.
        MsgBox("The application is terminating with error level " &
            CStr(returnValue) & ".")
        Return returnValue
    End Function
End Module

```

- `Main` can also take a `String` array as an argument. Each string in the array contains one of the command-line arguments used to invoke your program. You can take different actions depending on their values.

```

Module mainModule
    Function Main(ByVal cmdArgs() As String) As Integer
        MsgBox("The Main procedure is starting the application.")
        Dim returnValue As Integer = 0
        ' See if there are any arguments.
        If cmdArgs.Length > 0 Then
            For argNum As Integer = 0 To UBound(cmdArgs, 1)
                ' Insert code to examine cmdArgs(argNum) and take
                ' appropriate action based on its value.
            Next argNum
        End If
        ' Insert call to appropriate starting place in your code.
        ' On return, assign appropriate value to returnValue.
        ' 0 usually means successful completion.
        MsgBox("The application is terminating with error level " &
            CStr(returnValue) & ".")
        Return returnValue
    End Function
End Module

```

- You can declare `Main` to examine the command-line arguments but not return an exit code, as follows.

```

Module mainModule
    Sub Main(ByVal cmdArgs() As String)
        MsgBox("The Main procedure is starting the application.")
        Dim returnValue As Integer = 0
        ' See if there are any arguments.
        If cmdArgs.Length > 0 Then
            For argNum As Integer = 0 To UBound(cmdArgs, 1)
                ' Insert code to examine cmdArgs(argNum) and take
                ' appropriate action based on its value.
            Next argNum
        End If
        ' Insert call to appropriate starting place in your code.
        MsgBox("The application is terminating.")
    End Sub
End Module

```

References and the Imports Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

You can make external objects available to your project by choosing the **Add Reference** command on the **Project** menu. References in Visual Basic can point to assemblies, which are like type libraries but contain more information.

The Imports Statement

Assemblies include one or more namespaces. When you add a reference to an assembly, you can also add an `Imports` statement to a module that controls the visibility of that assembly's namespaces within the module. The `Imports` statement provides a scoping context that lets you use only the portion of the namespace necessary to supply a unique reference.

The `Imports` statement has the following syntax:

```
Imports [Aliasname =] Namespace
```

`Aliasname` refers to a short name you can use within code to refer to an imported namespace. `Namespace` is a namespace available through either a project reference, through a definition within the project, or through a previous `Imports` statement.

A module may contain any number of `Imports` statements. They must appear after any `Option` statements, if present, but before any other code.

NOTE

Do not confuse project references with the `Imports` statement or the `Declare` statement. Project references make external objects, such as objects in assemblies, available to Visual Basic projects. The `Imports` statement is used to simplify access to project references, but does not provide access to these objects. The `Declare` statement is used to declare a reference to an external procedure in a dynamic-link library (DLL).

Using Aliases with the Imports Statement

The `Imports` statement makes it easier to access methods of classes by eliminating the need to explicitly type the fully qualified names of references. Aliases let you assign a friendlier name to just one part of a namespace. For example, the carriage return/line feed sequence that causes a single piece of text to be displayed on multiple lines is part of the `ControlChars` module in the `Microsoft.VisualBasic` namespace. To use this constant in a program without an alias, you would need to type the following code:

```
MsgBox("Some text" & Microsoft.VisualBasic.ControlChars.CrLf &
      "Some more text")
```

`Imports` statements must always be the first lines immediately following any `Option` statements in a module. The following code fragment shows how to import and assign an alias to the `Microsoft.VisualBasic.ControlChars` module:

```
Imports CtrlChrs = Microsoft.VisualBasic.ControlChars
```

Future references to this namespace can be considerably shorter:

```
MsgBox("Some text" & CtrlChrs.CrLf & "Some more text")
```

If an `Imports` statement does not include an alias name, elements defined within the imported namespace can be used in the module without qualification. If the alias name is specified, it must be used as a qualifier for names contained within that namespace.

Namespaces in Visual Basic

2/28/2019 • 5 minutes to read • [Edit Online](#)

Namespaces organize the objects defined in an assembly. Assemblies can contain multiple namespaces, which can in turn contain other namespaces. Namespaces prevent ambiguity and simplify references when using large groups of objects such as class libraries.

For example, the .NET Framework defines the `ListBox` class in the `System.Windows.Forms` namespace. The following code fragment shows how to declare a variable using the fully qualified name for this class:

```
Dim LBox As System.Windows.Forms.ListBox
```

Avoiding Name Collisions

.NET Framework namespaces address a problem sometimes called *namespace pollution*, in which the developer of a class library is hampered by the use of similar names in another library. These conflicts with existing components are sometimes called *name collisions*.

For example, if you create a new class named `ListBox`, you can use it inside your project without qualification. However, if you want to use the .NET Framework `ListBox` class in the same project, you must use a fully qualified reference to make the reference unique. If the reference is not unique, Visual Basic produces an error stating that the name is ambiguous. The following code example demonstrates how to declare these objects:

```
' Define a new object based on your ListBox class.  
Dim LBC As New ListBox  
' Define a new Windows.Forms ListBox control.  
Dim MyLB As New System.Windows.Forms.ListBox
```

The following illustration shows two namespace hierarchies, both containing an object named `ListBox`.

By default, every executable file you create with Visual Basic contains a namespace with the same name as your project. For example, if you define an object within a project named `ListBoxProject`, the executable file `ListBoxProject.exe` contains a namespace called `ListBoxProject`.

Multiple assemblies can use the same namespace. Visual Basic treats them as a single set of names. For example, you can define classes for a namespace called `SomeNameSpace` in an assembly named `Assemb1`, and define additional classes for the same namespace from an assembly named `Assemb2`.

Fully Qualified Names

Fully qualified names are object references that are prefixed with the name of the namespace in which the object is defined. You can use objects defined in other projects if you create a reference to the class (by choosing **Add Reference** from the **Project** menu) and then use the fully qualified name for the object in your code. The following code fragment shows how to use the fully qualified name for an object from another project's namespace:

```
Dim LBC As New ListBoxProject.Form1.ListBox
```

Fully qualified names prevent naming conflicts because they make it possible for the compiler to determine which object is being used. However, the names themselves can get long and cumbersome. To get around this, you can use the `Imports` statement to define an *alias*—an abbreviated name you can use in place of a fully qualified name. For example, the following code example creates aliases for two fully qualified names, and uses these aliases to define two objects.

```
Imports LBControl = System.Windows.Forms.ListBox  
Imports MyListBox = ListBoxProject.Form1.ListBox
```

```
Dim LBC As LBControl  
Dim MyLB As MyListBox
```

If you use the `Imports` statement without an alias, you can use all the names in that namespace without qualification, provided they are unique to the project. If your project contains `Imports` statements for namespaces that contain items with the same name, you must fully qualify that name when you use it. Suppose, for example, your project contained the following two `Imports` statements:

```
' This namespace contains a class called Class1.  
Imports MyProj1  
' This namespace also contains a class called Class1.  
Imports MyProj2
```

If you attempt to use `Class1` without fully qualifying it, Visual Basic produces an error stating that the name `Class1` is ambiguous.

Namespace Level Statements

Within a namespace, you can define items such as modules, interfaces, classes, delegates, enumerations, structures, and other namespaces. You cannot define items such as properties, procedures, variables and events at the namespace level. These items must be declared within containers such as modules, structures, or classes.

Global Keyword in Fully Qualified Names

If you have defined a nested hierarchy of namespaces, code inside that hierarchy might be blocked from accessing the `System` namespace of the .NET Framework. The following example illustrates a hierarchy in which the `SpecialSpace.System` namespace blocks access to `System`.

```
Namespace SpecialSpace  
    Namespace System  
        Class abc  
            Function getValue() As System.Int32  
                Dim n As System.Int32  
                Return n  
            End Function  
        End Class  
    End Namespace  
End Namespace
```

As a result, the Visual Basic compiler cannot successfully resolve the reference to `System.Int32`, because `SpecialSpace.System` does not define `Int32`. You can use the `Global` keyword to start the qualification chain at

the outermost level of the .NET Framework class library. This allows you to specify the [System](#) namespace or any other namespace in the class library. The following example illustrates this.

```
Namespace SpecialSpace
    Namespace System
        Class abc
            Function getValue() As Global.System.Int32
                Dim n As Global.System.Int32
                Return n
            End Function
        End Class
    End Namespace
End Namespace
```

You can use `Global` to access other root-level namespaces, such as [Microsoft.VisualBasic](#), and any namespace associated with your project.

Global Keyword in Namespace Statements

You can also use the `Global` keyword in a [Namespace Statement](#). This lets you define a namespace out of the root namespace of your project.

All namespaces in your project are based on the root namespace for the project. Visual Studio assigns your project name as the default root namespace for all code in your project. For example, if your project is named `ConsoleApplication1`, its programming elements belong to namespace `ConsoleApplication1`. If you declare `Namespace Magnetosphere`, references to `Magnetosphere` in the project will access `ConsoleApplication1.Magnetosphere`.

The following examples use the `Global` keyword to declare a namespace out of the root namespace for the project.

```
Namespace Global.Magnetosphere
End Namespace

Namespace Global
    Namespace Magnetosphere
        End Namespace
    End Namespace
```

In a namespace declaration, `Global` cannot be nested in another namespace.

You can use the [Application Page, Project Designer \(Visual Basic\)](#) to view and modify the **Root Namespace** of the project. For new projects, the **Root Namespace** defaults to the project name. To cause `Global` to be the top-level namespace, you can clear the **Root Namespace** entry so that the box is empty. Clearing **Root Namespace** removes the need for the `Global` keyword in namespace declarations.

If a `Namespace` statement declares a name that is also a namespace in the .NET Framework, the .NET Framework namespace becomes unavailable if the `Global` keyword is not used in a fully qualified name. To enable access to that .NET Framework namespace without using the `Global` keyword, you can include the `Global` keyword in the `Namespace` statement.

The following example has the `Global` keyword in the `System.Text` namespace declaration.

If the `Global` keyword was not present in the namespace declaration, [StringBuilder](#) could not be accessed without specifying `Global.System.Text.StringBuilder`. For a project named `ConsoleApplication1`, references to

`System.Text` would access `ConsoleApplication1.System.Text` if the `Global` keyword was not used.

```
Module Module1
    Sub Main()
        Dim encoding As New System.Text.TitanEncoding

        ' If the namespace defined below is System.Text
        ' instead of Global.System.Text, then this statement
        ' causes a compile-time error.
        Dim sb As New System.Text.StringBuilder
    End Sub
End Module

Namespace Global.System.Text
    Class TitanEncoding

    End Class
End Namespace
```

Visual Basic Naming Conventions

1/23/2019 • 2 minutes to read • [Edit Online](#)

When you name an element in your Visual Basic application, the first character of that name must be an alphabetic character or an underscore. Note, however, that names beginning with an underscore are not compliant with the [Language Independence and Language-Independent Components \(CLS\)](#).

The following suggestions apply to naming.

- Begin each separate word in a name with a capital letter, as in `FindLastRecord` and `RedrawMyForm`.
- Begin function and method names with a verb, as in `InitNameArray` or `CloseDialog`.
- Begin class, structure, module, and property names with a noun, as in `EmployeeName` or `CarAccessory`.
- Begin interface names with the prefix "I", followed by a noun or a noun phrase, like `IComponent`, or with an adjective describing the interface's behavior, like `IPersistable`. Do not use the underscore, and use abbreviations sparingly, because abbreviations can cause confusion.
- Begin event handler names with a noun describing the type of event followed by the "`EventHandler`" suffix, as in "`MouseEventHandler`".
- In names of event argument classes, include the "`EventArgs`" suffix.
- If an event has a concept of "before" or "after," use a suffix in present or past tense, as in '`ControlAdd`' or "`ControlAdded`".
- For long or frequently used terms, use abbreviations to keep name lengths reasonable, for example, "HTML", instead of "Hypertext Markup Language". In general, variable names greater than 32 characters are difficult to read on a monitor set to a low resolution. Also, make sure your abbreviations are consistent throughout the entire application. Randomly switching in a project between "HTML" and "Hypertext Markup Language" can lead to confusion.
- Avoid using names in an inner scope that are the same as names in an outer scope. Errors can result if the wrong variable is accessed. If a conflict occurs between a variable and the keyword of the same name, you must identify the keyword by preceding it with the appropriate type library. For example, if you have a variable called `Date`, you can use the intrinsic `Date` function only by calling `DateTime.Date`.

Visual Basic Coding Conventions

3/1/2019 • 6 minutes to read • [Edit Online](#)

Microsoft develops samples and documentation that follow the guidelines in this topic. If you follow the same coding conventions, you may gain the following benefits:

- Your code will have a consistent look, so that readers can better focus on content, not layout.
- Readers understand your code more quickly because they can make assumptions based on previous experience.
- You can copy, change, and maintain the code more easily.
- You help ensure that your code demonstrates "best practices" for Visual Basic.

Naming Conventions

- For information about naming guidelines, see [Naming Guidelines](#) topic.
- Do not use "My" or "my" as part of a variable name. This practice creates confusion with the `My` objects.
- You do not have to change the names of objects in auto-generated code to make them fit the guidelines.

Layout Conventions

- Insert tabs as spaces, and use smart indenting with four-space indents.
- Use **Pretty listing (reformatting) of code** to reformat your code in the code editor. For more information, see [Options, Text Editor, Basic \(Visual Basic\)](#).
- Use only one statement per line. Don't use the Visual Basic line separator character (:).
- Avoid using the explicit line continuation character "\_" in favor of implicit line continuation wherever the language allows it.
- Use only one declaration per line.
- If **Pretty listing (reformatting) of code** doesn't format continuation lines automatically, manually indent continuation lines one tab stop. However, always left-align items in a list.

```
a As Integer,  
b As Integer
```

- Add at least one blank line between method and property definitions.

Commenting Conventions

- Put comments on a separate line instead of at the end of a line of code.
- Start comment text with an uppercase letter, and end comment text with a period.
- Insert one space between the comment delimiter ('') and the comment text.

```
' Here is a comment.
```

- Do not surround comments with formatted blocks of asterisks.

Program Structure

- When you use the `Main` method, use the default construct for new console applications, and use `My` for command-line arguments.

```
Sub Main()
    For Each argument As String In My.Application.CommandLineArgs
        ' Add code here to use the string variable.
    Next
End Sub
```

Language Guidelines

String Data Type

- To concatenate strings, use an ampersand (&).

```
MsgBox("hello" & vbCrLf & "goodbye")
```

- To append strings in loops, use the `StringBuilder` object.

```
Dim longString As New System.Text.StringBuilder
For count As Integer = 1 To 1000
    longString.Append(count)
Next
```

Relaxed Delegates in Event Handlers

Do not explicitly qualify the arguments (Object and EventArgs) to event handlers. If you are not using the event arguments that are passed to an event (for example, sender as Object, e as EventArgs), use relaxed delegates, and leave out the event arguments in your code:

```
Public Sub Form1_Load() Handles Form1.Load
End Sub
```

Unsigned Data Type

- Use `Integer` rather than unsigned types, except where they are necessary.

Arrays

- Use the short syntax when you initialize arrays on the declaration line. For example, use the following syntax.

```
Dim letters1 As String() = {"a", "b", "c"}
```

Do not use the following syntax.

```
Dim letters2() As String = New String() {"a", "b", "c"}
```

- Put the array designator on the type, not on the variable. For example, use the following syntax:

```
Dim letters4 As String() = {"a", "b", "c"}
```

Do not use the following syntax:

```
Dim letters3() As String = {"a", "b", "c"}
```

- Use the {} syntax when you declare and initialize arrays of basic data types. For example, use the following syntax:

```
Dim letters5 As String() = {"a", "b", "c"}
```

Do not use the following syntax:

```
Dim letters6(2) As String  
letters6(0) = "a"  
letters6(1) = "b"  
letters6(2) = "c"
```

Use the With Keyword

When you make a series of calls to one object, consider using the `With` keyword:

```
With orderLog  
    .Log = "Application"  
    .Source = "Application Name"  
    .MachineName = "Computer Name"  
End With
```

Use the Try...Catch and Using Statements when you use Exception Handling

Do not use `On Error Goto`.

Use the IsNot Keyword

Use the `IsNot` keyword instead of `Not...Is Nothing`.

New Keyword

- Use short instantiation. For example, use the following syntax:

```
Dim employees As New List(Of String)
```

The preceding line is equivalent to this:

```
Dim employees2 As List(Of String) = New List(Of String)
```

- Use object initializers for new objects instead of the parameterless constructor:

```
Dim orderLog As New EventLog With {  
    .Log = "Application",  
    .Source = "Application Name",  
    .MachineName = "Computer Name"}
```

Event Handling

- Use `Handles` rather than `AddHandler`:

```
Private Sub ToolStripMenuItem1_Click() Handles ToolStripMenuItem1.Click
End Sub
```

- Use `AddressOf`, and do not instantiate the delegate explicitly:

```
Dim closeItem As New ToolStripMenuItem(
    "Close", Nothing, AddressOf ToolStripMenuItem1_Click)
Me.MainMenuStrip.Items.Add(closeItem)
```

- When you define an event, use the short syntax, and let the compiler define the delegate:

```
Public Event SampleEvent As EventHandler(Of SampleEventArgs)
' or
Public Event SampleEvent(ByVal source As Object,
    ByVal e As SampleEventArgs)
```

- Do not verify whether an event is `Nothing` (null) before you call the `RaiseEvent` method. `RaiseEvent` checks for `Nothing` before it raises the event.

Using Shared Members

Call `Shared` members by using the class name, not from an instance variable.

Use XML Literals

XML literals simplify the most common tasks that you encounter when you work with XML (for example, load, query, and transform). When you develop with XML, follow these guidelines:

- Use XML literals to create XML documents and fragments instead of calling XML APIs directly.
- Import XML namespaces at the file or project level to take advantage of the performance optimizations for XML literals.
- Use the XML axis properties to access elements and attributes in an XML document.
- Use embedded expressions to include values and to create XML from existing values instead of using API calls such as the `Add` method:

```

Private Function GetHtmlDocument(
    ByVal items As IEnumerable(Of XElement)) As String

    Dim htmlDoc = <html>
        <body>
            <table border="0" cellspacing="2">
                <%=
                    From item In items
                    Select <tr>
                        <td style="width:480">
                            <%= item.<title>.Value %>
                        </td>
                        <td><%= item.<pubDate>.Value %></td>
                    </tr>
                %>
            </table>
        </body>
    </html>

    Return htmlDoc.ToString()
End Function

```

LINQ Queries

- Use meaningful names for query variables:

```

Dim seattleCustomers = From cust In customers
    Where cust.City = "Seattle"

```

- Provide names for elements in a query to make sure that property names of anonymous types are correctly capitalized using Pascal casing:

```

Dim customerOrders = From customer In customers
    Join order In orders
        On customer.CustomerID Equals order.CustomerID
    Select Customer = customer, Order = order

```

- Rename properties when the property names in the result would be ambiguous. For example, if your query returns a customer name and an order ID, rename them instead of leaving them as `Name` and `ID` in the result:

```

Dim customerOrders2 = From cust In customers
    Join ord In orders
        On cust.CustomerID Equals ord.CustomerID
    Select CustomerName = cust.Name,
        OrderID = ord.ID

```

- Use type inference in the declaration of query variables and range variables:

```

Dim customerList = From cust In customers

```

- Align query clauses under the `From` statement:

```

Dim newyorkCustomers = From cust In customers
    Where cust.City = "New York"
    Select cust.LastName, cust.CompanyName

```

- Use `Where` clauses before other query clauses so that later query clauses operate on the filtered set of data:

```
Dim newyorkCustomers2 = From cust In customers
    Where cust.City = "New York"
    Order By cust.LastName
```

- Use the `Join` clause to explicitly define a join operation instead of using the `Where` clause to implicitly define a join operation:

```
Dim customerList2 = From cust In customers
    Join order In orders
        On cust.CustomerID Equals order.CustomerID
    Select cust, order
```

Conditional Compilation in Visual Basic

2/28/2019 • 2 minutes to read • [Edit Online](#)

In *conditional compilation*, particular blocks of code in a program are compiled selectively while others are ignored.

For example, you may want to write debugging statements that compare the speed of different approaches to the same programming task, or you may want to localize an application for multiple languages. Conditional compilation statements are designed to run during compile time, not at run time.

You denote blocks of code to be conditionally compiled with the `#If...Then...#Else` directive. For example, to create French- and German-language versions of the same application from the same source code, you embed platform-specific code segments in `#If...Then` statements using the predefined constants `FrenchVersion` and `GermanVersion`. The following example demonstrates how:

```
#If FrenchVersion Then
    ' <code specific to the French language version>.
#ElseIf GermanVersion Then
    ' <code specific to the German language version>.
#Else
    ' <code specific to other versions>.
#End If
```

If you set the value of the `FrenchVersion` conditional compilation constant to `True` at compile time, the conditional code for the French version is compiled. If you set the value of the `GermanVersion` constant to `True`, the compiler uses the German version. If neither is set to `True`, the code in the last `Else` block runs.

NOTE

Autocompletion will not function when editing code and using conditional compilation directives if the code is not part of the current branch.

Declaring Conditional Compilation Constants

You can set conditional compilation constants in one of three ways:

- In the **Project Designer**
- At the command line when using the command-line compiler
- In your code

Conditional compilation constants have a special scope and cannot be accessed from standard code. The scope of a conditional compilation constant is dependent on the way it is set. The following table lists the scope of constants declared using each of the three ways mentioned above.

HOW CONSTANT IS SET	SCOPE OF CONSTANT
Project Designer	Public to all files in the project
Command line	Public to all files passed to the command-line compiler

HOW CONSTANT IS SET	SCOPE OF CONSTANT
#Const statement in code	Private to the file in which it is declared
TO SET CONSTANTS IN THE PROJECT DESIGNER	
- Before creating your executable file, set constants in the Project Designer by following the steps provided in Managing Project and Solution Properties .	
TO SET CONSTANTS AT THE COMMAND LINE	
<p>- Use the /d switch to enter conditional compilation constants, as in the following example:</p> <pre>vbc MyProj.vb /d:conFrenchVersion=-1:conANSI=0</pre> <p>No space is required between the /d switch and the first constant. For more information, see /define (Visual Basic). Command-line declarations override declarations entered in the Project Designer, but do not erase them. Arguments set in Project Designer remain in effect for subsequent compilations.</p> <p>When writing constants in the code itself, there are no strict rules as to their placement, since their scope is the entire module in which they are declared.</p>	
TO SET CONSTANTS IN YOUR CODE	
<p>- Place the constants in the declaration block of the module in which they are used. This helps keep your code organized and easier to read.</p>

How to: Break and Combine Statements in Code (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

When writing your code, you might at times create lengthy statements that necessitate horizontal scrolling in the Code Editor. Although this doesn't affect the way your code runs, it makes it difficult for you or anyone else to read the code as it appears on the monitor. In such cases, you should consider breaking the single long statement into several lines.

To break a single statement into multiple lines

- Use the line-continuation character, which is an underscore (`_`), at the point at which you want the line to break. The underscore must be immediately preceded by a space and immediately followed by a line terminator (carriage return).

NOTE

In some cases, if you omit the line-continuation character, the Visual Basic compiler will implicitly continue the statement on the next line of code. For a list of syntax elements for which you can omit the line-continuation character, see "Implicit Line Continuation" in [Statements](#).

In the following example, the statement is broken into four lines with line-continuation characters terminating all but the last line.

```
cmd.CommandText = _  
    "SELECT * FROM Titles JOIN Publishers " _  
    & "ON Publishers.PubId = Titles.PubID " _  
    & "WHERE Publishers.State = 'CA'"
```

Using this sequence makes your code easier to read, both online and when printed.

The line-continuation character must be the last character on a line. You can't follow it with anything else on the same line.

Some limitations exist as to where you can use the line-continuation character; for example, you can't use it in the middle of an argument name. You can break an argument list with the line-continuation character, but the individual names of the arguments must remain intact.

You can't continue a comment by using a line-continuation character. The compiler doesn't examine the characters in a comment for special meaning. For a multiple-line comment, repeat the comment symbol (`'`) on each line.

Although placing each statement on a separate line is the recommended method, Visual Basic also allows you to place multiple statements on the same line.

To place multiple statements on the same line

- Separate the statements with a colon (`:`), as in the following example.

```
text1.Text = "Hello" : text1.BackColor = System.Drawing.Color.Red
```

- [Statements](#)

How to: Collapse and Hide Sections of Code (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

The `#Region` directive enables you to collapse and hide sections of code in Visual Basic files. The `#Region` directive lets you specify a block of code that you can expand or collapse when using the Visual Studio code editor. The ability to hide code selectively makes your files more manageable and easier to read. For more information, see [Outlining](#).

`#Region` directives support code block semantics such as `#If...#End If`. This means they cannot begin in one block and end in another; the start and end must be in the same block. `#Region` directives are not supported within functions.

To collapse and hide a section of code

- Place the section of code between the `#Region` and `#End Region` statements, as in the following example:

```
#Region "This is the code to be collapsed"
    Private components As System.ComponentModel.Container
    Dim WithEvents Form1 As System.Windows.Forms.Form

    Private Sub InitializeComponent()
        components = New System.ComponentModel.Container
        Me.Text = "Form1"
    End Sub
#End Region
```

The `#Region` block can be used multiple times in a code file; thus, users can define their own blocks of procedures and classes that can, in turn, be collapsed. `#Region` blocks can also be nested within other `#Region` blocks.

NOTE

Hiding code does not prevent it from being compiled and does not affect `#If...#End If` statements.

- [Conditional Compilation](#)
- [#Region Directive](#)
- [#If...Then...#Else Directives](#)
- [Outlining](#)

How to: Label Statements (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Statement blocks are made up of lines of code delimited by colons. Lines of code preceded by an identifying string or integer are said to be *labeled*. Statement labels are used to mark a line of code to identify it for use with statements such as `On Error Goto`.

Labels may be either valid Visual Basic identifiers—such as those that identify programming elements—or integer literals. A label must appear at the beginning of a line of source code and must be followed by a colon, regardless of whether it is followed by a statement on the same line.

The compiler identifies labels by checking whether the beginning of the line matches any already-defined identifier. If it does not, the compiler assumes it is a label.

Labels have their own declaration space and do not interfere with other identifiers. A label's scope is the body of the method. Label declaration takes precedence in any ambiguous situation.

NOTE

Labels can be used only on executable statements inside methods.

To label a line of code

- Place an identifier, followed by a colon, at the beginning of the line of source code.

For example, the following lines of code are labeled with `Jump` and `120`, respectively:

```
Jump:  FileOpen(1, "testFile", OpenMode.Input)
      ' ...
120:   FileClose(1)
```

Special Characters in Code (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Sometimes you have to use special characters in your code, that is, characters that are not alphabetical or numeric. The punctuation and special characters in the Visual Basic character set have various uses, from organizing program text to defining the tasks that the compiler or the compiled program performs. They do not specify an operation to be performed.

Parentheses

Use parentheses when you define a procedure, such as a `Sub` or `Function`. You must enclose all procedure argument lists in parentheses. You also use parentheses for putting variables or arguments into logical groups, especially to override the default order of operator precedence in a complex expression. The following example illustrates this.

```
Dim a, b, c, d, e As Double
a = 3.2
b = 7.6
c = 2
d = b + c / a
e = (b + c) / a
```

Following execution of the previous code, the value of `d` is 8.225 and the value of `e` is 3. The calculation for `d` uses the default precedence of `/` over `+` and is equivalent to `d = b + (c / a)`. The parentheses in the calculation for `e` override the default precedence.

Separators

Separators do what their name suggests: they separate sections of code. In Visual Basic, the separator character is the colon (`:`). Use separators when you want to include multiple statements on a single line instead of separate lines. This saves space and improves the readability of your code. The following example shows three statements separated by colons.

```
a = 3.2 : b = 7.6 : c = 2
```

For more information, see [How to: Break and Combine Statements in Code](#).

The colon (`:`) character is also used to identify a statement label. For more information, see [How to: Label Statements](#).

Concatenation

Use the `&` operator for *concatenation*, or linking strings together. Do not confuse it with the `+` operator, which adds together numeric values. If you use the `+` operator to concatenate when you operate on numeric values, you can obtain incorrect results. The following example demonstrates this.

```
var1 = "10.01"
var2 = 11
resultA = var1 + var2
resultB = var1 & var2
```

Following execution of the previous code, the value of `resultA` is 21.01 and the value of `resultB` is "10.0111".

Member Access Operators

To access a member of a type, you use the dot (.) or exclamation point (!) operator between the type name and the member name.

Dot (.) Operator

Use the . operator on a class, structure, interface, or enumeration as a member access operator. The member can be a field, property, event, or method. The following example illustrates this.

```
Dim nextForm As New System.Windows.Forms.Form
' Access Text member (property) of Form class (on nextForm object).
nextForm.Text = "This is the next form"
' Access Close member (method) on nextForm.
nextForm.Close()
```

Exclamation Point (!) Operator

Use the ! operator only on a class or interface as a dictionary access operator. The class or interface must have a default property that accepts a single `String` argument. The identifier immediately following the ! operator becomes the argument value passed to the default property as a string. The following example demonstrates this.

```
Public Class hasDefault
    Default Public ReadOnly Property index(ByVal s As String) As Integer
        Get
            Return 32768 + AscW(s)
        End Get
    End Property
End Class
Public Class testHasDefault
    Public Sub compareAccess()
        Dim hD As hasDefault = New hasDefault()
        MsgBox("Traditional access returns " & hD.index("X") & vbCrLf &
               "Default property access returns " & hD("X") & vbCrLf &
               "Dictionary access returns " & hD!X)
    End Sub
End Class
```

The three output lines of `MsgBox` all display the value 32856. The first line uses the traditional access to property `index`, the second makes use of the fact that `index` is the default property of class `hasDefault`, and the third uses dictionary access to the class.

Note that the second operand of the ! operator must be a valid Visual Basic identifier not enclosed in double quotation marks (""). In other words, you cannot use a string literal or string variable. The following change to the last line of the `MsgBox` call generates an error because "x" is an enclosed string literal.

```
"Dictionary access returns " & hD!"X")
```

NOTE

References to default collections must be explicit. In particular, you cannot use the `!` operator on a late-bound variable.

The `!` character is also used as the `Single` type character.

- [Type Characters](#)

Comments in Code (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

As you read the code examples, you often encounter the comment symbol (''). This symbol tells the Visual Basic compiler to ignore the text following it, or the *comment*. Comments are brief explanatory notes added to code for the benefit of those reading it.

It is good programming practice to begin all procedures with a brief comment describing the functional characteristics of the procedure (what it does). This is for your own benefit and the benefit of anyone else who examines the code. You should separate the implementation details (how the procedure does it) from comments that describe the functional characteristics. When you include implementation details in the description, remember to update them when you update the function.

Comments can follow a statement on the same line, or occupy an entire line. Both are illustrated in the following code.

```
' This is a comment beginning at the left edge of the screen.  
text1.Text = "Hi!"    ' This is an inline comment.
```

If your comment requires more than one line, use the comment symbol on each line, as the following example illustrates.

```
' This comment is too long to fit on a single line, so we break  
' it into two lines. Some comments might need three or more lines.
```

Commenting Guidelines

The following table provides general guidelines for what types of comments can precede a section of code. These are suggestions; Visual Basic does not enforce rules for adding comments. Write what works best, both for you and for anyone else who reads your code.

Comment type	Comment description
Purpose	Describes what the procedure does (not how it does it)
Assumptions	Lists each external variable, control, open file, or other element accessed by the procedure
Effects	Lists each affected external variable, control, or file, and the effect it has (only if it is not obvious)
Inputs	Specifies the purpose of the argument
Returns	Explains the values returned by the procedure

Remember the following points:

- Every important variable declaration should be preceded by a comment describing the use of the variable being declared.

- Variables, controls, and procedures should be named clearly enough that commenting is needed only for complex implementation details.
- Comments cannot follow a line-continuation sequence on the same line.

You can add or remove comment symbols for a block of code by selecting one or more lines of code and choosing the **Comment** () and **Uncomment** () buttons on the **Edit** toolbar.

NOTE

You can also add comments to your code by preceding the text with the `REM` keyword. However, the `'` symbol and the **Comment/Uncomment** buttons are easier to use and require less space and memory.

Keywords as Element Names in Code (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Any program element — such as a variable, class, or member — can have the same name as a restricted keyword. For example, you can create a variable named `Loop`. However, to refer to your version of it — which has the same name as the restricted `Loop` keyword — you must either precede it with a full qualification string or enclose it in square brackets (`[]`), as the following example shows.

```
' The following statement precedes Loop with a full qualification string.  
sampleFormLoop.Visible = True  
' The following statement encloses Loop in square brackets.  
[Loop].Visible = True
```

If you do not do either of these, then Visual Basic assumes use of the intrinsic `Loop` keyword and produces an error, as in the following example:

```
' The following statement causes a compiler error.  
  
Loop.Visible = True
```

You can use square brackets when referring to forms and controls, and when declaring a variable or defining a procedure with the same name as a restricted keyword. It can be easy to forget to qualify names or include square brackets, and thus introduce errors into your code and make it harder to read. For this reason, we recommend that you not use restricted keywords as the names of program elements. However, if a future version of Visual Basic defines a new keyword that conflicts with an existing form or control name, then you can use this technique when updating your code to work with the new version.

NOTE

Your program also might include element names provided by other referenced assemblies. If these names conflict with restricted keywords, then placing square brackets around them causes Visual Basic to interpret them as your defined elements.

Me, My, MyBase, and MyClass in Visual Basic

1/23/2019 • 2 minutes to read • [Edit Online](#)

`Me`, `My`, `MyBase`, and `MyClass` in Visual Basic have similar names, but different purposes. This topic describes each of these entities in order to distinguish them.

Me

The `Me` keyword provides a way to refer to the specific instance of a class or structure in which the code is currently executing. `Me` behaves like either an object variable or a structure variable referring to the current instance. Using `Me` is particularly useful for passing information about the currently executing instance of a class or structure to a procedure in another class, structure, or module.

For example, suppose you have the following procedure in a module.

```
Sub ChangeFormColor(FormName As Form)
    Randomize()
    FormName.BackColor = Color.FromArgb(Rnd() * 256, Rnd() * 256, Rnd() * 256)
End Sub
```

You can call this procedure and pass the current instance of the `Form` class as an argument by using the following statement.

```
ChangeFormColor(Me)
```

My

The `My` feature provides easy and intuitive access to a number of .NET Framework classes, enabling the Visual Basic user to interact with the computer, application, settings, resources, and so on.

MyBase

The `MyBase` keyword behaves like an object variable referring to the base class of the current instance of a class. `MyBase` is commonly used to access base class members that are overridden or shadowed in a derived class. `MyBase.New` is used to explicitly call a base class constructor from a derived class constructor.

MyClass

The `MyClass` keyword behaves like an object variable referring to the current instance of a class as originally implemented. `Myclass` is similar to `Me`, but all method calls on it are treated as if the method were `NotOverridable`.

Visual Basic Limitations

1/23/2019 • 2 minutes to read • [Edit Online](#)

Earlier versions of Visual Basic enforced boundaries in code, such as the length of variable names, the number of variables allowed in modules, and module size. In Visual Basic .NET, these restrictions have been relaxed, giving you greater freedom in writing and arranging your code.

Physical limits are dependent more on run-time memory than on compile-time considerations. If you use prudent programming practices, and divide large applications into multiple classes and modules, then there is very little chance of encountering an internal Visual Basic limitation.

The following are some limitations that you might encounter in extreme cases:

- **Name Length.** There is a maximum number of characters for the name of every declared programming element. This maximum applies to an entire qualification string if the element name is qualified. See [Declared Element Names](#).
- **Line Length.** There is a maximum of 65535 characters in a physical line of source code. The logical source code line can be longer if you use line continuation characters. See [How to: Break and Combine Statements in Code](#).
- **Array Dimensions.** There is a maximum number of dimensions you can declare for an array. This limits how many indexes you can use to specify an array element. See [Array Dimensions in Visual Basic](#).
- **String Length.** There is a maximum number of Unicode characters you can store in a single string. See [String Data Type](#).
- **Environment String Length.** There is a maximum of 32768 characters for any environment string used as a command-line argument. This is a limitation on all platforms.

Visual Basic Language Features

9/7/2018 • 2 minutes to read • [Edit Online](#)

The following topics introduce and discuss the essential components of Visual Basic, an object-oriented programming language. After creating the user interface for your application using forms and controls, you need to write the code that defines the application's behavior. As with any modern programming language, Visual Basic supports a number of common programming constructs and language elements.

If you have programmed in other languages, much of the material covered in this section might seem familiar. While most of the constructs are similar to those in other languages, the event-driven nature of Visual Basic introduces some subtle differences.

If you are new to programming, the material in this section serves as an introduction to the basic building blocks for writing code. Once you understand the basics, you can create powerful applications using Visual Basic.

In This Section

[Arrays](#)

Discusses making your code more compact and powerful by declaring and using arrays, which hold multiple related values.

[Collection Initializers](#)

Describes collection initializers, which enable you to create a collection and populate it with an initial set of values.

[Constants and Enumerations](#)

Discusses storing unchanging values for repeated use, including sets of related constant values.

[Control Flow](#)

Shows how to regulate the flow of your program's execution.

[Data Types](#)

Describes what kinds of data a programming element can hold and how that data is stored.

[Declared Elements](#)

Covers programming elements you can declare, their names and characteristics, and how the compiler resolves references to them.

[Delegates](#)

Provides an introduction to delegates and how they are used in Visual Basic.

[Early and Late Binding](#)

Describes binding, which is performed by the compiler when an object is assigned to an object variable, and the differences between early-bound and late-bound objects.

[Error Types](#)

Provides an overview of syntax errors, run-time errors, and logic errors.

[Events](#)

Shows how to declare and use events.

[Interfaces](#)

Describes what interfaces are and how you can use them in your applications.

[LINQ](#)

Provides links to topics that introduce Language-Integrated Query (LINQ) features and programming.

[Objects and Classes](#)

Provides an overview of objects and classes, how they are used, their relationships to each other, and the properties, methods, and events they expose.

[Operators and Expressions](#)

Describes the code elements that manipulate value-holding elements, how to use them efficiently, and how to combine them to yield new values.

[Procedures](#)

Describes `Sub`, `Function`, `Property`, and `Operator` procedures, as well as advanced topics such as recursive and overloaded procedures.

[Statements](#)

Describes declaration and executable statements.

[Strings](#)

Provides links to topics that describe the basic concepts about using strings in Visual Basic.

[Variables](#)

Introduces variables and describes how to use them in Visual Basic.

[XML](#)

Provides links to topics that describe how to use XML in Visual Basic.

Related Sections

[Collections](#)

Describes some of the types of collections that are provided by the .NET Framework. Demonstrates how to use simple collections and collections of key/value pairs.

[Visual Basic Language Reference](#)

Provides reference information on various aspects of Visual Basic programming.

Arrays in Visual Basic

3/5/2019 • 28 minutes to read • [Edit Online](#)

An array is a set of values, which are termed *elements*, that are logically related to each other. For example, an array may consist of the number of students in each grade in a grammar school; each element of the array is the number of students in a single grade. Similarly, an array may consist of a student's grades for a class; each element of the array is a single grade.

It is possible individual variables to store each of our data items. For example, if our application analyzes student grades, we can use a separate variable for each student's grade, such as `englishGrade1`, `englishGrade2`, etc. This approach has three major limitations:

- We have to know at design time exactly how many grades we have to handle.
- Handling large numbers of grades quickly becomes unwieldy. This in turn makes an application much more likely to have serious bugs.
- It is difficult to maintain. Each new grade that we add requires that the application be modified, recompiled, and redeployed.

By using an array, you can refer to these related values by the same name, and use a number that's called an *index* or *subscript* to identify an individual element based on its position in the array. The indexes of an array range from 0 to one less than the total number of elements in the array. When you use Visual Basic syntax to define the size of an array, you specify its highest index, not the total number of elements in the array. You can work with the array as a unit, and the ability to iterate its elements frees you from needing to know exactly how many elements it contains at design time.

Some quick examples before explanation:

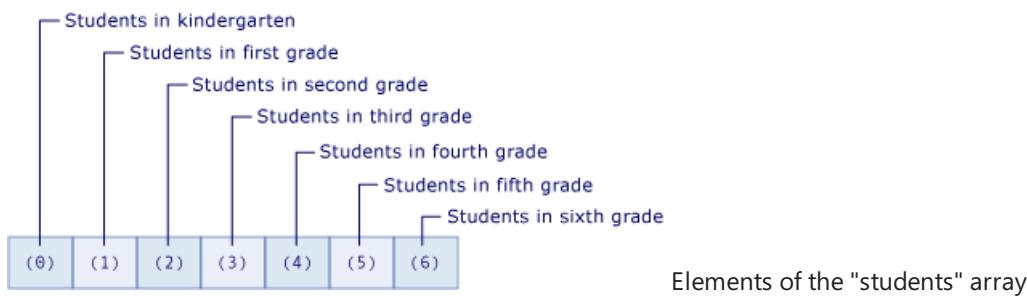

```
' Declare a single-dimension array of 5 numbers.  
Dim numbers(4) As Integer  
  
' Declare a single-dimension array and set its 4 values.  
Dim numbers = New Integer() {1, 2, 4, 8}  
  
' Change the size of an existing array to 16 elements and retain the current values.  
ReDim Preserve numbers(15)  
  
' Redefine the size of an existing array and reset the values.  
ReDim numbers(15)  
  
' Declare a 6 x 6 multidimensional array.  
Dim matrix(5, 5) As Double  
  
' Declare a 4 x 3 multidimensional array and set array element values.  
Dim matrix = New Integer(3, 2) {{1, 2, 3}, {2, 3, 4}, {3, 4, 5}, {4, 5, 6}}  
  
' Declare a jagged array  
Dim sales()() As Double = New Double(11)() {}
```

Array elements in a simple array

Let's create an array named `students` to store the number of students in each grade in a grammar school. The indexes of the elements range from 0 through 6. Using this array is simpler than declaring seven variables.

The following illustration shows the `students` array. For each element of the array:

- The index of the element represents the grade (index 0 represents kindergarten).
- The value that's contained in the element represents the number of students in that grade.

The following example contains the Visual Basic code that creates and uses the array:

```

Module SimpleArray
    Public Sub Main()
        ' Declare an array with 7 elements.
        Dim students(6) As Integer

        ' Assign values to each element.
        students(0) = 23
        students(1) = 19
        students(2) = 21
        students(3) = 17
        students(4) = 19
        students(5) = 20
        students(6) = 22

        ' Display the value of each element.
        For ctr As Integer = 0 To 6
            Dim grade As String = If(ctr = 0, "kindergarten", $"grade {ctr}")
            Console.WriteLine($"Students in {grade}: {students(ctr)}")
        Next
    End Sub
End Module
' The example displays the following output:
'   Students in kindergarten: 23
'   Students in grade 1: 19
'   Students in grade 2: 21
'   Students in grade 3: 17
'   Students in grade 4: 19
'   Students in grade 5: 20
'   Students in grade 6: 22

```

The example does three things:

- It declares a `students` array with seven elements. The number `6` in the array declaration indicates the last index in the array; it is one less than the number of elements in the array.
- It assigns values to each element in the array. Array elements are accessed by using the array name and including the index of the individual element in parentheses.
- It lists each value of the array. The example uses a `For` statement to access each element of the array by its index number.

The `students` array in the preceding example is a one-dimensional array because it uses one index. An array that uses more than one index or subscript is called *multidimensional*. For more information, see the rest of this article and [Array Dimensions in Visual Basic](#).

Creating an array

You can define the size of an array in several ways:

- You can specify the size when the array is declared:

```
' Declare an array with 10 elements.  
Dim cargoWeights(9) As Double  
' Declare a 24 x 2 array.  
Dim hourlyTemperatures(23, 1) As Integer  
' Declare a jagged array with 31 elements.  
Dim januaryInquiries(30)() As String
```

- You can use a `New` clause to supply the size of an array when it's created:

```
' Declare an array with 10 elements.  
Dim cargoWeights() As Double = New Double(9) {}  
' Declare a 24 x 2 array.  
Dim hourlyTemperatures(,) As Integer = New Integer(23, 1) {}  
' Declare a jagged array with 31 elements.  
Dim januaryInquiries()() As String = New String(30)() {}
```

If you have an existing array, you can redefine its size by using the `ReDim` statement. You can specify that the `ReDim` statement keep the values that are in the array, or you can specify that it create an empty array. The following example shows different uses of the `ReDim` statement to modify the size of an existing array.

```
' Assign a new array size and retain the current values.  
ReDim Preserve cargoWeights(20)  
' Assign a new array size and retain only the first five values.  
ReDim Preserve cargoWeights(4)  
' Assign a new array size and discard all current element values.  
ReDim cargoWeights(15)
```

For more information, see the [ReDim Statement](#).

Storing values in an array

You can access each location in an array by using an index of type `Integer`. You can store and retrieve values in an array by referencing each array location by using its index enclosed in parentheses. Indexes for multidimensional arrays are separated by commas (,). You need one index for each array dimension.

The following example shows some statements that store and retrieve values in arrays.

```

Module Example
    Public Sub Main()
        ' Create a 10-element integer array.
        Dim numbers(9) As Integer
        Dim value As Integer = 2

        ' Write values to it.
        For ctr As Integer = 0 To 9
            numbers(ctr) = value
            value *= 2
        Next

        ' Read and sum the array values.
        Dim sum As Integer
        For ctr As Integer = 0 To 9
            sum += numbers(ctr)
        Next
        Console.WriteLine($"The sum of the values is {sum:N0}")
    End Sub
End Module
' The example displays the following output:
'   The sum of the values is 2,046

```

Populating an array with array literals

By using an array literal, you can populate an array with an initial set of values at the same time that you create it. An array literal consists of a list of comma-separated values that are enclosed in braces ({}).

When you create an array by using an array literal, you can either supply the array type or use type inference to determine the array type. The following example shows both options.

```

' Array literals with explicit type definition.
Dim numbers = New Integer() {1, 2, 4, 8}
' Array literals with type inference.
Dim doubles = {1.5, 2, 9.9, 18}
' Array literals with explicit type definition.
Dim articles() As String = { "the", "a", "an" }

' Array literals with explicit widening type definition.
Dim values() As Double = { 1, 2, 3, 4, 5 }

```

When you use type inference, the type of the array is determined by the *dominant type* in the list of literal values. The dominant type is the type to which all other types in the array can widen. If this unique type can't be determined, the dominant type is the unique type to which all other types in the array can narrow. If neither of these unique types can be determined, the dominant type is `Object`. For example, if the list of values that's supplied to the array literal contains values of type `Integer`, `Long`, and `Double`, the resulting array is of type `Double`. Because `Integer` and `Long` widen only to `Double`, `Double` is the dominant type. For more information, see [Widening and Narrowing Conversions](#).

NOTE

You can use type inference only for arrays that are defined as local variables in a type member. If an explicit type definition is absent, arrays defined with array literals at the class level are of type `Object[]`. For more information, see [Local type inference](#).

Note that the previous example defines `values` as an array of type `Double` even though all the array literals are of type `Integer`. You can create this array because the values in the array literal can widen to `Double`.

values.

You can also create and populate a multidimensional array by using *nested array literals*. Nested array literals must have a number of dimensions that's consistent with the resulting array. The following example creates a two-dimensional array of integers by using nested array literals.

```
' Create and populate a 2 x 2 array.  
Dim grid1 = {{1, 2}, {3, 4}}  
' Create and populate a 2 x 2 array with 3 elements.  
Dim grid2(,) = {{1, 2}, {3, 4}, {5, 6}}
```

When using nested array literals to create and populate an array, an error occurs if the number of elements in the nested array literals don't match. An error also occurs if you explicitly declare the array variable to have a different number of dimensions than the array literals.

Just as you can for one-dimensional arrays, you can rely on type inference when creating a multidimensional array with nested array literals. The inferred type is the dominant type for all the values in all the array literals for all nesting level. The following example creates a two-dimensional array of type `Double[,]` from values that are of type `Integer` and `Double`.

```
Dim arr = {{1, 2.0}, {3, 4}, {5, 6}, {7, 8}}
```

For additional examples, see [How to: Initialize an Array Variable in Visual Basic](#).

Iterating through an array

When you iterate through an array, you access each element in the array from the lowest index to the highest or from the highest to the lowest. Typically, use either the [For...Next Statement](#) or the [For Each...Next Statement](#) to iterate through the elements of an array. When you don't know the upper bounds of the array, you can call the [Array.GetUpperBound](#) method to get the highest value of the index. Although lowest index value is almost always 0, you can call the [Array.GetLowerBound](#) method to get the lowest value of the index.

The following example iterates through a one-dimensional array by using the [For...Next](#) statement.

```
Module IterateArray  
    Public Sub Main()  
        Dim numbers = {10, 20, 30}  
  
        For index = 0 To numbers.GetUpperBound(0)  
            Console.WriteLine(numbers(index))  
        Next  
    End Sub  
End Module  
' The example displays the following output:  
' 10  
' 20  
' 30
```

The following example iterates through a multidimensional array by using a [For...Next](#) statement. The [GetUpperBound](#) method has a parameter that specifies the dimension. `GetUpperBound(0)` returns the highest index of the first dimension, and `GetUpperBound(1)` returns the highest index of the second dimension.

```

Module IterateArray
    Public Sub Main()
        Dim numbers = {{1, 2}, {3, 4}, {5, 6}}

        For index0 = 0 To numbers.GetUpperBound(0)
            For index1 = 0 To numbers.GetUpperBound(1)
                Console.WriteLine($"{numbers(index0, index1)} ")
            Next
            Console.WriteLine()
        Next
    End Sub
End Module
' The example displays the following output:
' Output
'   1 2
'   3 4
'   5 6

```

The following example uses a [For Each...Next Statement](#) to iterate through a one-dimensional array and a two-dimensional array.

```

Module IterateWithForEach
    Public Sub Main()
        ' Declare and iterate through a one-dimensional array.
        Dim numbers1 = {10, 20, 30}

        For Each number In numbers1
            Console.WriteLine(number)
        Next
        Console.WriteLine()

        Dim numbers = {{1, 2}, {3, 4}, {5, 6}}

        For Each number In numbers
            Console.WriteLine(number)
        Next
    End Sub
End Module
' The example displays the following output:
'   10
'   20
'   30
'
'   1
'   2
'   3
'   4
'   5
'   6

```

Array size

The size of an array is the product of the lengths of all its dimensions. It represents the total number of elements currently contained in the array. For example, the following example declares a 2-dimensional array with four elements in each dimension. As the output from the example shows, the array's size is 16 (or $(3 + 1) * (3 + 1)$).

```

Module Example
    Public Sub Main()
        Dim arr(3, 3) As Integer
        Console.WriteLine(arr.Length)
    End Sub
End Module
' The example displays the following output:
'     16

```

NOTE

This discussion of array size does not apply to jagged arrays. For information on jagged arrays and determining the size of a jagged array, see the [Jagged arrays](#) section.

You can find the size of an array by using the [Array.Length](#) property. You can find the length of each dimension of a multidimensional array by using the [Array.GetLength](#) method.

You can resize an array variable by assigning a new array object to it or by using the [ReDim Statement](#) statement. The following example uses the `ReDim` statement to change a 100-element array to a 51-element array.

```

Module Example
    Public Sub Main()
        Dim arr(99) As Integer
        Console.WriteLine(arr.Length)

        Redim arr(50)
        Console.WriteLine(arr.Length)
    End Sub
End Module
' The example displays the following output:
'     100
'     51

```

There are several things to keep in mind when dealing with the size of an array.

Dimension Length	The index of each dimension is 0-based, which means it ranges from 0 to its upper bound. Therefore, the length of a given dimension is one greater than the declared upper bound of that dimension.
Length Limits	The length of every dimension of an array is limited to the maximum value of the <code>Integer</code> data type, which is Int32.MaxValue or $(2 ^ 31) - 1$. However, the total size of an array is also limited by the memory available on your system. If you attempt to initialize an array that exceeds the amount of available memory, the runtime throws an OutOfMemoryException .

Size and Element Size	An array's size is independent of the data type of its elements. The size always represents the total number of elements, not the number of bytes that they consume in memory.
Memory Consumption	It is not safe to make any assumptions regarding how an array is stored in memory. Storage varies on platforms of different data widths, so the same array can consume more memory on a 64-bit system than on a 32-bit system. Depending on system configuration when you initialize an array, the common language runtime (CLR) can assign storage either to pack elements as close together as possible, or to align them all on natural hardware boundaries. Also, an array requires a storage overhead for its control information, and this overhead increases with each added dimension.

The array type

Every array has a data type, which differs from the data type of its elements. There is no single data type for all arrays. Instead, the data type of an array is determined by the number of dimensions, or *rank*, of the array, and the data type of the elements in the array. Two array variables are of the same data type only when they have the same rank and their elements have the same data type. The lengths of the dimensions of an array do not influence the array data type.

Every array inherits from the [System.Array](#) class, and you can declare a variable to be of type `Array`, but you cannot create an array of type `Array`. For example, although the following code declares the `arr` variable to be of type `Array` and calls the [Array.CreateInstance](#) method to instantiate the array, the array's type proves to be `Object[]`.

```
Module Example
    Public Sub Main()
        Dim arr As Array = Array.CreateInstance(GetType(Object), 19)
        Console.WriteLine(arr.Length)
        Console.WriteLine(arr.GetType().Name)
    End Sub
End Module
' The example displays the following output:
'   19
'   Object[]
```

Also, the [ReDim Statement](#) cannot operate on a variable declared as type `Array`. For these reasons, and for type safety, it is advisable to declare every array as a specific type.

You can find out the data type of either an array or its elements in several ways.

- You can call the [GetType](#) method on the variable to get a [Type](#) object that represents the run-time type of the variable. The [Type](#) object holds extensive information in its properties and methods.
- You can pass the variable to the [TypeName](#) function to get a `String` with the name of run-time type.

The following example calls the both the `GetType` method and the `TypeName` function to determine the type of an array. The array type is `Byte(,)`. Note that the [Type.BaseType](#) property also indicates that the base type of the byte array is the [Array](#) class.

```

Module Example
    Public Sub Main()
        Dim bytes(9,9) As Byte
        Console.WriteLine($"Type of {nameof(bytes)} array: {bytes.GetType().Name}")
        Console.WriteLine($"Base class of {nameof(bytes)}: {bytes.GetType().BaseType.Name}")
        Console.WriteLine()
        Console.WriteLine($"Type of {nameof(bytes)} array: {TypeName(bytes)}")
    End Sub
End Module
' The example displays the following output:
' Type of bytes array: Byte[,]
' Base class of bytes: Array
'
' Type of bytes array: Byte(,)

```

Arrays as return values and parameters

To return an array from a [Function](#) procedure, specify the array data type and the number of dimensions as the return type of the [Function Statement](#). Within the function, declare a local array variable with same data type and number of dimensions. In the [Return Statement](#), include the local array variable without parentheses.

To specify an array as a parameter to a [Sub](#) or [Function](#) procedure, define the parameter as an array with a specified data type and number of dimensions. In the call to the procedure, pass an array variable with the same data type and number of dimensions.

In the following example, the `GetNumbers` function returns an `Integer()`, a one-dimensional array of type `Integer`. The `ShowNumbers` procedure accepts an `Integer()` argument.

```

Module ReturnValuesAndParams
    Public Sub Main()
        Dim numbers As Integer() = GetNumbers()
        ShowNumbers(numbers)
    End Sub

    Private Function GetNumbers() As Integer()
        Dim numbers As Integer() = {10, 20, 30}
        Return numbers
    End Function

    Private Sub ShowNumbers(numbers As Integer())
        For index = 0 To numbers.GetUpperBound(0)
            Console.WriteLine($"{numbers(index)} ")
        Next
    End Sub
End Module
' The example displays the following output:
' 10
' 20
' 30

```

In the following example, the `GetNumbersMultiDim` function returns an `Integer(,)`, a two-dimensional array of type `Integer`. The `ShowNumbersMultiDim` procedure accepts an `Integer(,)` argument.

```

Module Example
    Public Sub Main()
        Dim numbers As Integer(,) = GetNumbersMultidim()
        ShowNumbersMultidim(numbers)
    End Sub

    Private Function GetNumbersMultidim() As Integer(,)
        Dim numbers As Integer(,) = {{1, 2}, {3, 4}, {5, 6}}
        Return numbers
    End Function

    Private Sub ShowNumbersMultidim(numbers As Integer(,))
        For index0 = 0 To numbers.GetUpperBound(0)
            For index1 = 0 To numbers.GetUpperBound(1)
                Console.WriteLine($"{numbers(index0, index1)} ")
            Next
            Console.WriteLine()
        Next
    End Sub
End Module
' The example displays the following output:
'      1 2
'      3 4
'      5 6

```

Jagged arrays

Sometimes the data structure in your application is two-dimensional but not rectangular. For example, you might use an array to store data about the high temperature of each day of the month. The first dimension of the array represents the month, but the second dimension represents the number of days, and the number of days in a month is not uniform. A *jagged array*, which is also called an *array of arrays*, is designed for such scenarios. A jagged array is an array whose elements are also arrays. A jagged array and each element in a jagged array can have one or more dimensions.

The following example uses an array of months, each element of which is an array of days. The example shows how to create a jagged array, assign values to it, and retrieve and display its values.

```

Imports System.Globalization

Module JaggedArray
    Public Sub Main()
        ' Declare the jagged array of 12 elements. Each element is an array of Double.
        Dim sales(11)() As Double
        ' Set each element of the sales array to a Double array of the appropriate size.
        For month As Integer = 0 To 11
            ' The number of days in the month determines the appropriate size.
            Dim daysInMonth As Integer =
                DateTime.DaysInMonth(Year(Now), month + 1)
            sales(month) = New Double(daysInMonth - 1) {}
        Next

        ' Store values in each element.
        For month As Integer = 0 To 11
            For dayOfMonth = 0 To sales(month).GetUpperBound(0)
                sales(month)(dayOfMonth) = (month * 100) + dayOfMonth
            Next
        Next

        ' Retrieve and display the array values.
        Dim monthNames = DateTimeFormatInfo.CurrentInfo.AbbreviatedMonthNames

```

```

' Display the month names.
Console.Write("    ")
For ctr = 0 To sales.GetUpperBound(0)
    Console.WriteLine($" {monthNames(ctr)}    ")
Next
Console.WriteLine()
' Display data for each day in each month.
For dayInMonth = 0 To 30
    Console.WriteLine($"{dayInMonth + 1,2}.    ")
    For monthNumber = 0 To sales.GetUpperBound(0)
        If dayInMonth > sales(monthNumber).GetUpperBound(0) Then
            Console.WriteLine("          ")
        Else
            Console.WriteLine($"{sales(monthNumber)(dayInMonth),-5}    ")
        End If
    Next
    Console.WriteLine()
Next
End Sub
End Module
' The example displays the following output:
'   Jan   Feb   Mar   Apr   May   Jun   Jul   Aug   Sep   Oct   Nov   Dec
' 1.  0    100   200   300   400   500   600   700   800   900   1000  1100
' 2.  1    101   201   301   401   501   601   701   801   901   1001  1101

' 21. 20   120   220   320   420   520   620   720   820   920   1020  1120
' 22. 21   121   221   321   421   521   621   721   821   921   1021  1121
' 23. 22   122   222   322   422   522   622   722   822   922   1022  1122
' 24. 23   123   223   323   423   523   623   723   823   923   1023  1123
' 25. 24   124   224   324   424   524   624   724   824   924   1024  1124
' 26. 25   125   225   325   425   525   625   725   825   925   1025  1125
' 27. 26   126   226   326   426   526   626   726   826   926   1026  1126
' 28. 27   127   227   327   427   527   627   727   827   927   1027  1127
' 29. 28   128   228   328   428   528   628   728   828   928   1028  1128
' 30. 29   129   229   329   429   529   629   729   829   929   1029  1129
' 31. 30   130   230   330   430   530   630   730   830   930   1030  1130

```

The previous example assigns values to the jagged array on an element-by-element basis by using a `For...Next` loop. You can also assign values to the elements of a jagged array by using nested array literals. However, the attempt to use nested array literals (for example, `Dim valuesJagged = {{1, 2}, {2, 3, 4}}`) generates compiler error [BC30568](#). To correct the error, enclose the inner array literals in parentheses. The parentheses force the array literal expression to be evaluated, and the resulting values are used with the outer array literal, as the following example shows.

```

Module Example
    Public Sub Main()
        Dim values1d = { 1, 2, 3 }
        Dim values2d = {{1, 2}, {2, 3}, {3, 4}}
        Dim valuesjagged = {{1, 2}}, {{2, 3}, {4}}
    End Sub
End Module

```

A jagged array is a one-dimensional array whose elements contain arrays. Therefore, the [Array.Length](#) property and the [Array.GetLength\(0\)](#) method return the number of elements in the one-dimensional array, and [Array.GetLength\(1\)](#) throws an [IndexOutOfRangeException](#) because a jagged array is not multidimensional. You determine the number of elements in each subarray by retrieving the value of each subarray's [Array.Length](#) property. The following example illustrates how to determine the number of elements in a jagged array.

```

Module Example
    Public Sub Main()
        Dim jagged = {{1, 2}, {2, 3, 4}, {5, 6}, {7, 8, 9, 10}}
        Console.WriteLine($"The value of jagged.Length: {jagged.Length}")
        Dim total = jagged.Length
        For ctr As Integer = 0 To jagged.GetUpperBound(0)
            Console.WriteLine($"Element {ctr + 1} has {jagged(ctr).Length} elements.")
            total += jagged(ctr).Length
        Next
        Console.WriteLine($"The total number of elements in the jagged array: {total}")
    End Sub
End Module
' The example displays the following output:
'   The value of jagged.Length: 4.
'   Element 1 has 3 elements.
'   Element 2 has 2 elements.
'   Element 3 has 2 elements.
'   Element 4 has 4 elements.
'   The total number of elements in the jagged array: 15

```

Zero-length arrays

Visual Basic differentiates between a uninitialized array (an array whose value is [Nothing](#)) and a *zero-length array* or empty array (an array that has no elements.) An uninitialized array is one that has not been dimensioned or had any values assigned to it. For example:

```
Dim arr() As String
```

A zero-length array is declared with a dimension of -1. For example:

```
Dim arrZ(-1) As String
```

You might need to create a zero-length array under the following circumstances:

- Without risking a [NullReferenceException](#) exception, your code must access members of the [Array](#) class, such as [Length](#) or [Rank](#), or call a Visual Basic function such as [UBound](#).
- You want to keep your code simple by not having to check for [Nothing](#) as a special case.

- Your code interacts with an application programming interface (API) that either requires you to pass a zero-length array to one or more procedures or returns a zero-length array from one or more procedures.

Splitting an array

In some cases, you may need to split a single array into multiple arrays. This involves identifying the point or points at which the array is to be split, and then splitting the array into two or more separate arrays.

NOTE

This section does not discuss splitting a single string into a string array based on some delimiter. For information on splitting a string, see the [String.Split](#) method.

The most common criteria for splitting an array are:

- The number of elements in the array. For example, you might want to split an array of more than a specified number of elements into a number of approximately equal parts. For this purpose, you can use the value returned by either the [Array.Length](#) or [Array.GetLength](#) method.
- The value of an element, which serves as a delimiter that indicates where the array should be split. You can search for a specific value by calling the [Array.FindIndex](#) and [Array.FindLastIndex](#) methods.

Once you've determined the index or indexes at which the array should be split, you can then create the individual arrays by calling the [Array.Copy](#) method.

The following example splits an array into two arrays of approximately equal size. (If the total number of array elements is odd, the first array has one more element than the second.)

```
Module Example
Public Sub Main()
    ' Create an array of 100 elements.
    Dim arr(99) As Integer
    ' Populate the array.
    Dim rnd As New Random()
    For ctr = 0 To arr.GetUpperBound(0)
        arr(ctr) = rnd.Next()
    Next

    ' Determine how many elements should be in each array.
    Dim divisor = 2
    Dim remainder As Integer
    Dim boundary = Math.DivRem(arr.GetLength(0), divisor, remainder)

    ' Copy the array.
    Dim arr1(boundary - 1 + remainder), arr2(boundary - 1) As Integer
    Array.Copy(arr, 0, arr1, 0, boundary + remainder)
    Array.Copy(arr, boundary + remainder, arr2, 0, arr.Length - boundary)
End Sub
End Module
```

The following example splits a string array into two arrays based on the presence of an element whose value is "zzz", which serves as the array delimiter. The new arrays do not include the element that contains the delimiter.

```

Module Example
    Public Sub Main()
        Dim rnd As New Random()

        ' Create an array of 100 elements.
        Dim arr(99) As String
        ' Populate each element with an arbitrary ASCII character.
        For ctr = 0 To arr.GetUpperBound(0)
            arr(ctr) = ChrW(Rnd.Next(&h21, &h7F))
        Next
        ' Get a random number that will represent the point to insert the delimiter.
        arr(rnd.Next(0, arr.GetUpperBound(0))) = "zzz"

        ' Find the delimiter.
        Dim location = Array.FindIndex(arr, Function(x) x = "zzz")

        ' Create the arrays.
        Dim arr1(location - 1) As String
        Dim arr2(arr.GetUpperBound(0) - location - 1) As String

        ' Populate the two arrays.
        Array.Copy(arr, 0, arr1, 0, location)
        Array.Copy(arr, location + 1, arr2, 0, arr.GetUpperBound(0) - location)
    End Sub
End Module

```

Joining arrays

You can also combine a number of arrays into a single larger array. To do this, you also use the [Array.Copy](#) method.

NOTE

This section does not discuss joining a string array into a single string. For information on joining a string array, see the [String.Join](#) method.

Before copying the elements of each array into the new array, you must first ensure that you have initialized the array so that it is large enough to accommodate the new array. You can do this in one of two ways:

- Use the [ReDim Preserve](#) statement to dynamically expand the array before adding new elements to it. This is the easiest technique, but it can result in performance degradation and excessive memory consumption when you are copying large arrays.
- Calculate the total number of elements needed for the new large array, then add the elements of each source array to it.

The following example uses the second approach to add four arrays with ten elements each to a single array.

```

Imports System.Collections.Generic
Imports System.Threading.Tasks

Module Example
    Public Sub Main()
        Dim tasks As New List(Of Task(Of Integer()))
        ' Generate four arrays.
        For ctr = 0 To 3
            Dim value = ctr
            tasks.Add(Task.Run(Function()
                Dim arr(9) As Integer
                For ndx = 0 To arr.GetUpperBound(0)
                    arr(ndx) = value
                Next
                Return arr
            End Function))
        Next
        Task.WaitAll(tasks.ToArray())
        ' Compute the number of elements in all arrays.
        Dim elements = 0
        For Each task In tasks
            elements += task.Result.Length
        Next
        Dim newArray(elements - 1) As Integer
        Dim index = 0
        For Each task In tasks
            Dim n = task.Result.Length
            Array.Copy(task.Result, 0, newArray, index, n)
            index += n
        Next
        Console.WriteLine($"The new array has {newArray.Length} elements.")
    End Sub
End Module
' The example displays the following output:
'     The new array has 40 elements.

```

Since in this case the source arrays are all small, we can also dynamically expand the array as we add the elements of each new array to it. The following example does that.

```

Imports System.Collections.Generic
Imports System.Threading.Tasks

Module Example
    Public Sub Main()
        Dim tasks As New List(Of Task(Of Integer()))
        ' Generate four arrays.
        For ctr = 0 To 3
            Dim value = ctr
            tasks.Add(Task.Run(Function()
                Dim arr(9) As Integer
                For ndx = 0 To arr.GetUpperBound(0)
                    arr(ndx) = value
                Next
                Return arr
            End Function))
        Next
        Task.WaitAll(tasks.ToArray())
    End Sub
End Module
' Dimension the target array and copy each element of each source array to it.
Dim newArray() As Integer = {}
' Define the next position to copy to in newArray.
Dim index = 0
For Each task In tasks
    Dim n = Task.Result.Length
    ReDim Preserve newArray(newArray.GetUpperBound(0) + n)
    Array.Copy(task.Result, 0, newArray, index, n)
    index += n
Next
Console.WriteLine($"The new array has {newArray.Length} elements.")
End Sub
End Module
' The example displays the following output:
'     The new array has 40 elements.

```

Collections as an alternative to arrays

Arrays are most useful for creating and working with a fixed number of strongly typed objects. Collections provide a more flexible way to work with groups of objects. Unlike arrays, which require that you explicitly change the size of an array with the [ReDim Statement](#), collections grow and shrink dynamically as the needs of an application change.

When you use [ReDim](#) to redimension an array, Visual Basic creates a new array and releases the previous one. This takes execution time. Therefore, if the number of items you are working with changes frequently, or you cannot predict the maximum number of items you need, you'll usually obtain better performance by using a collection.

For some collections, you can assign a key to any object that you put into the collection so that you can quickly retrieve the object by using the key.

If your collection contains elements of only one data type, you can use one of the classes in the [System.Collections.Generic](#) namespace. A generic collection enforces type safety so that no other data type can be added to it.

For more information about collections, see [Collections](#).

Collection Initializers (Visual Basic)

3/8/2019 • 5 minutes to read • [Edit Online](#)

Collection initializers provide a shortened syntax that enables you to create a collection and populate it with an initial set of values. Collection initializers are useful when you are creating a collection from a set of known values, for example, a list of menu options or categories, an initial set of numeric values, a static list of strings such as day or month names, or geographic locations such as a list of states that is used for validation.

For more information about collections, see [Collections](#).

You identify a collection initializer by using the `From` keyword followed by braces (`{}`). This is similar to the array literal syntax that is described in [Arrays](#). The following examples show various ways to use collection initializers to create collections.

```
' Create an array of type String().
Dim winterMonths = {"December", "January", "February"}

' Create an array of type Integer()
Dim numbers = {1, 2, 3, 4, 5}

' Create a list of menu options. (Requires an extension method
' named Add for List(Of MenuOption)
Dim menuOptions = New List(Of MenuOption) From {{1, "Home"}, 
                                                {2, "Products"}, 
                                                {3, "News"}, 
                                                {4, "Contact Us"}}
```

NOTE

C# also provides collection initializers. C# collection initializers provide the same functionality as Visual Basic collection initializers. For more information about C# collection initializers, see [Object and Collection Initializers](#).

Syntax

A collection initializer consists of a list of comma-separated values that are enclosed in braces (`{}`), preceded by the `From` keyword, as shown in the following code.

```
Dim names As New List(Of String) From {"Christa", "Brian", "Tim"}
```

When you create a collection, such as a `List<T>` or a `Dictionary< TKey, TValue >`, you must supply the collection type before the collection initializer, as shown in the following code.

```
Public Class AppMenu
    Public Property Items As List(Of String) =
        New List(Of String) From {"Home", "About", "Contact"}
End Class
```

NOTE

You cannot combine both a collection initializer and an object initializer to initialize the same collection object. You can use object initializers to initialize objects in a collection initializer.

Creating a Collection by Using a Collection Initializer

When you create a collection by using a collection initializer, each value that is supplied in the collection initializer is passed to the appropriate `Add` method of the collection. For example, if you create a `List<T>` by using a collection initializer, each string value in the collection initializer is passed to the `Add` method. If you want to create a collection by using a collection initializer, the specified type must be valid collection type. Examples of valid collection types include classes that implement the `IEnumerable<T>` interface or inherit the `CollectionBase` class. The specified type must also expose an `Add` method that meets the following criteria.

- The `Add` method must be available from the scope in which the collection initializer is being called. The `Add` method does not have to be public if you are using the collection initializer in a scenario where non-public methods of the collection can be accessed.
- The `Add` method must be an instance member or `Shared` member of the collection class, or an extension method.
- An `Add` method must exist that can be matched, based on overload resolution rules, to the types that are supplied in the collection initializer.

For example, the following code example shows how to create a `List(Of Customer)` collection by using a collection initializer. When the code is run, each `Customer` object is passed to the `Add(Customer)` method of the generic list.

```
Dim customers = New List(Of Customer) From
{
    New Customer("City Power & Light", "http://www.cpandl.com/"),
    New Customer("Wide World Importers", "http://www.wideworldimporters.com/"),
    New Customer("Lucerne Publishing", "http://www.lucernepublishing.com/")
}
```

The following code example shows equivalent code that does not use a collection initializer.

```
Dim customers = New List(Of Customer)
customers.Add(New Customer("City Power & Light", "http://www.cpandl.com/"))
customers.Add(New Customer("Wide World Importers", "http://www.wideworldimporters.com/"))
customers.Add(New Customer("Lucerne Publishing", "http://www.lucernepublishing.com/"))
```

If the collection has an `Add` method that has parameters that match the constructor for the `Customer` object, you could nest parameter values for the `Add` method within collection initializers, as discussed in the next section. If the collection does not have such an `Add` method, you can create one as an extension method. For an example of how to create an `Add` method as an extension method for a collection, see [How to: Create an Add Extension Method Used by a Collection Initializer](#). For an example of how to create a custom collection that can be used with a collection initializer, see [How to: Create a Collection Used by a Collection Initializer](#).

Nesting Collection Initializers

You can nest values within a collection initializer to identify a specific overload of an `Add` method for the collection that is being created. The values passed to the `Add` method must be separated by commas and enclosed in braces (`{}`), like you would do in an array literal or collection initializer.

When you create a collection by using nested values, each element of the nested value list is passed as an argument to the `Add` method that matches the element types. For example, the following code example creates a `Dictionary< TKey, TValue >` in which the keys are of type `Integer` and the values are of type `String`. Each of the nested value lists is matched to the `Add` method for the `Dictionary`.

```
Dim days = New Dictionary(Of Integer, String) From
    {{0, "Sunday"}, {1, "Monday"}}
```

The previous code example is equivalent to the following code.

```
Dim days = New Dictionary(Of Integer, String)
days.Add(0, "Sunday")
days.Add(1, "Monday")
```

Only nested value lists from the first level of nesting are sent to the `Add` method for the collection type. Deeper levels of nesting are treated as array literals and the nested value lists are not matched to the `Add` method of any collection.

Constants and Enumerations in Visual Basic

5/4/2018 • 2 minutes to read • [Edit Online](#)

Constants are a way to use meaningful names in place of a value that does not change. Constants store values that, as the name implies, remain constant throughout the execution of an application. You can use constants to provide meaningful names, instead of numbers, making your code more readable.

Enumerations provide a convenient way to work with sets of related constants, and to associate constant values with names. For example, you can declare an enumeration for a set of integer constants associated with the days of the week, and then use the names of the days rather than their integer values in your code.

Control Flow in Visual Basic

5/4/2018 • 2 minutes to read • [Edit Online](#)

Left unregulated, a program proceeds through its statements from beginning to end. Some very simple programs can be written with only this unidirectional flow. However, much of the power and utility of any programming language comes from the ability to change execution order with control statements and loops.

Control structures allow you to regulate the flow of your program's execution. Using control structures, you can write Visual Basic code that makes decisions or that repeats actions. Other control structures let you guarantee disposal of a resource or run a series of statements on the same object reference.

Data Types in Visual Basic

1/23/2019 • 2 minutes to read • [Edit Online](#)

The *data type* of a programming element refers to what kind of data it can hold and how it stores that data. Data types apply to all values that can be stored in computer memory or participate in the evaluation of an expression. Every variable, literal, constant, enumeration, property, procedure parameter, procedure argument, and procedure return value has a data type.

Declared Data Types

You define a programming element with a declaration statement, and you specify its data type with the `As` clause. The following table shows the statements you use to declare various elements.

PROGRAMMING ELEMENT	DATA TYPE DECLARATION
Variable	In a Dim Statement <code>Dim amount As Double</code> <code>Static yourName As String</code> <code>Public billsPaid As Decimal = 0</code>
Literal	With a literal type character; see "Literal Type Characters" in Type Characters <code>Dim searchChar As Char = "." C</code>
Constant	In a Const Statement <code>Const modulus As Single = 4.17825F</code>
Enumeration	In an Enum Statement <code>Public Enum colors</code>
Property	In a Property Statement <code>Property region() As String</code>
Procedure parameter	In a Sub Statement , Function Statement , or Operator Statement <code>Sub addSale(ByVal amount As Double)</code>
Procedure argument	In the calling code; each argument is a programming element that has already been declared, or an expression containing declared elements <code>subString = Left(inputString , 5)</code>

PROGRAMMING ELEMENT	DATA TYPE DECLARATION
Procedure return value	In a Function Statement or Operator Statement <pre>Function convert(ByVal b As Byte) As String</pre>

For a list of Visual Basic data types, see [Data Types](#).

Type characters (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

In addition to specifying a data type in a declaration statement, you can force the data type of some programming elements with a *type character*. The type character must immediately follow the element, with no intervening characters of any kind.

The type character is not part of the name of the element. An element defined with a type character can be referenced without the type character.

Identifier type characters

Visual Basic supplies a set of *identifier type characters* that you can use in a declaration to specify the data type of a variable or constant. The following table shows the available identifier type characters with examples of usage.

IDENTIFIER TYPE CHARACTER	DATA TYPE	EXAMPLE
%	Integer	Dim L%
&	Long	Dim M&
@	Decimal	Const W@ = 37.5
!	Single	Dim Q!
#	Double	Dim X#
\$	String	Dim V\$ = "Secret"

No identifier type characters exist for the `Boolean`, `Byte`, `Char`, `Date`, `Object`, `SByte`, `Short`, `UInteger`, `ULong`, or `UShort` data types, or for any composite data types such as arrays or structures.

In some cases, you can append the `$` character to a Visual Basic function, for example `Left$` instead of `Left`, to obtain a returned value of type `String`.

In all cases, the identifier type character must immediately follow the identifier name.

Literal type characters

A *literal* is a textual representation of a particular value of a data type.

Default literal types

The form of a literal as it appears in your code ordinarily determines its data type. The following table shows these default types.

TEXTUAL FORM OF LITERAL	DEFAULT DATA TYPE	EXAMPLE
Numeric, no fractional part	Integer	2147483647

TEXTUAL FORM OF LITERAL	DEFAULT DATA TYPE	EXAMPLE
Numeric, no fractional part, too large for Integer	Long	2147483648
Numeric, fractional part	Double	1.2
Enclosed in double quotation marks	String	"A"
Enclosed within number signs	Date	#5/17/1993 9:32 AM#

Forced literal types

Visual Basic supplies a set of *literal type characters*, which you can use to force a literal to assume a data type other than the one its form indicates. You do this by appending the character to the end of the literal. The following table shows the available literal type characters with examples of usage.

LITERAL TYPE CHARACTER	DATA TYPE	EXAMPLE
S	Short	I = 347S
I	Integer	J = 347I
L	Long	K = 347L
D	Decimal	X = 347D
F	Single	Y = 347F
R	Double	Z = 347R
US	UShort	L = 347US
UI	UInteger	M = 347UI
UL	ULong	N = 347UL
C	Char	Q = ".C"

No literal type characters exist for the Boolean, Byte, Date, Object, SByte, or String data types, or for any composite data types such as arrays or structures.

Literals can also use the identifier type characters (% , & , @ , ! , # , \$), as can variables, constants, and expressions. However, the literal type characters (S , I , L , D , F , R , C) can be used only with literals.

In all cases, the literal type character must immediately follow the literal value.

Hexadecimal, binary, and octal literals

The compiler normally interprets an integer literal to be in the decimal (base 10) number system. You can also define an integer literal as a hexadecimal (base 16) number with the &H prefix, as a binary (base 2) number with the &B prefix, and as an octal (base 8) number with the &O prefix. The digits that follow the prefix must be appropriate for the number system. The following table illustrates this.

NUMBER BASE	PREFIX	VALID DIGIT VALUES	EXAMPLE
Hexadecimal (base 16)	&H	0-9 and A-F	&HFFFF
Binary (base 2)	&B	0-1	&B01111100
Octal (base 8)	&O	0-7	&077

Starting in Visual Basic 2017, you can use the underscore character (`_`) as a group separator to enhance the readability of an integral literal. The following example uses the `_` character to group a binary literal into 8-bit groups:

```
Dim number As Integer = &B00100010_11000101_11001111_11001101
```

You can follow a prefixed literal with a literal type character. The following example shows this.

```
Dim counter As Short = &H8000S
Dim flags As UShort = &H8000US
```

In the previous example, `counter` has the decimal value of -32768, and `flags` has the decimal value of +32768.

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As Integer = &H_C305_F860
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Elementary Data Types (Visual Basic)

8/24/2018 • 2 minutes to read • [Edit Online](#)

Visual Basic supplies a set of predefined data types, which you can use for many of your programming elements. This section describes these types and how to use them.

NOTE

Every elementary data type in Visual Basic is supported by a structure or a class that is in the [System](#) namespace. The compiler uses each data type keyword as an alias for the underlying structure or class. For example, declaring a variable by using the reserved word `Byte` is the same as declaring it by using the fully qualified structure name `System.Byte`.

In This Section

[Numeric Data Types](#)

Describes the integral and non-integral numeric types.

[Character Data Types](#)

Describes the `char` and `String` types.

[Data Types](#)

Provides an overview of the elementary data types supplied by Visual Basic.

Numeric Data Types (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

Visual Basic supplies several *numeric data types* for handling numbers in various representations. *Integral* types represent only whole numbers (positive, negative, and zero), and *nonintegral* types represent numbers with both integer and fractional parts.

For a table showing a side-by-side comparison of the Visual Basic data types, see [Data Types](#).

Integral Numeric Types

Integral data types are those that represent only numbers without fractional parts.

The *signed* integral data types are [SByte Data Type](#) (8-bit), [Short Data Type](#) (16-bit), [Integer Data Type](#) (32-bit), and [Long Data Type](#) (64-bit). If a variable always stores integers rather than fractional numbers, declare it as one of these types.

The *unsigned* integral types are [Byte Data Type](#) (8-bit), [UShort Data Type](#) (16-bit), [UInteger Data Type](#) (32-bit), and [ULong Data Type](#) (64-bit). If a variable contains binary data, or data of unknown nature, declare it as one of these types.

Performance

Arithmetic operations are faster with integral types than with other data types. They are fastest with the [Integer](#) and [UInteger](#) types in Visual Basic.

Large Integers

If you need to hold an integer larger than the [Integer](#) data type can hold, you can use the [Long](#) data type instead. [Long](#) variables can hold numbers from -9,223,372,036,854,775,808 through 9,223,372,036,854,775,807.

Operations with [Long](#) are slightly slower than with [Integer](#).

If you need even larger values, you can use the [Decimal Data Type](#). You can hold numbers from -79,228,162,514,264,337,593,543,950,335 through 79,228,162,514,264,337,593,543,950,335 in a [Decimal](#) variable if you do not use any decimal places. However, operations with [Decimal](#) numbers are considerably slower than with any other numeric data type.

Small Integers

If you do not need the full range of the [Integer](#) data type, you can use the [Short](#) data type, which can hold integers from -32,768 through 32,767. For the smallest integer range, the [SByte](#) data type holds integers from -128 through 127. If you have a very large number of variables that hold small integers, the common language runtime can sometimes store your [Short](#) and [SByte](#) variables more efficiently and save memory consumption. However, operations with [Short](#) and [SByte](#) are somewhat slower than with [Integer](#).

Unsigned Integers

If you know that your variable never needs to hold a negative number, you can use the *unsigned* types [Byte](#), [UShort](#), [UInteger](#), and [ULong](#). Each of these data types can hold a positive integer twice as large as its corresponding signed type ([SByte](#), [Short](#), [Integer](#), and [Long](#)). In terms of performance, each unsigned type is exactly as efficient as its corresponding signed type. In particular, [UInteger](#) shares with [Integer](#) the distinction of being the most efficient of all the elementary numeric data types.

Nonintegral Numeric Types

Nonintegral data types are those that represent numbers with both integer and fractional parts.

The nonintegral numeric data types are `Decimal` (128-bit fixed point), `Single Data Type` (32-bit floating point), and `Double Data Type` (64-bit floating point). They are all signed types. If a variable can contain a fraction, declare it as one of these types.

`Decimal` is not a floating-point data type. `Decimal` numbers have a binary integer value and an integer scaling factor that specifies what portion of the value is a decimal fraction.

You can use `Decimal` variables for money values. The advantage is the precision of the values. The `Double` data type is faster and requires less memory, but it is subject to rounding errors. The `Decimal` data type retains complete accuracy to 28 decimal places.

Floating-point (`single` and `Double`) numbers have larger ranges than `Decimal` numbers but can be subject to rounding errors. Floating-point types support fewer significant digits than `Decimal` but can represent values of greater magnitude.

Nonintegral number values can be expressed as mmmEeee, in which mmm is the *mantissa* (the significant digits) and eee is the *exponent* (a power of 10). The highest positive values of the nonintegral types are 7.9228162514264337593543950335E+28 for `Decimal`, 3.4028235E+38 for `Single`, and 1.79769313486231570E+308 for `Double`.

Performance

`Double` is the most efficient of the fractional data types, because the processors on current platforms perform floating-point operations in double precision. However, operations with `Double` are not as fast as with the integral types such as `Integer`.

Small Magnitudes

For numbers with the smallest possible magnitude (closest to 0), `Double` variables can hold numbers as small as -4.94065645841246544E-324 for negative values and 4.94065645841246544E-324 for positive values.

Small Fractional Numbers

If you do not need the full range of the `Double` data type, you can use the `Single` data type, which can hold floating-point numbers from -3.4028235E+38 through 3.4028235E+38. The smallest magnitudes for `Single` variables are -1.401298E-45 for negative values and 1.401298E-45 for positive values. If you have a very large number of variables that hold small floating-point numbers, the common language runtime can sometimes store your `Single` variables more efficiently and save memory consumption.

Character Data Types (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Visual Basic provides *character data types* to deal with printable and displayable characters. While they both deal with Unicode characters, `char` holds a single character whereas `string` contains an indefinite number of characters.

For a table that displays a side-by-side comparison of the Visual Basic data types, see [Data Types](#).

Char Type

The `Char` data type is a single two-byte (16-bit) Unicode character. If a variable always stores exactly one character, declare it as `Char`. For example:

```
' Initialize the prefix variable to the character 'a'.
Dim prefix As Char = "a"
```

Each possible value in a `Char` or `String` variable is a *code point*, or character code, in the Unicode character set. Unicode characters include the basic ASCII character set, various other alphabet letters, accents, currency symbols, fractions, diacritics, and mathematical and technical symbols.

NOTE

The Unicode character set reserves the code points D800 through DFFF (55296 through 55551 decimal) for *surrogate pairs*, which require two 16-bit values to represent a single code point. A `char` variable cannot hold a surrogate pair, and a `String` uses two positions to hold such a pair.

For more information, see [Char Data Type](#).

String Type

The `String` data type is a sequence of zero or more two-byte (16-bit) Unicode characters. If a variable can contain an indefinite number of characters, declare it as `String`. For example:

```
' Initialize the name variable to "Monday".
Dim name As String = "Monday"
```

For more information, see [String Data Type](#).

- [Composite Data Types](#)
- [Generic Types in Visual Basic](#)
- [Value Types and Reference Types](#)
- [Type Conversions in Visual Basic](#)
- [Troubleshooting Data Types](#)
- [Type Characters](#)

Miscellaneous Data Types (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Visual Basic supplies several data types that are not oriented toward numbers or characters. Instead, they deal with specialized data such as yes/no values, date/time values, and object addresses.

For a table showing a side-by-side comparison of the Visual Basic data types, see [Data Types](#).

Boolean Type

The [Boolean Data Type](#) is an unsigned value that is interpreted as either `True` or `False`. Its data width depends on the implementing platform. If a variable can contain only two-state values such as true/false, yes/no, or on/off, declare it as `Boolean`.

Date Type

The [Date Data Type](#) is a 64-bit value that holds both date and time information. Each increment represents 100 nanoseconds of elapsed time since the beginning (12:00 AM) of January 1 of the year 1 in the Gregorian calendar. If a variable can contain a date value, a time value, or both, declare it as `Date`.

Object Type

The [Object Data Type](#) is a 32-bit address that points to an object instance within your application or in some other application. An `object` variable can refer to any object your application recognizes, or to data of any data type. This includes both *value types*, such as `Integer`, `Boolean`, and structure instances, and *reference types*, which are instances of objects created from classes such as `String` and `Form`, and array instances.

If a variable stores a pointer to an instance of a class that you do not know at compile time, or if it can point to data of various data types, declare it as `Object`.

The advantage of the `Object` data type is that you can use it to store data of any data type. The disadvantage is that you incur extra operations that take more execution time and make your application perform slower. If you use an `Object` variable for value types, you incur *boxing* and *unboxing*. If you use it for reference types, you incur *late binding*.

- [Character Data Types](#)
- [Troubleshooting Data Types](#)
- [Early and Late Binding](#)

Composite Data Types (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

In addition to the elementary data types Visual Basic supplies, you can also assemble items of different types to create *composite data types* such as structures, arrays, and classes. You can build composite data types from elementary types and from other composite types. For example, you can define an array of structure elements, or a structure with array members.

Data Types

A composite type is different from the data type of any of its components. For example, an array of `Integer` elements is not of the `Integer` data type.

An array data type is normally represented using the element type, parentheses, and commas as necessary. For example, a one-dimensional array of `String` elements is represented as `String()`, and a two-dimensional array of `Boolean` elements is represented as `Boolean(,)`.

Structure Types

There is no single data type comprising all structures. Instead, each definition of a structure represents a unique data type, even if two structures define identical elements in the same order. However, if you create two or more instances of the same structure, Visual Basic considers them to be of the same data type.

Tuples

A tuple is a lightweight structure that contains two or more fields whose types are predefined. Tuples are supported starting with Visual Basic 2017. Tuples are most commonly used to return multiple values from a single method call without having to pass arguments by reference or packaging the returned fields in a more heavy-weight class or structure. See the [Tuples](#) topic for more information on tuples.

Array Types

There is no single data type comprising all arrays. The data type of a particular instance of an array is determined by the following:

- The fact of being an array
- The rank (number of dimensions) of the array
- The element type of the array

In particular, the length of a given dimension is not part of the instance's data type. The following example illustrates this.

```
Dim arrayA( ) As Byte = New Byte(12) {}
Dim arrayB( ) As Byte = New Byte(100) {}
Dim arrayC( ) As Short = New Short(100) {}
Dim arrayD( , ) As Short
Dim arrayE( , ) As Short = New Short(4, 10) {}
```

In the preceding example, array variables `arrayA` and `arrayB` are considered to be of the same data type — `Byte()` — even though they are initialized to different lengths. Variables `arrayB` and `arrayC` are not of the same

type because their element types are different. Variables `arrayC` and `arrayD` are not of the same type because their ranks are different. Variables `arrayD` and `arrayE` have the same type — `Short(,)` — because their ranks and element types are the same, even though `arrayD` is not yet initialized.

For more information on arrays, see [Arrays](#).

Class Types

There is no single data type comprising all classes. Although one class can inherit from another class, each is a separate data type. Multiple instances of the same class are of the same data type. If you assign one class instance variable to another, not only do they have the same data type, they point to the same class instance in memory.

For more information on classes, see [Objects and Classes](#).

How to: Hold More Than One Value in a Variable (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

A variable holds more than one value if you declare it to be of a *composite data type*.

[Composite Data Types](#) include structures, arrays, and classes. A variable of a composite data type can hold a combination of elementary data types and other composite types. Structures and classes can hold code as well as data.

To hold more than one value in a variable

1. Determine what composite data type you want to use for your variable.
2. If the composite data type is not already defined, define it so that your variable can use it.
 - Define a structure with a [Structure Statement](#).
 - Define an array with a [Dim Statement](#).
 - Define a class with a [Class Statement](#).
3. Declare your variable with a `Dim` statement.
4. Follow the variable name with an `As` clause.
5. Follow the `As` keyword with the name of the appropriate composite data type.

Generic Types in Visual Basic (Visual Basic)

2/28/2019 • 7 minutes to read • [Edit Online](#)

A *generic type* is a single programming element that adapts to perform the same functionality for a variety of data types. When you define a generic class or procedure, you do not have to define a separate version for each data type for which you might want to perform that functionality.

An analogy is a screwdriver set with removable heads. You inspect the screw you need to turn and select the correct head for that screw (slotted, crossed, starred). Once you insert the correct head in the screwdriver handle, you perform the exact same function with the screwdriver, namely turning the screw.

Screwdriver set as a generic tool

When you define a generic type, you parameterize it with one or more data types. This allows the using code to tailor the data types to its requirements. Your code can declare several different programming elements from the generic element, each one acting on a different set of data types. But the declared elements all perform the identical logic, no matter what data types they are using.

For example, you might want to create and use a queue class that operates on a specific data type such as `String`. You can declare such a class from `System.Collections.Generic.Queue<T>`, as the following example shows.

```
Public stringQ As New System.Collections.Generic.Queue(Of String)
```

You can now use `stringQ` to work exclusively with `String` values. Because `stringQ` is specific for `String` instead of being generalized for `object` values, you do not have late binding or type conversion. This saves execution time and reduces run-time errors.

For more information on using a generic type, see [How to: Use a Generic Class](#).

Example of a Generic Class

The following example shows a skeleton definition of a generic class.

```
Public Class classHolder(Of t)
    Public Sub processNewItem(ByVal newItem As t)
        Dim tempItem As t
        ' Insert code that processes an item of data type t.
    End Sub
End Class
```

In the preceding skeleton, `t` is a *type parameter*, that is, a placeholder for a data type that you supply when

you declare the class. Elsewhere in your code, you can declare various versions of `classHolder` by supplying various data types for `t`. The following example shows two such declarations.

```
Public integerClass As New classHolder(Of Integer)
Friend stringClass As New classHolder(Of String)
```

The preceding statements declare *constructed classes*, in which a specific type replaces the type parameter. This replacement is propagated throughout the code within the constructed class. The following example shows what the `processNewItem` procedure looks like in `integerClass`.

```
Public Sub processNewItem(ByVal newItem As Integer)
    Dim tempItem As Integer
    ' Inserted code now processes an Integer item.
End Sub
```

For a more complete example, see [How to: Define a Class That Can Provide Identical Functionality on Different Data Types](#).

Eligible Programming Elements

You can define and use generic classes, structures, interfaces, procedures, and delegates. Note that the .NET Framework defines several generic classes, structures, and interfaces that represent commonly used generic elements. The `System.Collections.Generic` namespace provides dictionaries, lists, queues, and stacks. Before defining your own generic element, see if it is already available in `System.Collections.Generic`.

Procedures are not types, but you can define and use generic procedures. See [Generic Procedures in Visual Basic](#).

Advantages of Generic Types

A generic type serves as a basis for declaring several different programming elements, each of which operates on a specific data type. The alternatives to a generic type are:

1. A single type operating on the `Object` data type.
2. A set of *type-specific* versions of the type, each version individually coded and operating on one specific data type such as `String`, `Integer`, or a user-defined type such as `customer`.

A generic type has the following advantages over these alternatives:

- **Type Safety.** Generic types enforce compile-time type checking. Types based on `Object` accept any data type, and you must write code to check whether an input data type is acceptable. With generic types, the compiler can catch type mismatches before run time.
- **Performance.** Generic types do not have to *box* and *unbox* data, because each one is specialized for one data type. Operations based on `Object` must box input data types to convert them to `Object` and unbox data destined for output. Boxing and unboxing reduce performance.

Types based on `Object` are also late-bound, which means that accessing their members requires extra code at run time. This also reduces performance.

- **Code Consolidation.** The code in a generic type has to be defined only once. A set of type-specific versions of a type must replicate the same code in each version, with the only difference being the specific data type for that version. With generic types, the type-specific versions are all generated from the original generic type.

- **Code Reuse.** Code that does not depend on a particular data type can be reused with various data types if it is generic. You can often reuse it even with a data type that you did not originally predict.
- **IDE Support.** When you use a constructed type declared from a generic type, the integrated development environment (IDE) can give you more support while you are developing your code. For example, IntelliSense can show you the type-specific options for an argument to a constructor or method.
- **Generic Algorithms.** Abstract algorithms that are type-independent are good candidates for generic types. For example, a generic procedure that sorts items using the [IComparable](#) interface can be used with any data type that implements [IComparable](#).

Constraints

Although the code in a generic type definition should be as type-independent as possible, you might need to require a certain capability of any data type supplied to your generic type. For example, if you want to compare two items for the purpose of sorting or collating, their data type must implement the [IComparable](#) interface. You can enforce this requirement by adding a *constraint* to the type parameter.

Example of a Constraint

The following example shows a skeleton definition of a class with a constraint that requires the type argument to implement [IComparable](#).

```
Public Class itemManager(Of t As IComparable)
    ' Insert code that defines class members.
End Class
```

If subsequent code attempts to construct a class from `itemManager` supplying a type that does not implement [IComparable](#), the compiler signals an error.

Types of Constraints

Your constraint can specify the following requirements in any combination:

- The type argument must implement one or more interfaces
- The type argument must be of the type of, or inherit from, at most one class
- The type argument must expose a parameterless constructor accessible to the code that creates objects from it
- The type argument must be a *reference type*, or it must be a *value type*

If you need to impose more than one requirement, you use a comma-separated *constraint list* inside braces (`{ }`). To require an accessible constructor, you include the [New Operator](#) keyword in the list. To require a reference type, you include the [Class](#) keyword; to require a value type, you include the [Structure](#) keyword.

For more information on constraints, see [Type List](#).

Example of Multiple Constraints

The following example shows a skeleton definition of a generic class with a constraint list on the type parameter. In the code that creates an instance of this class, the type argument must implement both the [IComparable](#) and [IDisposable](#) interfaces, be a reference type, and expose an accessible parameterless constructor.

```
Public Class thisClass(Of t As {IComparable, IDisposable, Class, New})
    ' Insert code that defines class members.
End Class
```

Important Terms

Generic types introduce and use the following terms:

- *Generic Type*. A definition of a class, structure, interface, procedure, or delegate for which you supply at least one data type when you declare it.
- *Type Parameter*. In a generic type definition, a placeholder for a data type you supply when you declare the type.
- *Type Argument*. A specific data type that replaces a type parameter when you declare a constructed type from a generic type.
- *Constraint*. A condition on a type parameter that restricts the type argument you can supply for it. A constraint can require that the type argument must implement a particular interface, be or inherit from a particular class, have an accessible parameterless constructor, or be a reference type or a value type. You can combine these constraints, but you can specify at most one class.
- *Constructed Type*. A class, structure, interface, procedure, or delegate declared from a generic type by supplying type arguments for its type parameters.

How to: Define a Class That Can Provide Identical Functionality on Different Data Types (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

You can define a class from which you can create objects that provide identical functionality on different data types. To do this, you specify one or more *type parameters* in the definition. The class can then serve as a template for objects that use various data types. A class defined in this way is called a *generic class*.

The advantage of defining a generic class is that you define it just once, and your code can use it to create many objects that use a wide variety of data types. This results in better performance than defining the class with the `Object` type.

In addition to classes, you can also define and use generic structures, interfaces, procedures, and delegates.

To define a class with a type parameter

1. Define the class in the normal way.
2. Add `(of typeparameter)` immediately after the class name to specify a type parameter.
3. If you have more than one type parameter, make a comma-separated list inside the parentheses. Do not repeat the `of` keyword.
4. If your code performs operations on a type parameter other than simple assignment, follow that type parameter with an `As` clause to add one or more *constraints*. A constraint guarantees that the type supplied for that type parameter satisfies a requirement such as the following:
 - Supports an operation, such as `>`, that your code performs
 - Supports a member, such as a method, that your code accesses
 - Exposes a parameterless constructor

If you do not specify any constraints, the only operations and members your code can use are those supported by the [Object Data Type](#). For more information, see [Type List](#).

5. Identify every class member that is to be declared with a supplied type, and declare it `As typeparameter`. This applies to internal storage, procedure parameters, and return values.
6. Be sure your code uses only operations and methods that are supported by any data type it can supply to `itemType`.

The following example defines a class that manages a very simple list. It holds the list in the internal array `items`, and the using code can declare the data type of the list elements. A parameterized constructor allows the using code to set the upper bound of `items`, and the default constructor sets this to 9 (for a total of 10 items).

```

Public Class simpleList(Of itemType)
    Private items() As itemType
    Private top As Integer
    Private nextp As Integer
    Public Sub New()
        Me.New(9)
    End Sub
    Public Sub New(ByVal t As Integer)
        MyBase.New()
        items = New itemType(t) {}
        top = t
        nextp = 0
    End Sub
    Public Sub add(ByVal i As itemType)
        insert(i, nextp)
    End Sub
    Public Sub insert(ByVal i As itemType, ByVal p As Integer)
        If p > nextp OrElse p < 0 Then
            Throw New System.ArgumentOutOfRangeException("p",
                " less than 0 or beyond next available list position")
        ElseIf nextp > top Then
            Throw New System.ArgumentException("No room to insert at ",
                "p")
        ElseIf p < nextp Then
            For j As Integer = nextp To p + 1 Step -1
                items(j) = items(j - 1)
            Next j
        End If
        items(p) = i
        nextp += 1
    End Sub
    Public Sub remove(ByVal p As Integer)
        If p >= nextp OrElse p < 0 Then
            Throw New System.ArgumentOutOfRangeException("p",
                " less than 0 or beyond last list item")
        ElseIf nextp = 0 Then
            Throw New System.ArgumentException("List empty; cannot remove ",
                "p")
        ElseIf p < nextp - 1 Then
            For j As Integer = p To nextp - 2
                items(j) = items(j + 1)
            Next j
        End If
        nextp -= 1
    End Sub
    Public ReadOnly Property listLength() As Integer
        Get
            Return nextp
        End Get
    End Property
    Public ReadOnly Property listItem(ByVal p As Integer) As itemType
        Get
            If p >= nextp OrElse p < 0 Then
                Throw New System.ArgumentOutOfRangeException("p",
                    " less than 0 or beyond last list item")
            End If
            Return items(p)
        End Get
    End Property
End Class

```

You can declare a class from `simpleList` to hold a list of `Integer` values, another class to hold a list of `String` values, and another to hold `Date` values. Except for the data type of the list members, objects created from all these classes behave identically.

The type argument that the using code supplies to `itemType` can be an intrinsic type such as `Boolean` or `Double`, a structure, an enumeration, or any type of class, including one that your application defines.

You can test the class `simpleList` with the following code.

```
Public Sub useSimpleList()
    Dim iList As New simpleList(Of Integer)(2)
    Dim sList As New simpleList(Of String)(3)
    Dim dList As New simpleList(Of Date)(2)
    iList.add(10)
    iList.add(20)
    iList.add(30)
    sList.add("First")
    sList.add("extra")
    sList.add("Second")
    sList.add("Third")
    sList.remove(1)
    dList.add(#1/1/2003#)
    dList.add(#3/3/2003#)
    dList.insert(#2/2/2003#, 1)
    Dim s =
        "Simple list of 3 Integer items (reported length " &
        CStr(iList.listLength) & ")" &
        vbCrLf & CStr(iList.listItem(0)) &
        vbCrLf & CStr(iList.listItem(1)) &
        vbCrLf & CStr(iList.listItem(2)) &
        vbCrLf &
        "Simple list of 4 - 1 String items (reported length " &
        CStr(sList.listLength) & ")" &
        vbCrLf & CStr(sList.listItem(0)) &
        vbCrLf & CStr(sList.listItem(1)) &
        vbCrLf & CStr(sList.listItem(2)) &
        vbCrLf &
        "Simple list of 2 + 1 Date items (reported length " &
        CStr(dList.listLength) & ")" &
        vbCrLf & CStr(dList.listItem(0)) &
        vbCrLf & CStr(dList.listItem(1)) &
        vbCrLf & CStr(dList.listItem(2))
    MsgBox(s)
End Sub
```

How to: Use a Generic Class (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

A class that takes *type parameters* is called a *generic class*. If you are using a generic class, you can generate a *constructed class* from it by supplying a *type argument* for each of these parameters. You can then declare a variable of the constructed class type, and you can create an instance of the constructed class and assign it to that variable.

In addition to classes, you can also define and use generic structures, interfaces, procedures, and delegates.

The following procedure takes a generic class defined in the .NET Framework and creates an instance from it.

To use a class that takes a type parameter

1. At the beginning of your source file, include an [Imports Statement \(.NET Namespace and Type\)](#) to import the `System.Collections.Generic` namespace. This allows you to refer to the `System.Collections.Generic.Queue<T>` class without having to fully qualify it to differentiate it from other queue classes such as `System.Collections.Queue`.
2. Create the object in the normal way, but add `(Of type)` immediately after the class name.

The following example uses the same class (`System.Collections.Generic.Queue<T>`) to create two queue objects that hold items of different data types. It adds items to the end of each queue and then removes and displays items from the front of each queue.

```
Public Sub usequeue()
    Dim queueDouble As New System.Collections.Generic.Queue(Of Double)
    Dim queueString As New System.Collections.Generic.Queue(Of String)
    queueDouble.Enqueue(1.1)
    queueDouble.Enqueue(2.2)
    queueDouble.Enqueue(3.3)
    queueDouble.Enqueue(4.4)
    queueString.Enqueue("First string of three")
    queueString.Enqueue("Second string of three")
    queueString.Enqueue("Third string of three")
    Dim s As String = "Queue of Double items (reported length " &
        CStr(queueDouble.Count) & ")"
    For i As Integer = 1 To queueDouble.Count
        s &= vbCrLf & CStr(queueDouble.Dequeue())
    Next i
    s &= vbCrLf & "Queue of String items (reported length " &
        CStr(queueString.Count) & ")"
    For i As Integer = 1 To queueString.Count
        s &= vbCrLf & queueString.Dequeue()
    Next i
    MsgBox(s)
End Sub
```

Generic Procedures in Visual Basic

2/28/2019 • 3 minutes to read • [Edit Online](#)

A *generic procedure*, also called a *generic method*, is a procedure defined with at least one type parameter. This allows the calling code to tailor the data types to its requirements each time it calls the procedure.

A procedure is not generic simply by virtue of being defined inside a generic class or a generic structure. To be generic, the procedure must take at least one type parameter, in addition to any normal parameters it might take. A generic class or structure can contain nongeneric procedures, and a nongeneric class, structure, or module can contain generic procedures.

A generic procedure can use its type parameters in its normal parameter list, in its return type if it has one, and in its procedure code.

Type Inference

You can call a generic procedure without supplying any type arguments at all. If you call it this way, the compiler attempts to determine the appropriate data types to pass to the procedure's type arguments. This is called *type inference*. The following code shows a call in which the compiler infers that it should pass type `String` to the type parameter `t`.

```
Public Sub testSub(Of t)(ByVal arg As t)
End Sub
Public Sub callTestSub()
    testSub("Use this string")
End Sub
```

If the compiler cannot infer the type arguments from the context of your call, it reports an error. One possible cause of such an error is an array rank mismatch. For example, suppose you define a normal parameter as an array of a type parameter. If you call the generic procedure supplying an array of a different rank (number of dimensions), the mismatch causes type inference to fail. The following code shows a call in which a two-dimensional array is passed to a procedure that expects a one-dimensional array.

```
Public Sub demoSub(Of t)(ByVal arg() As t)
End Sub

Public Sub callDemoSub()
    Dim twoDimensions(,) As Integer
    demoSub(twoDimensions)
End Sub
```

You can invoke type inference only by omitting all the type arguments. If you supply one type argument, you must supply them all.

Type inference is supported only for generic procedures. You cannot invoke type inference on generic classes, structures, interfaces, or delegates.

Example

Description

The following example defines a generic `Function` procedure to find a particular element in an array. It defines

one type parameter and uses it to construct the two parameters in the parameter list.

Code

```
Public Function findElement(Of T As IComparable) (
    ByVal searchArray As T(), ByVal searchValue As T) As Integer

    If searchArray.GetLength(0) > 0 Then
        For i As Integer = 0 To searchArray.GetUpperBound(0)
            If searchArray(i).CompareTo(searchValue) = 0 Then Return i
        Next i
    End If

    Return -1
End Function
```

Comments

The preceding example requires the ability to compare `searchValue` against each element of `searchArray`. To guarantee this ability, it constrains the type parameter `T` to implement the `IComparable<T>` interface. The code uses the `CompareTo` method instead of the `=` operator, because there is no guarantee that a type argument supplied for `T` supports the `=` operator.

You can test the `findElement` procedure with the following code.

```
Public Sub tryFindElement()
    Dim stringArray() As String = {"abc", "def", "xyz"}
    Dim stringSearch As String = "abc"
    Dim integerArray() As Integer = {7, 8, 9}
    Dim integerSearch As Integer = 8
    Dim dateArray() As Date = {[#4/17/1969#, #9/20/1998#, #5/31/2004#]}
    Dim dateSearch As Date = Microsoft.VisualBasic.DateAndTime.Today
    MsgBox(CStr(findElement(Of String)(stringArray, stringSearch)))
    MsgBox(CStr(findElement(Of Integer)(integerArray, integerSearch)))
    MsgBox(CStr(findElement(Of Date)(dateArray, dateSearch)))
End Sub
```

The preceding calls to `MsgBox` display "0", "1", and "-1" respectively.

Nullable Value Types (Visual Basic)

1/23/2019 • 5 minutes to read • [Edit Online](#)

Sometimes you work with a value type that does not have a defined value in certain circumstances. For example, a field in a database might have to distinguish between having an assigned value that is meaningful and not having an assigned value. Value types can be extended to take either their normal values or a null value. Such an extension is called a *nullable type*.

Each nullable type is constructed from the generic `Nullable<T>` structure. Consider a database that tracks work-related activities. The following example constructs a nullable `Boolean` type and declares a variable of that type. You can write the declaration in three ways:

```
Dim ridesBusToWork1? As Boolean  
Dim ridesBusToWork2 As Boolean?  
Dim ridesBusToWork3 As Nullable(Of Boolean)
```

The variable `ridesBusToWork` can hold a value of `True`, a value of `False`, or no value at all. Its initial default value is no value at all, which in this case could mean that the information has not yet been obtained for this person. In contrast, `False` could mean that the information has been obtained and the person does not ride the bus to work.

You can declare variables and properties with nullable types, and you can declare an array with elements of a nullable type. You can declare procedures with nullable types as parameters, and you can return a nullable type from a `Function` procedure.

You cannot construct a nullable type on a reference type such as an array, a `String`, or a class. The underlying type must be a value type. For more information, see [Value Types and Reference Types](#).

Using a Nullable Type Variable

The most important members of a nullable type are its `HasValue` and `Value` properties. For a variable of a nullable type, `HasValue` tells you whether the variable contains a defined value. If `HasValue` is `True`, you can read the value from `Value`. Note that both `HasValue` and `Value` are `ReadOnly` properties.

Default Values

When you declare a variable with a nullable type, its `HasValue` property has a default value of `False`. This means that by default the variable has no defined value, instead of the default value of its underlying value type. In the following example, the variable `numberOfChildren` initially has no defined value, even though the default value of the `Integer` type is 0.

```
Dim numberOfChildren? As Integer
```

A null value is useful to indicate an undefined or unknown value. If `numberOfChildren` had been declared as `Integer`, there would be no value that could indicate that the information is not currently available.

Storing Values

You store a value in a variable or property of a nullable type in the typical way. The following example assigns a value to the variable `numberOfChildren` declared in the previous example.

```
numberOfChildren = 2
```

If a variable or property of a nullable type contains a defined value, you can cause it to revert to its initial state of not having a value assigned. You do this by setting the variable or property to `Nothing`, as the following example shows.

```
numberOfChildren = Nothing
```

NOTE

Although you can assign `Nothing` to a variable of a nullable type, you cannot test it for `Nothing` by using the equal sign. Comparison that uses the equal sign, `someVar = Nothing`, always evaluates to `Nothing`. You can test the variable's `HasValue` property for `False`, or test by using the `Is` or `IsNot` operator.

Retrieving Values

To retrieve the value of a variable of a nullable type, you should first test its `HasValue` property to confirm that it has a value. If you try to read the value when `HasValue` is `False`, Visual Basic throws an `InvalidOperationException` exception. The following example shows the recommended way to read the variable `numberOfChildren` of the previous examples.

```
If numberOfChildren.HasValue Then  
    MsgBox("There are " & CStr(numberOfChildren) & " children.")  
Else  
    MsgBox("It is not known how many children there are.")  
End If
```

Comparing Nullable Types

When nullable `Boolean` variables are used in Boolean expressions, the result can be `True`, `False`, or `Nothing`. The following is the truth table for `And` and `Or`. Because `b1` and `b2` now have three possible values, there are nine combinations to evaluate.

B1	B2	B1 AND B2	B1 OR B2
<code>Nothing</code>	<code>Nothing</code>	<code>Nothing</code>	<code>Nothing</code>
<code>Nothing</code>	<code>True</code>	<code>Nothing</code>	<code>True</code>
<code>Nothing</code>	<code>False</code>	<code>False</code>	<code>Nothing</code>
<code>True</code>	<code>Nothing</code>	<code>Nothing</code>	<code>True</code>
<code>True</code>	<code>True</code>	<code>True</code>	<code>True</code>
<code>True</code>	<code>False</code>	<code>False</code>	<code>True</code>
<code>False</code>	<code>Nothing</code>	<code>False</code>	<code>Nothing</code>
<code>False</code>	<code>True</code>	<code>False</code>	<code>True</code>
<code>False</code>	<code>False</code>	<code>False</code>	<code>False</code>

When the value of a Boolean variable or expression is `Nothing`, it is neither `true` nor `false`. Consider the

following example.

```
Dim b1? As Boolean
Dim b2? As Boolean
b1 = True
b2 = Nothing

' The following If statement displays "Expression is not true".
If (b1 And b2) Then
    Console.WriteLine("Expression is true")
Else
    Console.WriteLine("Expression is not true")
End If

' The following If statement displays "Expression is not false".
If Not (b1 And b2) Then
    Console.WriteLine("Expression is false")
Else
    Console.WriteLine("Expression is not false")
End If
```

In this example, `b1 And b2` evaluates to `Nothing`. As a result, the `Else` clause is executed in each `If` statement, and the output is as follows:

```
Expression is not true
```

```
Expression is not false
```

NOTE

`AndAlso` and `OrElse`, which use short-circuit evaluation, must evaluate their second operands when the first evaluates to `Nothing`.

Propagation

If one or both of the operands of an arithmetic, comparison, shift, or type operation is nullable, the result of the operation is also nullable. If both operands have values that are not `Nothing`, the operation is performed on the underlying values of the operands, as if neither were a nullable type. In the following example, variables `compare1` and `sum1` are implicitly typed. If you rest the mouse pointer over them, you will see that the compiler infers nullable types for both of them.

```
' Variable n is a nullable type, but both m and n have proper values.
Dim m As Integer = 3
Dim n? As Integer = 2

' The comparison evaluated is 3 > 2, but compare1 is inferred to be of
' type Boolean?.
Dim compare1 = m > n
' The values summed are 3 and 2, but sum1 is inferred to be of type Integer?.
Dim sum1 = m + n

' The following line displays: 3 * 2 * 5 * True
Console.WriteLine($"{m} * {n} * {sum1} * {compare1}")
```

If one or both operands have a value of `Nothing`, the result will be `Nothing`.

```
' Change the value of n to Nothing.  
n = Nothing  
  
Dim compare2 = m > n  
Dim sum2 = m + n  
  
' Because the values of n, compare2, and sum2 are all Nothing, the  
' following line displays: 3 * <null> * <null> * <null>  
Console.WriteLine($"{m} * {If(n, "<null>")} * {If(sum2, "<null>")} * {If(compare2, "<null>")})
```

Using Nullable Types with Data

A database is one of the most important places to use nullable types. Not all database objects currently support nullable types, but the designer-generated table adapters do. See "TableAdapter Support for Nullable Types" in [TableAdapter Overview](#).

Value Types and Reference Types

1/23/2019 • 2 minutes to read • [Edit Online](#)

In Visual Basic, data types are implemented based on their classification. The Visual Basic data types can be classified according to whether a variable of a particular type stores its own data or a pointer to the data. If it stores its own data it is a *value type*; if it holds a pointer to data elsewhere in memory it is a *reference type*.

Value Types

A data type is a *value type* if it holds the data within its own memory allocation. Value types include the following:

- All numeric data types
- `Boolean`, `Char`, and `Date`
- All structures, even if their members are reference types
- Enumerations, since their underlying type is always `SByte`, `Short`, `Integer`, `Long`, `Byte`, `UShort`, `UInteger`, or `ULong`

Every structure is a value type, even if it contains reference type members. For this reason, value types such as `Char` and `Integer` are implemented by .NET Framework structures.

You can declare a value type by using the reserved keyword, for example, `Decimal`. You can also use the `New` keyword to initialize a value type. This is especially useful if the type has a constructor that takes parameters. An example of this is the `Decimal(Int32, Int32, Int32, Boolean, Byte)` constructor, which builds a new `Decimal` value from the supplied parts.

Reference Types

A *reference type* contains a pointer to another memory location that holds the data. Reference types include the following:

- `String`
- All arrays, even if their elements are value types
- Class types, such as `Form`
- Delegates

A class is a *reference type*. For this reason, reference types such as `Object` and `String` are supported by .NET Framework classes. Note that every array is a reference type, even if its members are value types.

Since every reference type represents an underlying .NET Framework class, you must use the [New Operator](#) keyword when you initialize it. The following statement initializes an array.

```
Dim totals() As Single = New Single(8) {}
```

Elements That Are Not Types

The following programming elements do not qualify as types, because you cannot specify any of them as a data

type for a declared element:

- Namespaces
- Modules
- Events
- Properties and procedures
- Variables, constants, and fields

Working with the Object Data Type

You can assign either a reference type or a value type to a variable of the `Object` data type. An `Object` variable always holds a pointer to the data, never the data itself. However, if you assign a value type to an `Object` variable, it behaves as if it holds its own data. For more information, see [Object Data Type](#).

You can find out whether an `Object` variable is acting as a reference type or a value type by passing it to the `IsReference` method in the `Information` class of the `Microsoft.VisualBasic` namespace. `Information.IsReference` returns `True` if the content of the `Object` variable represents a reference type.

Type Conversions in Visual Basic

8/24/2018 • 2 minutes to read • [Edit Online](#)

The process of changing a value from one data type to another type is called *conversion*. Conversions are either *widening* or *narrowing*, depending on the data capacities of the types involved. They are also *implicit* or *explicit*, depending on the syntax in the source code.

In This Section

[Widening and Narrowing Conversions](#)

Explains conversions classified by whether the destination type can hold the data.

[Implicit and Explicit Conversions](#)

Discusses conversions classified by whether Visual Basic performs them automatically.

[Conversions Between Strings and Other Types](#)

Illustrates converting between strings and numeric, `Boolean`, or date/time values.

[How to: Convert an Object to Another Type in Visual Basic](#)

Shows how to convert an `Object` variable to any other data type.

[Array Conversions](#)

Steps you through the process of converting between arrays of different data types.

Widening and Narrowing Conversions (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

An important consideration with a type conversion is whether the result of the conversion is within the range of the destination data type.

A *widening conversion* changes a value to a data type that can allow for any possible value of the original data. Widening conversions preserve the source value but can change its representation. This occurs if you convert from an integral type to `Decimal`, or from `Char` to `String`.

A *narrowing conversion* changes a value to a data type that might not be able to hold some of the possible values. For example, a fractional value is rounded when it is converted to an integral type, and a numeric type being converted to `Boolean` is reduced to either `True` or `False`.

Widening Conversions

The following table shows the standard widening conversions.

DATA TYPE	WIDENS TO DATA TYPES <sup>1</sup>
<code>SByte</code>	<code>SByte</code> , <code>Short</code> , <code>Integer</code> , <code>Long</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code>
<code>Byte</code>	<code>Byte</code> , <code>Short</code> , <code>UShort</code> , <code>Integer</code> , <code>UInteger</code> , <code>Long</code> , <code>ULong</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code>
<code>Short</code>	<code>Short</code> , <code>Integer</code> , <code>Long</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code>
<code>UShort</code>	<code>UShort</code> , <code>Integer</code> , <code>UInteger</code> , <code>Long</code> , <code>ULong</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code>
<code>Integer</code>	<code>Integer</code> , <code>Long</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code> <sup>2</sup>
<code>UInteger</code>	<code>UInteger</code> , <code>Long</code> , <code>ULong</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code> <sup>2</sup>
<code>Long</code>	<code>Long</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code> <sup>2</sup>
<code>ULong</code>	<code>ULong</code> , <code>Decimal</code> , <code>Single</code> , <code>Double</code> <sup>2</sup>
<code>Decimal</code>	<code>Decimal</code> , <code>Single</code> , <code>Double</code> <sup>2</sup>
<code>Single</code>	<code>Single</code> , <code>Double</code>
<code>Double</code>	<code>Double</code>
Any enumerated type (Enum)	Its underlying integral type and any type to which the underlying type widens.
<code>Char</code>	<code>Char</code> , <code>String</code>

DATA TYPE	WIDENS TO DATA TYPES
Char array	Char array, String
Any type	Object
Any derived type	Any base type from which it is derived <sup>3</sup> .
Any type	Any interface it implements.
Nothing	Any data type or object type.

<sup>1</sup> By definition, every data type widens to itself.

<sup>2</sup> Conversions from Integer, UInteger, Long, ULong, or Decimal to Single or Double might result in loss of precision, but never in loss of magnitude. In this sense they do not incur information loss.

<sup>3</sup> It might seem surprising that a conversion from a derived type to one of its base types is widening. The justification is that the derived type contains all the members of the base type, so it qualifies as an instance of the base type. In the opposite direction, the base type does not contain any new members defined by the derived type.

Widening conversions always succeed at run time and never incur data loss. You can always perform them implicitly, whether the [Option Strict Statement](#) sets the type checking switch to `On` or to `Off`.

Narrowing Conversions

The standard narrowing conversions include the following:
