- The reverse directions of the widening conversions in the preceding table (except that every type widens to itself)
- Conversions in either direction between Boolean and any numeric type
- Conversions from any numeric type to any enumerated type (`Enum`)
- Conversions in either direction between String and any numeric type, Boolean, or Date
- Conversions from a data type or object type to a type derived from it

Narrowing conversions do not always succeed at run time, and can fail or incur data loss. An error occurs if the destination data type cannot receive the value being converted. For example, a numeric conversion can result in an overflow. The compiler does not allow you to perform narrowing conversions implicitly unless the [Option Strict Statement](#) sets the type checking switch to `Off`.

NOTE

The narrowing-conversion error is suppressed for conversions from the elements in a `For Each...Next` collection to the loop control variable. For more information and examples, see the "Narrowing Conversions" section in [For Each...Next Statement](#).

When to Use Narrowing Conversions

You use a narrowing conversion when you know the source value can be converted to the destination data type without error or data loss. For example, if you have a `String` that you know contains either "True" or "False," you can use the `CBool` keyword to convert it to `Boolean`.

Exceptions During Conversion

Because widening conversions always succeed, they do not throw exceptions. Narrowing conversions, when they fail, most commonly throw the following exceptions:

- [InvalidCastException](#) — if no conversion is defined between the two types
- [OverflowException](#) — (integral types only) if the converted value is too large for the target type

If a class or structure defines a [CType Function](#) to serve as a conversion operator to or from that class or structure, that `CType` can throw any exception it deems appropriate. In addition, that `CType` might call Visual Basic functions or .NET Framework methods, which in turn could throw a variety of exceptions.

Changes During Reference Type Conversions

A conversion from a *reference type* copies only the pointer to the value. The value itself is neither copied nor changed in any way. The only thing that can change is the data type of the variable holding the pointer. In the following example, the data type is converted from the derived class to its base class, but the object that both variables now point to is unchanged.

```
' Assume class cSquare inherits from class cShape.  
Dim shape As cShape  
Dim square As cSquare = New cSquare  
' The following statement performs a widening  
' conversion from a derived class to its base class.  
shape = square
```

Implicit and Explicit Conversions (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

An *implicit conversion* does not require any special syntax in the source code. In the following example, Visual Basic implicitly converts the value of `k` to a single-precision floating-point value before assigning it to `q`.

```
Dim k As Integer
Dim q As Double
' Integer widens to Double, so you can do this with Option Strict On.
k = 432
q = k
```

An *explicit conversion* uses a type conversion keyword. Visual Basic provides several such keywords, which coerce an expression in parentheses to the desired data type. These keywords act like functions, but the compiler generates the code inline, so execution is slightly faster than with a function call.

In the following extension of the preceding example, the `CInt` keyword converts the value of `q` back to an integer before assigning it to `k`.

```
' q had been assigned the value 432 from k.
q = Math.Sqrt(q)
k = CInt(q)
' k now has the value 21 (rounded square root of 432).
```

Conversion Keywords

The following table shows the available conversion keywords.

TYPE CONVERSION KEYWORD	CONVERTS AN EXPRESSION TO DATA TYPE	ALLOWABLE DATA TYPES OF EXPRESSION TO BE CONVERTED
<code>CBool</code>	Boolean Data Type	Any numeric type (including <code>Byte</code> , <code>SByte</code> , and enumerated types), <code>String</code> , <code>Object</code>
<code>CByte</code>	Byte Data Type	Any numeric type (including <code>SByte</code> and enumerated types), <code>Boolean</code> , <code>String</code> , <code>Object</code>

<code>CUShort</code>	UShort Data Type	Any numeric type (including <code>Byte</code> , <code>SByte</code> , and enumerated types), <code>Boolean</code> , <code>String</code> , <code>Object</code>

The CType Function

The [CType Function](#) operates on two arguments. The first is the expression to be converted, and the second is the destination data type or object class. Note that the first argument must be an expression, not a type.

`CType` is an *inline function*, meaning the compiled code makes the conversion, often without generating a function call. This improves performance.

For a comparison of `CType` with the other type conversion keywords, see [DirectCast Operator](#) and [TryCast Operator](#).

Elementary Types

The following example demonstrates the use of `CType`.

```
k = CType(q, Integer)
' The following statement coerces w to the specific object class Label.
f = CType(w, Label)
```

Composite Types

You can use `CType` to convert values to composite data types as well as to elementary types. You can also use it to coerce an object class to the type of one of its interfaces, as in the following example.

```
' Assume class cZone implements interface iZone.
Dim h As Object
' The first argument to CType must be an expression, not a type.
Dim cZ As cZone
' The following statement coerces a cZone object to its interface iZone.
h = CType(cZ, iZone)
```

Array Types

`CType` can also convert array data types, as in the following example.

```
Dim v() As classV
Dim obArray() As Object
' Assume some object array has been assigned to obArray.
' Check for run-time type compatibility.
If TypeOf obArray Is classV()
    ' obArray can be converted to classV.
    v = CType(obArray, classV())
End If
```

For more information and an example, see [Array Conversions](#).

Types Defining CType

You can define `CType` on a class or structure you have defined. This allows you to convert values to and from the type of your class or structure. For more information and an example, see [How to: Define a Conversion Operator](#).

NOTE

Values used with a conversion keyword must be valid for the destination data type, or an error occurs. For example, if you attempt to convert a `Long` to an `Integer`, the value of the `Long` must be within the valid range for the `Integer` data type.

Specifying `CType` to convert from one class type to another fails at run time if the source type does not derive from the destination type. Such a failure throws an `InvalidOperationException` exception.

However, if one of the types is a structure or class you have defined, and if you have defined `CType` on that structure or class, a conversion can succeed if it satisfies the requirements of your `CType`. See [How to: Define a Conversion Operator](#).

Performing an explicit conversion is also known as *casting* an expression to a given data type or object class.

Conversions Between Strings and Other Types (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

You can convert a numeric, `Boolean`, or date/time value to a `String`. You can also convert in the reverse direction — from a string value to numeric, `Boolean`, or `Date` — provided the contents of the string can be interpreted as a valid value of the destination data type. If they cannot, a run-time error occurs.

The conversions for all these assignments, in either direction, are narrowing conversions. You should use the type conversion keywords (`CBool`, `CByte`, `CDate`, `CDbl`, `CDec`, `CInt`, `CLng`, `CSByte`, `CShort`, `CSng`, `CStr`, `CUInt`, `CULng`, `CUShort`, and `CType`). The `Format` and `Val` functions give you additional control over conversions between strings and numbers.

If you have defined a class or structure, you can define type conversion operators between `String` and the type of your class or structure. For more information, see [How to: Define a Conversion Operator](#).

Conversion of Numbers to Strings

You can use the `Format` function to convert a number to a formatted string, which can include not only the appropriate digits but also formatting symbols such as a currency sign (such as `$`), thousands separators or *digit grouping symbols* (such as `,`), and a decimal separator (such as `.`). `Format` automatically uses the appropriate symbols according to the **Regional Options** settings specified in the Windows **Control Panel**.

Note that the concatenation (`&`) operator can convert a number to a string implicitly, as the following example shows.

```
' The following statement converts count to a String value.  
Str = "The total count is " & count
```

Conversion of Strings to Numbers

You can use the `Val` function to explicitly convert the digits in a string to a number. `Val` reads the string until it encounters a character other than a digit, space, tab, line feed, or period. The sequences "&O" and "&H" alter the base of the number system and terminate the scanning. Until it stops reading, `Val` converts all appropriate characters to a numeric value. For example, the following statement returns the value `141.825`.

```
Val(" 14 1.825 miles")
```

When Visual Basic converts a string to a numeric value, it uses the **Regional Options** settings specified in the Windows **Control Panel** to interpret the thousands separator, decimal separator, and currency symbol. This means that a conversion might succeed under one setting but not another. For example, `"$14.20"` is acceptable in the English (United States) locale but not in any French locale.

How to: Convert an Object to Another Type in Visual Basic

1/23/2019 • 2 minutes to read • [Edit Online](#)

You convert an `Object` variable to another data type by using a conversion keyword such as [CType Function](#).

Example

The following example converts an `Object` variable to an `Integer` and a `String`.

```
Public Sub objectConversion(ByVal anObject As Object)
    Dim anInteger As Integer
    Dim aString As String
    anInteger = CType(anObject, Integer)
    aString = CType(anObject, String)
End Sub
```

If you know that the contents of an `Object` variable are of a particular data type, it is better to convert the variable to that data type. If you continue to use the `Object` variable, you incur either *boxing* and *unboxing* (for a value type) or *late binding* (for a reference type). These operations all take extra execution time and make your performance slower.

Compiling the Code

This example requires:

- A reference to the [System](#) namespace.

Array Conversions (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

You can convert an array type to a different array type provided you meet the following conditions:

- **Equal Rank.** The ranks of the two arrays must be the same, that is, they must have the same number of dimensions. However, the lengths of the respective dimensions do not need to be the same.
- **Element Data Type.** The data types of the elements of both arrays must be reference types. You cannot convert an `Integer` array to a `Long` array, or even to an `Object` array, because at least one value type is involved. For more information, see [Value Types and Reference Types](#).
- **Convertibility.** A conversion, either widening or narrowing, must be possible between the element types of the two arrays. An example that fails this requirement is an attempted conversion between a `String` array and an array of a class derived from `System.Attribute`. These two types have nothing in common, and no conversion of any kind exists between them.

A conversion of one array type to another is widening or narrowing depending on whether the conversion of the respective elements is widening or narrowing. For more information, see [Widening and Narrowing Conversions](#).

Conversion to an Object Array

When you declare an `Object` array without initializing it, its element type is `Object` as long as it remains uninitialized. When you set it to an array of a specific class, it takes on the type of that class. However, its underlying type is still `Object`, and you can subsequently set it to another array of an unrelated class. Since all classes derive from `Object`, you can change the array's element type from any class to any other class.

In the following example, no conversion exists between types `student` and `String`, but both derive from `Object`, so all assignments are valid.

```
' Assume student has already been defined as a class.  
Dim testArray() As Object  
' testArray is still an Object array at this point.  
Dim names() As String = New String(3) {"Name0", "Name1", "Name2", "Name3"}  
testArray = New student(3) {}  
' testArray is now of type student().  
testArray = names  
' testArray is now a String array.
```

Underlying Type of an Array

If you originally declare an array with a specific class, its underlying element type is that class. If you subsequently set it to an array of another class, there must be a conversion between the two classes.

In the following example, `students` is a `student` array. Since no conversion exists between `String` and `student`, the last statement fails.

```
Dim students() As student  
Dim names() As String = New String(3) {"Name0", "Name1", "Name2", "Name3"}  
students = New Student(3) {}  
' The following statement fails at compile time.  
students = names
```

Structures (Visual Basic)

8/24/2018 • 2 minutes to read • [Edit Online](#)

A *structure* is a generalization of the user-defined type (UDT) supported by previous versions of Visual Basic. In addition to fields, structures can expose properties, methods, and events. A structure can implement one or more interfaces, and you can declare individual access levels for each field.

You can combine data items of different types to create a structure. A structure associates one or more *elements* with each other and with the structure itself. When you declare a structure, it becomes a *composite data type*, and you can declare variables of that type.

Structures are useful when you want a single variable to hold several related pieces of information. For example, you might want to keep an employee's name, telephone extension, and salary together. You could use several variables for this information, or you could define a structure and use it for a single employee variable. The advantage of the structure becomes apparent when you have many employees and therefore many instances of the variable.

How to: Declare a Structure (Visual Basic)

1/25/2019 • 2 minutes to read • [Edit Online](#)

You begin a structure declaration with the [Structure Statement](#), and you end it with the `End Structure` statement. Between these two statements you must declare at least one *element*. The elements can be of any data type, but at least one must be either a nonshared variable or a nonshared, noncustom event.

You cannot initialize any of the structure elements in the structure declaration. When you declare a variable to be of a structure type, you assign values to the elements by accessing them through the variable.

For a discussion of the differences between structures and classes, see [Structures and Classes](#).

For demonstration purposes, consider a situation where you want to keep track of an employee's name, telephone extension, and salary. A structure allows you to do this in a single variable.

To declare a structure

1. Create the beginning and ending statements for the structure.

You can specify the access level of a structure using the [Public](#), [Protected](#), [Friend](#), or [Private](#) keyword, or you can let it default to `Public`.

```
Private Structure employee  
End Structure
```

2. Add elements to the body of the structure.

A structure must have at least one element. You must declare every element and specify an access level for it. If you use the [Dim Statement](#) without any keywords, the accessibility defaults to `Public`.

```
Private Structure employee  
    Public givenName As String  
    Public familyName As String  
    Public phoneExtension As Long  
    Private salary As Decimal  
    Public Sub giveRaise(raise As Double)  
        salary *= raise  
    End Sub  
    Public Event salaryReviewTime()  
End Structure
```

The `salary` field in the preceding example is `Private`, which means it is inaccessible outside the structure, even from the containing class. However, the `giveRaise` procedure is `Public`, so it can be called from outside the structure. Similarly, you can raise the `salaryReviewTime` event from outside the structure.

In addition to variables, `Sub` procedures, and events, you can also define constants, `Function` procedures, and properties in a structure. You can designate at most one property as the *default property*, provided it takes at least one argument. You can handle an event with a [Shared](#) `Sub` procedure. For more information, see [How to: Declare and Call a Default Property in Visual Basic](#).

Structure Variables (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Once you have created a structure, you can declare procedure-level and module-level variables as that type. For example, you can create a structure that records information about a computer system. The following example demonstrates this.

```
Public Structure systemInfo
    Public CPU As String
    Public memory As Long
    Public purchaseDate As Date
End Structure
```

You can now declare variables of that type. The following declaration illustrates this.

```
Dim mySystem, yourSystem As systemInfo
```

NOTE

In classes and modules, structures declared using the [Dim Statement](#) default to public access. If you intend a structure to be private, make sure you declare it using the [Private keyword](#).

Access to Structure Values

To assign and retrieve values from the elements of a structure variable, you use the same syntax as you use to set and get properties on an object. You place the member access operator (`.`) between the structure variable name and the element name. The following example accesses elements of the variables previously declared as type `systemInfo`.

```
mySystem.CPU = "486"
Dim tooOld As Boolean
If yourSystem.purchaseDate < #1/1/1992# Then tooOld = True
```

Assigning Structure Variables

You can also assign one variable to another if both are of the same structure type. This copies all the elements of one structure to the corresponding elements in the other. The following declaration illustrates this.

```
yourSystem = mySystem
```

If a structure element is a reference type, such as a `String`, `Object`, or array, the pointer to the data is copied. In the previous example, if `systemInfo` had included an object variable, then the preceding example would have copied the pointer from `mySystem` to `yourSystem`, and a change to the object's data through one structure would be in effect when accessed through the other structure.

Structures and Other Programming Elements (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

You can use structures in conjunction with arrays, objects, and procedures, as well as with each other. The interactions use the same syntax as these elements use individually.

NOTE

You cannot initialize any of the structure elements in the structure declaration. You can assign values only to elements of a variable that has been declared to be of a structure type.

Structures and Arrays

A structure can contain an array as one or more of its elements. The following example illustrates this.

```
Public Structure systemInfo
    Public cPU As String
    Public memory As Long
    Public diskDrives() As String
    Public purchaseDate As Date
End Structure
```

You access the values of an array within a structure the same way you access a property on an object. The following example illustrates this.

```
Dim mySystem As systemInfo
ReDim mySystem.diskDrives(3)
mySystem.diskDrives(0) = "1.44 MB"
```

You can also declare an array of structures. The following example illustrates this.

```
Dim allSystems(100) As systemInfo
```

You follow the same rules to access the components of this data architecture. The following example illustrates this.

```
ReDim allSystems(5).diskDrives(3)
allSystems(5).CPU = "386SX"
allSystems(5).diskDrives(2) = "100M SCSI"
```

Structures and Objects

A structure can contain an object as one or more of its elements. The following example illustrates this.

```

Protected Structure userInput
    Public userName As String
    Public inputForm As System.Windows.Forms.Form
    Public userFileNumber As Integer
End Structure

```

You should use a specific object class in such a declaration, rather than `Object`.

Structures and Procedures

You can pass a structure as a procedure argument. The following example illustrates this.

```

Public currentCPUName As String = "700MHz Pentium compatible"
Public currentMemorySize As Long = 256
Public Sub fillSystem(ByRef someSystem As systemInfo)
    someSystem.cPU = currentCPUName
    someSystem.memory = currentMemorySize
    someSystem.purchaseDate = Now
End Sub

```

The preceding example passes the structure *by reference*, which allows the procedure to modify its elements so that the changes take effect in the calling code. If you want to protect a structure against such modification, pass it by value.

You can also return a structure from a `Function` procedure. The following example illustrates this.

```

Dim allSystems(100) As systemInfo
Function findByDate(ByVal searchDate As Date) As systemInfo
    Dim i As Integer
    For i = 1 To 100
        If allSystems(i).purchaseDate = searchDate Then Return allSystems(i)
    Next i
    ' Process error: system with desired purchase date not found.
End Function

```

Structures Within Structures

Structures can contain other structures. The following example illustrates this.

```

Public Structure driveInfo
    Public type As String
    Public size As Long
End Structure
Public Structure systemInfo
    Public cPU As String
    Public memory As Long
    Public diskDrives() As driveInfo
    Public purchaseDate As Date
End Structure

```

```

Dim allSystems(100) As systemInfo
ReDim allSystems(1).diskDrives(3)
allSystems(1).diskDrives(0).type = "Floppy"

```

You can also use this technique to encapsulate a structure defined in one module within a structure defined in a different module.

Structures can contain other structures to an arbitrary depth.

Structures and Classes (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

Visual Basic unifies the syntax for structures and classes, with the result that both entities support most of the same features. However, there are also important differences between structures and classes.

Classes have the advantage of being reference types — passing a reference is more efficient than passing a structure variable with all its data. On the other hand, structures do not require allocation of memory on the global heap.

Because you cannot inherit from a structure, structures should be used only for objects that do not need to be extended. Use structures when the object you wish to create has a small instance size, and take into account the performance characteristics of classes versus structures.

Similarities

Structures and classes are similar in the following respects:

- Both are *container* types, meaning that they contain other types as members.
- Both have members, which can include constructors, methods, properties, fields, constants, enumerations, events, and event handlers. However, do not confuse these members with the declared *elements* of a structure.
- Members of both can have individualized access levels. For example, one member can be declared `Public` and another `Private`.
- Both can implement interfaces.
- Both can have shared constructors, with or without parameters.
- Both can expose a *default property*, provided that property takes at least one parameter.
- Both can declare and raise events, and both can declare delegates.

Differences

Structures and classes differ in the following particulars:

- Structures are *value types*; classes are *reference types*. A variable of a structure type contains the structure's data, rather than containing a reference to the data as a class type does.
- Structures use stack allocation; classes use heap allocation.
- All structure elements are `Public` by default; class variables and constants are `Private` by default, while other class members are `Public` by default. This behavior for class members provides compatibility with the Visual Basic 6.0 system of defaults.
- A structure must have at least one nonshared variable or nonshared, noncustom event element; a class can be completely empty.
- Structure elements cannot be declared as `Protected`; class members can.
- A structure procedure can handle events only if it is a `Shared Sub` procedure, and only by means of the `AddHandler Statement`; any class procedure can handle events, using either the `Handles` keyword or the

`AddHandler` statement. For more information, see [Events](#).

- Structure variable declarations cannot specify initializers or initial sizes for arrays; class variable declarations can.
- Structures implicitly inherit from the [System.ValueType](#) class and cannot inherit from any other type; classes can inherit from any class or classes other than [System.ValueType](#).
- Structures are not inheritable; classes are.
- Structures are never terminated, so the common language runtime (CLR) never calls the [Finalize](#) method on any structure; classes are terminated by the garbage collector (GC), which calls [Finalize](#) on a class when it detects there are no active references remaining.
- A structure does not require a constructor; a class does.
- Structures can have nonshared constructors only if they take parameters; classes can have them with or without parameters.

Every structure has an implicit public constructor without parameters. This constructor initializes all the structure's data elements to their default values. You cannot redefine this behavior.

Instances and Variables

Because structures are value types, each structure variable is permanently bound to an individual structure instance. But classes are reference types, and an object variable can refer to various class instances at different times. This distinction affects your usage of structures and classes in the following ways:

- **Initialization.** A structure variable implicitly includes an initialization of the elements using the structure's parameterless constructor. Therefore, `Dim s As struct1` is equivalent to `Dim s As struct1 = New struct1()`.
- **Assigning Variables.** When you assign one structure variable to another, or pass a structure instance to a procedure argument, the current values of all the variable elements are copied to the new structure. When you assign one object variable to another, or pass an object variable to a procedure, only the reference pointer is copied.
- **Assigning Nothing.** You can assign the value [Nothing](#) to a structure variable, but the instance continues to be associated with the variable. You can still call its methods and access its data elements, although variable elements are reinitialized by the assignment.

In contrast, if you set an object variable to `Nothing`, you dissociate it from any class instance, and you cannot access any members through the variable until you assign another instance to it.

- **Multiple Instances.** An object variable can have different class instances assigned to it at different times, and several object variables can refer to the same class instance at the same time. Changes you make to the values of class members affect those members when accessed through another variable pointing to the same instance.

Structure elements, however, are isolated within their own instance. Changes to their values are not reflected in any other structure variables, even in other instances of the same `Structure` declaration.

- **Equality.** Equality testing of two structures must be performed with an element-by-element test. Two object variables can be compared using the [Equals](#) method. [Equals](#) indicates whether the two variables point to the same instance.

Tuples (Visual Basic)

1/23/2019 • 11 minutes to read • [Edit Online](#)

Starting with Visual Basic 2017, the Visual Basic language offers built-in support for tuples that makes creating tuples and accessing the elements of tuples easier. A tuple is a light-weight data structure that has a specific number and sequence of values. When you instantiate the tuple, you define the number and the data type of each value (or element). For example, a 2-tuple (or pair) has two elements. The first might be a `Boolean` value, while the second is a `String`. Because tuples make it easy to store multiple values in a single object, they are often used as a lightweight way to return multiple values from a method.

IMPORTANT

Tuple support requires the `ValueTuple` type. If the .NET Framework 4.7 is not installed, you must add the NuGet package `System.ValueTuple`, which is available on the NuGet Gallery. Without this package, you may get a compilation error similar to, "Predefined type 'ValueTuple(Of...)' is not defined or imported."

Instantiating and using a tuple

You instantiate a tuple by enclosing its comma-delimited values in parentheses. Each of those values then becomes a field of the tuple. For example, the following code defines a triple (or 3-tuple) with a `Date` as its first value, a `String` as its second, and a `Boolean` as its third.

```
Dim holiday = (#07/04/2017#, "Independence Day", True)
```

By default, the name of each field in a tuple consists of the string `Item` along with the field's one-based position in the tuple. For this 3-tuple, the `Date` field is `Item1`, the `String` field is `Item2`, and the `Boolean` field is `Item3`. The following example displays the values of fields of the tuple instantiated in the previous line of code

```
Console.WriteLine($"{holiday.Item1} is {holiday.Item2}" +  
    $"{If(holiday.Item3, ", a national holiday", String.Empty)}")  
' Output: 7/4/2017 12:00:00 AM Is Independence Day, a national holiday
```

The fields of a Visual Basic tuple are read-write; after you've instantiated a tuple, you can modify its values. The following example modifies two of the three fields of the tuple created in the previous example and displays the result.

```
holiday.Item1 = #01/01/2018#  
holiday.Item2 = "New Year's Day"  
Console.WriteLine($"{holiday.Item1} is {holiday.Item2}" +  
    $"{If(holiday.Item3, ", a national holiday", String.Empty)}")  
' Output: 1/1/2018 12:00:00 AM Is New Year's Day, a national holiday
```

Instantiating and using a named tuple

Rather than using default names for a tuple's fields, you can instantiate a *named tuple* by assigning your own names to the tuple's elements. The tuple's fields can then be accessed by their assigned names or by their default names. The following example instantiates the same 3-tuple as previously, except that it explicitly names the first field `EventDate`, the second `Name`, and the third `IsHoliday`. It then displays the field values, modifies them, and

displays the field values again.

```
Dim holiday = (EventDate:=#07/04/2017#, Name:="Independence Day", IsHoliday:=True)
Console.WriteLine($"{holiday.EventDate} Is {holiday.Name}" +
    $"{If(holiday.IsHoliday, ", a national holiday", String.Empty)}")
holiday.Item1 = #01/01/2018#
holiday.Item2 = "New Year's Day"
Console.WriteLine($"{holiday.Item1} is {holiday.Item2}" +
    $"{If(holiday.Item3, ", a national holiday", String.Empty)})")
' The example displays the following output:
'   7/4/2017 12:00:00 AM Is Independence Day, a national holiday
'   1/1/2018 12:00:00 AM Is New Year's Day, a national holiday
```

Inferred tuple element names

Starting with Visual Basic 15.3, Visual Basic can infer the names of tuple elements; you do not have to assign them explicitly. Inferred tuple names are useful when you initialize a tuple from a set of variables, and you want the tuple element name to be the same as the variable name.

The following example creates a `stateInfo` tuple that contains three explicitly named elements, `state`, `stateName`, and `capital`. Note that, in naming the elements, the tuple initialization statement simply assigns the named elements the values of the identically named variables.

```
Dim state = "MI"
Dim stateName = "Michigan"
Dim capital = "Lansing"
Dim stateInfo = ( state:=state, stateName:=stateName, capital:=capital )
Console.WriteLine($"{stateInfo.stateName}: 2-letter code: {stateInfo.State}, Capital {stateInfo.capital}")
' The example displays the following output:
'   Michigan: 2-letter code: MI, Capital Lansing
```

Because elements and variables have the same name, the Visual Basic compiler can infer the names of the fields, as the following example shows.

```
Dim state = "MI"
Dim stateName = "Michigan"
Dim capital = "Lansing"
Dim stateInfo = ( state, stateName, capital )
Console.WriteLine($"{stateInfo.stateName}: 2-letter code: {stateInfo.State}, Capital {stateInfo.capital}")
' The example displays the following output:
'   Michigan: 2-letter code: MI, Capital Lansing
```

To enable inferred tuple element names, you must define the version of the Visual Basic compiler to use in your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.3</LangVersion>
</PropertyGroup>
```

The version number can be any version of the Visual Basic compiler starting with 15.3. Rather than hard-coding a specific compiler version, you can also specify "Latest" as the value of `LangVersion` to compile with the most recent version of the Visual Basic compiler installed on your system.

For more information, see [setting the Visual Basic language version](#).

In some cases, the Visual Basic compiler cannot infer the tuple element name from the candidate name, and the tuple field can only be referenced using its default name, such as `Item1`, `Item2`, etc. These include:

- The candidate name is the same as the name of a tuple member, such as `Item3`, `Rest`, or `ToString`.
- The candidate name is duplicated in the tuple.

When field name inference fails, Visual Basic does not generate a compiler error, nor is an exception thrown at runtime. Instead, tuple fields must be referenced by their predefined names, such as `Item1` and `Item2`.

Tuples versus structures

A Visual Basic tuple is a value type that is an instance of one of the **System.ValueTuple** generic types. For example, the `holiday` tuple defined in the previous example is an instance of the `ValueTuple<T1,T2,T3>` structure. It is designed to be a lightweight container for data. Since the tuple aims to make it easy to create an object with multiple data items, it lacks some of the features that a custom structure might have. These include:

- Custom members. You cannot define your own properties, methods, or events for a tuple.
- Validation. You cannot validate the data assigned to fields.
- Immutability. Visual Basic tuples are mutable. In contrast, a custom structure allows you to control whether an instance is mutable or immutable.

If custom members, property and field validation, or immutability are important, you should use the Visual Basic [Structure](#) statement to define a custom value type.

A Visual Basic tuple does inherit the members of its **ValueTuple** type. In addition to its fields, these include the following methods:

MEMBER	DESCRIPTION
<code>CompareTo</code>	Compares the current tuple to another tuple with the same number of elements.
<code>Equals</code>	Determines whether the current tuple is equal to another tuple or object.
<code>GetHashCode</code>	Calculates the hash code for the current instance.
<code>ToString</code>	Returns the string representation of this tuple, which takes the form <code>(Item1, Item2...)</code> , where <code>Item1</code> and <code>Item2</code> represent the values of the tuple's fields.

In addition, the **ValueTuple** types implement [IStructuralComparable](#) and [IStructuralEquatable](#) interfaces, which allow you to define customer comparers.

Assignment and tuples

Visual Basic supports assignment between tuple types that have the same number of fields. The field types can be converted if one of the following is true:

- The source and target field are of the same type.
- A widening (or implicit) conversion of the source type to the target type is defined.
- `Option Strict` is `On`, and a narrowing (or explicit) conversion of the source type to the target type is defined. This conversion can throw an exception if the source value is outside the range of the target type.

Other conversions are not considered for assignments. Let's look at the kinds of assignments that are allowed between tuple types.

Consider these variables used in the following examples:

```
' The number and field types of all these tuples are compatible.  
' The only difference is the field names being used.  
Dim unnamed = (42, "The meaning of life")  
Dim anonymous = (16, "a perfect square")  
Dim named = (Answer:=42, Message:="The meaning of life")  
Dim differentNamed = (SecretConstant:=42, Label:="The meaning of life")
```

The first two variables, `unnamed` and `anonymous`, do not have semantic names provided for the fields. Their field names are the default `Item1` and `Item2`. The last two variables, `named` and `differentNamed` have semantic field names. Note that these two tuples have different names for the fields.

All four of these tuples have the same number of fields (referred to as 'arity'), and the types of those fields are identical. Therefore, all of these assignments work:

```
' Assign named to unnamed.  
named = unnamed  
  
' Despite the assignment, named still has fields that can be referred to as 'answer' and 'message'.  
Console.WriteLine($"{named.Answer}, {named.Message}")  
' Output: 42, The meaning of life  
  
' Assign unnamed to anonymous.  
anonymous = unnamed  
' Because of the assignment, the value of the elements of anonymous changed.  
Console.WriteLine($"{anonymous.Item1}, {anonymous.Item2}")  
' Output: 42, The meaning of life  
  
' Assign one named tuple to the other.  
named = differentNamed  
' The field names are not assigned. 'named' still has 'answer' and 'message' fields.  
Console.WriteLine($"{named.Answer}, {named.Message}")  
' Output: 42, The meaning of life
```

Notice that the names of the tuples are not assigned. The values of the fields are assigned following the order of the fields in the tuple.

Finally, notice that we can assign the `named` tuple to the `conversion` tuple, even though the first field of `named` is an `Integer`, and the first field of `conversion` is a `Long`. This assignment succeeds because converting an `Integer` to a `Long` is a widening conversion.

```
' Assign an (Integer, String) tuple to a (Long, String) tuple (using implicit conversion).  
Dim conversion As (Long, String) = named  
Console.WriteLine($"{conversion.Item1} ({conversion.Item1.GetType().Name}), " +  
    $"{conversion.Item2} ({conversion.Item2.GetType().Name})")  
' Output: 42 (Int64), The meaning of life (String)
```

Tuples with different numbers of fields are not assignable:

```
' Does not compile.  
' VB30311: Value of type '(Integer, Integer, Integer)' cannot be converted  
'           to '(Answer As Integer, Message As String)'  
var differentShape = (1, 2, 3)  
named = differentShape
```

Tuples as method return values

A method can return only a single value. Frequently, though, you'd like a method call to return multiple values. There are several ways to work around this limitation:

- You can create a custom class or structure whose properties or fields represent values returned by the method. This is a heavyweight solution; it requires that you define a custom type whose only purpose is to retrieve values from a method call.
- You can return a single value from the method, and return the remaining values by passing them by reference to the method. This involves the overhead of instantiating a variable and risks inadvertently overwriting the value of the variable that you pass by reference.
- You can use a tuple, which provides a lightweight solution to retrieving multiple return values.

For example, the **TryParse** methods in .NET return a `Boolean` value that indicates whether the parsing operation succeeded. The result of the parsing operation is returned in a variable passed by reference to the method.

Normally, a call to the a parsing method such as `Int32.TryParse` looks like the following:

```
Dim numericString As String = "123456"
Dim number As Integer
Dim result = Int32.TryParse(numericString, number)
Console.WriteLine($"{If(result, $"Success: {number:N0}", "Failure"))")
'      Output: 123,456
```

We can return a tuple from the parsing operation if we wrap the call to the `Int32.TryParse` method in our own method. In the following example, `NumericLibrary.ParseInteger` calls the `Int32.TryParse` method and returns a named tuple with two elements.

```
Imports System.Globalization

Public Module NumericLibrary
    Public Function ParseInteger(value As String) As (Success As Boolean, Number As Int32)
        Dim number As Integer
        Return (Int32.TryParse(value, NumberStyles.Any, CultureInfo.InvariantCulture, number), number)
    End Function
End Module
```

You can then call the method with code like the following:

```
Dim numericString As String = "123,456"
Dim result = ParseInteger(numericString)
Console.WriteLine($"{If(result.Success, $"Success: {result.Number:N0}", "Failure"))")
Console.ReadLine()
'      Output: Success: 123,456
```

Visual Basic tuples and tuples in the .NET Framework

A Visual Basic tuple is an instance of one of the **System.ValueTuple** generic types, which were introduced in the .NET Framework 4.7. The .NET Framework also includes a set of generic **System.Tuple** classes. These classes, however, differ from Visual Basic tuples and the **System.ValueTuple** generic types in a number of ways:

- The elements of the **Tuple** classes are properties named `Item1`, `Item2`, and so on. In Visual Basic tuples and the **ValueTuple** types, tuple elements are fields.
- You cannot assign meaningful names to the elements of a **Tuple** instance or of a **ValueTuple** instance. Visual Basic allows you to assign names that communicate the meaning of the fields.
- The properties of a **Tuple** instance are read-only; the tuples are immutable. In Visual Basic tuples and the

ValueTuple types, tuple fields are read-write; the tuples are mutable.

- The generic **Tuple** types are reference types. Using these **Tuple** types means allocating objects. On hot paths, this can have a measurable impact on your application's performance. Visual Basic tuples and the **ValueTuple** types are value types.

Extension methods in the [TupleExtensions](#) class make it easy to convert between Visual Basic tuples and .NET **Tuple** objects. The **ToTuple** method converts a Visual Basic tuple to a .NET **Tuple** object, and the **ToValueTuple** method converts a .NET **Tuple** object to a Visual Basic tuple.

The following example creates a tuple, converts it to a .NET **Tuple** object, and converts it back to a Visual Basic tuple. The example then compares this tuple with the original one to ensure that they are equal.

```
Module Example
    Sub Main()
        Dim cityInfo = (name:="New York", area:=468.5, population:=8_550_405)
        Console.WriteLine($"{cityInfo}, type {cityInfo.GetType().Name}")

        ' Convert the Visual Basic tuple to a .NET tuple.
        Dim cityInfoT = TupleExtensions.ToTuple(cityInfo)
        Console.WriteLine($"{cityInfoT}, type {cityInfoT.GetType().Name}")

        ' Convert the .NET tuple back to a Visual Basic tuple and ensure they are the same.
        Dim cityInfo2 = TupleExtensions.ToValueTuple(cityInfoT)
        Console.WriteLine($"{cityInfo2}, type {cityInfo2.GetType().Name}")
        Console.WriteLine($"{NameOf(cityInfo)} = {NameOf(cityInfo2)}: {cityInfo.Equals(cityInfo2)}")
        Console.ReadLine()
    End Sub
End Module
' The example displays the following output:
' (New York, 468.5, 8550405), type ValueTuple`3
' (New York, 468.5, 8550405), type Tuple`3
' (New York, 468.5, 8550405), type ValueTuple`3
' cityInfo = cityInfo2 : True
```

Efficient Use of Data Types (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Undeclared variables and variables declared without a data type are assigned the `Object` data type. This makes it easy to write programs quickly, but it can cause them to execute more slowly.

Strong Typing

Specifying data types for all your variables is known as *strong typing*. Using strong typing has several advantages:

- It enables IntelliSense support for your variables. This allows you to see their properties and other members as you type in the code.
- It takes advantage of compiler type checking. This catches statements that can fail at run time due to errors such as overflow. It also catches calls to methods on objects that do not support them.
- It results in faster execution of your code.

Most Efficient Data Types

For variables that never contain fractions, the integral data types are more efficient than the nonintegral types. In Visual Basic, `Integer` and `UInteger` are the most efficient numeric types.

For fractional numbers, `Double` is the most efficient data type, because the processors on current platforms perform floating-point operations in double precision. However, operations with `Double` are not as fast as with the integral types such as `Integer`.

Specifying Data Type

Use the [Dim Statement](#) to declare a variable of a specific type. You can simultaneously specify its access level by using the [Public](#), [Protected](#), [Friend](#), or [Private](#) keyword, as in the following example.

```
Private x As Double  
Protected s As String
```

Character Conversion

The `AscW` and `ChrW` functions operate in Unicode. You should use them in preference to `Asc` and `Chr`, which must translate into and out of Unicode.

Troubleshooting Data Types (Visual Basic)

2/28/2019 • 7 minutes to read • [Edit Online](#)

This page lists some common problems that can occur when you perform operations on intrinsic data types.

Floating-Point Expressions Do Not Compare as Equal

When you work with floating-point numbers ([Single Data Type](#) and [Double Data Type](#)), remember that they are stored as binary fractions. This means they cannot hold an exact representation of any quantity that is not a binary fraction (of the form $k / (2^n)$ where k and n are integers). For example, 0.5 (= 1/2) and 0.3125 (= 5/16) can be held as precise values, whereas 0.2 (= 1/5) and 0.3 (= 3/10) can be only approximations.

Because of this imprecision, you cannot rely on exact results when you operate on floating-point values. In particular, two values that are theoretically equal might have slightly different representations.

TO COMPARE FLOATING-POINT QUANTITIES

1. Calculate the absolute value of their difference by using the [Abs](#) method of the [Math](#) class in the [System](#) namespace.
2. Determine an acceptable maximum difference, such that you can consider the two quantities to be equal for practical purposes if their difference is no larger.
3. Compare the absolute value of the difference to the acceptable difference.

The following example demonstrates both incorrect and correct comparison of two `Double` values.

```
Dim oneThird As Double = 1.0 / 3.0
Dim pointThrees As Double = 0.333333333333333

' The following comparison does not indicate equality.
Dim exactlyEqual As Boolean = (oneThird = pointThrees)

' The following comparison indicates equality.
Dim closeEnough As Double = 0.00000000000001
Dim absoluteDifference As Double = Math.Abs(oneThird - pointThrees)
Dim practicallyEqual As Boolean = (absoluteDifference < closeEnough)

MsgBox("1.0 / 3.0 is represented as " & oneThird.ToString("G17") &
      vbCrLf & "0.333333333333333 is represented as " &
      pointThrees.ToString("G17") &
      vbCrLf & "Exact comparison generates " & CStr(exactlyEqual) &
      vbCrLf & "Acceptable difference comparison generates " &
      CStr(practicallyEqual))
```

The previous example uses the [ToString](#) method of the `Double` structure so that it can specify better precision than the `cstr` keyword uses. The default is 15 digits, but the "G17" format extends it to 17 digits.

Mod Operator Does Not Return Accurate Result

Because of the imprecision of floating-point storage, the [Mod Operator](#) can return an unexpected result when at least one of the operands is floating-point.

The [Decimal Data Type](#) does not use floating-point representation. Many numbers that are inexact in `Single` and `Double` are exact in `Decimal` (for example 0.2 and 0.3). Although arithmetic is slower in `Decimal` than in floating-point, it might be worth the performance decrease to achieve better precision.

TO FIND THE INTEGER REMAINDER OF FLOATING-POINT QUANTITIES

1. Declare variables as `Decimal`.
2. Use the literal type character `D` to force literals to `Decimal`, in case their values are too large for the `Long` data type.

The following example demonstrates the potential imprecision of floating-point operands.

```
Dim two As Double = 2.0
Dim zeroPointTwo As Double = 0.2
Dim quotient As Double = two / zeroPointTwo
Dim doubleRemainder As Double = two Mod zeroPointTwo

MsgBox("2.0 is represented as " & two.ToString("G17") &
vbCrLf & "0.2 is represented as " & zeroPointTwo.ToString("G17") &
vbCrLf & "2.0 / 0.2 generates " & quotient.ToString("G17") &
vbCrLf & "2.0 Mod 0.2 generates " &
doubleRemainder.ToString("G17"))

Dim decimalRemainder As Decimal = 2D Mod 0.2D
MsgBox("2.0D Mod 0.2D generates " & CStr(decimalRemainder))
```

The previous example uses the `ToString` method of the `Double` structure so that it can specify better precision than the `cstr` keyword uses. The default is 15 digits, but the "G17" format extends it to 17 digits.

Because `zeroPointTwo` is `Double`, its value for 0.2 is an infinitely repeating binary fraction with a stored value of 0.2000000000000001. Dividing 2.0 by this quantity yields 9.999999999999995 with a remainder of 0.1999999999999991.

In the expression for `decimalRemainder`, the literal type character `D` forces both operands to `Decimal`, and 0.2 has a precise representation. Therefore the `Mod` operator yields the expected remainder of 0.0.

Note that it is not sufficient to declare `decimalRemainder` as `Decimal`. You must also force the literals to `Decimal`, or they use `Double` by default and `decimalRemainder` receives the same inaccurate value as `doubleRemainder`.

Boolean Type Does Not Convert to Numeric Type Accurately

[Boolean Data Type](#) values are not stored as numbers, and the stored values are not intended to be equivalent to numbers. For compatibility with earlier versions, Visual Basic provides conversion keywords ([CType Function](#), `CBool`, `CInt`, and so on) to convert between `Boolean` and numeric types. However, other languages sometimes perform these conversions differently, as do the .NET Framework methods.

You should never write code that relies on equivalent numeric values for `True` and `False`. Whenever possible, you should restrict usage of `Boolean` variables to the logical values for which they are designed. If you must mix `Boolean` and numeric values, make sure that you understand the conversion method that you select.

Conversion in Visual Basic

When you use the `CType` or `CBool` conversion keywords to convert numeric data types to `Boolean`, 0 becomes `False` and all other values become `True`. When you convert `Boolean` values to numeric types by using the conversion keywords, `False` becomes 0 and `True` becomes -1.

Conversion in the Framework

The `ToInt32` method of the `Convert` class in the `System` namespace converts `True` to +1.

If you must convert a `Boolean` value to a numeric data type, be careful about which conversion method you

use.

Character Literal Generates Compiler Error

In the absence of any type characters, Visual Basic assumes default data types for literals. The default type for a character literal — enclosed in quotation marks (" ") — is `String`.

The `String` data type does not widen to the [Char Data Type](#). This means that if you want to assign a literal to a `Char` variable, you must either make a narrowing conversion or force the literal to the `Char` type.

TO CREATE A CHAR LITERAL TO ASSIGN TO A VARIABLE OR CONSTANT

1. Declare the variable or constant as `Char`.
2. Enclose the character value in quotation marks (" ").
3. Follow the closing double quotation mark with the literal type character `C` to force the literal to `char`. This is necessary if the type checking switch ([Option Strict Statement](#)) is `On`, and it is desirable in any case.

The following example demonstrates both unsuccessful and successful assignments of a literal to a `Char` variable.

```
Dim charVar As Char
' The following statement attempts to convert a String literal to Char.
' Because Option Strict is On, it generates a compiler error.
charVar = "Z"
' The following statement succeeds because it specifies a Char literal.
charVar = "Z"c
' The following statement succeeds because it converts String to Char.
charVar = CChar("Z")
```

There is always a risk in using narrowing conversions, because they can fail at run time. For example, a conversion from `String` to `Char` can fail if the `String` value contains more than one character. Therefore, it is better programming to use the `c` type character.

String Conversion Fails at Run Time

The [String Data Type](#) participates in very few widening conversions. `String` widens only to itself and `Object`, and only `Char` and `Char()` (a `char` array) widen to `String`. This is because `String` variables and constants can contain values that other data types cannot contain.

When the type checking switch ([Option Strict Statement](#)) is `On`, the compiler disallows all implicit narrowing conversions. This includes those involving `String`. Your code can still use conversion keywords such as `CStr` and [CType Function](#), which direct the .NET Framework to attempt the conversion.

NOTE

The narrowing-conversion error is suppressed for conversions from the elements in a `For Each...Next` collection to the loop control variable. For more information and examples, see the "Narrowing Conversions" section in [For Each...Next Statement](#).

Narrowing Conversion Protection

The disadvantage of narrowing conversions is that they can fail at run time. For example, if a `String` variable contains anything other than "True" or "False," it cannot be converted to `Boolean`. If it contains punctuation characters, conversion to any numeric type fails. Unless you know that your `String` variable always holds values that the destination type can accept, you should not try a conversion.

If you must convert from `String` to another data type, the safest procedure is to enclose the attempted conversion in the [Try...Catch...Finally Statement](#). This lets you deal with a run-time failure.

Character Arrays

A single `char` and an array of `char` elements both widen to `String`. However, `String` does not widen to `char()`. To convert a `String` value to a `char` array, you can use the [ToCharArray](#) method of the `System.String` class.

Meaningless Values

In general, `String` values are not meaningful in other data types, and conversion is highly artificial and dangerous. Whenever possible, you should restrict usage of `String` variables to the character sequences for which they are designed. You should never write code that relies on equivalent values in other types.

Delegates (Visual Basic)

3/8/2019 • 5 minutes to read • [Edit Online](#)

Delegates are objects that refer to methods. They are sometimes described as *type-safe function pointers* because they are similar to function pointers used in other programming languages. But unlike function pointers, Visual Basic delegates are a reference type based on the class [System.Delegate](#). Delegates can reference both shared methods — methods that can be called without a specific instance of a class — and instance methods.

Delegates and Events

Delegates are useful in situations where you need an intermediary between a calling procedure and the procedure being called. For example, you might want an object that raises events to be able to call different event handlers under different circumstances. Unfortunately, the object raising the events cannot know ahead of time which event handler is handling a specific event. Visual Basic lets you dynamically associate event handlers with events by creating a delegate for you when you use the `AddHandler` statement. At run time, the delegate forwards calls to the appropriate event handler.

Although you can create your own delegates, in most cases Visual Basic creates the delegate and takes care of the details for you. For example, an `Event` statement implicitly defines a delegate class named `<EventName>EventHandler` as a nested class of the class containing the `Event` statement, and with the same signature as the event. The `AddressOf` statement implicitly creates an instance of a delegate that refers to a specific procedure. The following two lines of code are equivalent. In the first line, you see the explicit creation of an instance of `EventHandler`, with a reference to method `Button1_Click` sent as the argument. The second line is a more convenient way to do the same thing.

```
AddHandler Button1.Click, New EventHandler(AddressOf Button1_Click)
' The following line of code is shorthand for the previous line.
AddHandler Button1.Click, AddressOf Me.Button1_Click
```

You can use the shorthand way of creating delegates anywhere the compiler can determine the delegate's type by the context.

Declaring Events that Use an Existing Delegate Type

In some situations, you may want to declare an event to use an existing delegate type as its underlying delegate. The following syntax demonstrates how:

```
Delegate Sub DelegateType()
Event AnEvent As DelegateType
```

This is useful when you want to route multiple events to the same handler.

Delegate Variables and Parameters

You can use delegates for other, non-event related tasks, such as free threading or with procedures that need to call different versions of functions at run time.

For example, suppose you have a classified-ad application that includes a list box with the names of cars. The ads are sorted by title, which is normally the make of the car. A problem you may face occurs when some cars include the year of the car before the make. The problem is that the built-in sort functionality of the list box sorts only by

character codes; it places all the ads starting with dates first, followed by the ads starting with the make.

To fix this, you can create a sort procedure in a class that uses the standard alphabetic sort on most list boxes, but is able to switch at run time to the custom sort procedure for car ads. To do this, you pass the custom sort procedure to the sort class at run time, using delegates.

AddressOf and Lambda Expressions

Each delegate class defines a constructor that is passed the specification of an object method. An argument to a delegate constructor must be a reference to a method, or a lambda expression.

To specify a reference to a method, use the following syntax:

```
AddressOf [ expression ] methodName
```

The compile-time type of the `expression` must be the name of a class or an interface that contains a method of the specified name whose signature matches the signature of the delegate class. The `methodName` can be either a shared method or an instance method. The `methodName` is not optional, even if you create a delegate for the default method of the class.

To specify a lambda expression, use the following syntax:

```
Function ([ parm As type , parm2 As type2 , ...]) expression
```

The following example shows both `AddressOf` and lambda expressions used to specify the reference for a delegate.

```

Module Module1

Sub Main()
    ' Create an instance of InOrderClass and assign values to the properties.
    ' InOrderClass method ShowInOrder displays the numbers in ascending
    ' or descending order, depending on the comparison method you specify.
    Dim inOrder As New InOrderClass
    inOrder.Num1 = 5
    inOrder.Num2 = 4

    ' Use AddressOf to send a reference to the comparison function you want
    ' to use.
    inOrder.ShowInOrder(AddressOf GreaterThan)
    inOrder.ShowInOrder(AddressOf LessThan)

    ' Use lambda expressions to do the same thing.
    inOrder.ShowInOrder(Function(m, n) m > n)
    inOrder.ShowInOrder(Function(m, n) m < n)
End Sub

Function GreaterThan(ByVal num1 As Integer, ByVal num2 As Integer) As Boolean
    Return num1 > num2
End Function

Function LessThan(ByVal num1 As Integer, ByVal num2 As Integer) As Boolean
    Return num1 < num2
End Function

Class InOrderClass
    ' Define the delegate function for the comparisons.
    Delegate Function CompareNumbers(ByVal num1 As Integer, ByVal num2 As Integer) As Boolean
    ' Display properties in ascending or descending order.
    Sub ShowInOrder(ByVal compare As CompareNumbers)
        If compare(_num1, _num2) Then
            Console.WriteLine(_num1 & " " & _num2)
        Else
            Console.WriteLine(_num2 & " " & _num1)
        End If
    End Sub

    Private _num1 As Integer
    Property Num1() As Integer
        Get
            Return _num1
        End Get
        Set(ByVal value As Integer)
            _num1 = value
        End Set
    End Property

    Private _num2 As Integer
    Property Num2() As Integer
        Get
            Return _num2
        End Get
        Set(ByVal value As Integer)
            _num2 = value
        End Set
    End Property
End Class
End Module

```

The signature of the function must match that of the delegate type. For more information about lambda expressions, see [Lambda Expressions](#). For more examples of lambda expression and `AddressOf` assignments to delegates, see [Relaxed Delegate Conversion](#).

Early and Late Binding (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

The Visual Basic compiler performs a process called `binding` when an object is assigned to an object variable. An object is *early bound* when it is assigned to a variable declared to be of a specific object type. Early bound objects allow the compiler to allocate memory and perform other optimizations before an application executes. For example, the following code fragment declares a variable to be of type `FileStream`:

```
' Create a variable to hold a new object.  
Dim FS As System.IO.FileStream  
' Assign a new object to the variable.  
FS = New System.IO.FileStream("C:\tmp.txt",  
    System.IO.FileMode.Open)
```

Because `FileStream` is a specific object type, the instance assigned to `FS` is early bound.

By contrast, an object is *late bound* when it is assigned to a variable declared to be of type `Object`. Objects of this type can hold references to any object, but lack many of the advantages of early-bound objects. For example, the following code fragment declares an object variable to hold an object returned by the `CreateObject` function:

```
' To use this example, you must have Microsoft Excel installed on your computer.  
' Compile with Option Strict Off to allow late binding.  
Sub TestLateBinding()  
    Dim xlApp As Object  
    Dim xlBook As Object  
    Dim xlSheet As Object  
    xlApp = CreateObject("Excel.Application")  
    ' Late bind an instance of an Excel workbook.  
    xlBook = xlApp.Workbooks.Add  
    ' Late bind an instance of an Excel worksheet.  
    xlSheet = xlBook.Worksheets(1)  
    xlSheet.Activate()  
    ' Show the application.  
    xlSheet.Application.Visible = True  
    ' Place some text in the second row of the sheet.  
    xlSheet.Cells(2, 2) = "This is column B row 2"  
End Sub
```

Advantages of Early Binding

You should use early-bound objects whenever possible, because they allow the compiler to make important optimizations that yield more efficient applications. Early-bound objects are significantly faster than late-bound objects and make your code easier to read and maintain by stating exactly what kind of objects are being used. Another advantage to early binding is that it enables useful features such as automatic code completion and Dynamic Help because the Visual Studio integrated development environment (IDE) can determine exactly what type of object you are working with as you edit the code. Early binding reduces the number and severity of run-time errors because it allows the compiler to report errors when a program is compiled.

NOTE

Late binding can only be used to access type members that are declared as `Public`. Accessing members declared as `Friend` or `Protected Friend` results in a run-time error.

Error Types (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

In Visual Basic, errors (also called *exceptions*) fall into one of three categories: syntax errors, run-time errors, and logic errors.

Syntax Errors

Syntax errors are those that appear while you write code. Visual Basic checks your code as you type it in the **Code Editor** window and alerts you if you make a mistake, such as misspelling a word or using a language element improperly. Syntax errors are the most common type of errors. You can fix them easily in the coding environment as soon as they occur.

NOTE

The `Option Explicit` statement is one means of avoiding syntax errors. It forces you to declare, in advance, all the variables to be used in the application. Therefore, when those variables are used in the code, any typographic errors are caught immediately and can be fixed.

Run-Time Errors

Run-time errors are those that appear only after you compile and run your code. These involve code that may appear to be correct in that it has no syntax errors, but that will not execute. For example, you might correctly write a line of code to open a file. But if the file is corrupted, the application cannot carry out the `Open` function, and it stops running. You can fix most run-time errors by rewriting the faulty code, and then recompiling and rerunning it.

Logic Errors

Logic errors are those that appear once the application is in use. They are most often unwanted or unexpected results in response to user actions. For example, a mistyped key or other outside influence might cause your application to stop working within expected parameters, or altogether. Logic errors are generally the hardest type to fix, since it is not always clear where they originate.

Events (Visual Basic)

3/1/2019 • 6 minutes to read • [Edit Online](#)

While you might visualize a Visual Studio project as a series of procedures that execute in a sequence, in reality, most programs are event driven—meaning the flow of execution is determined by external occurrences called *events*.

An event is a signal that informs an application that something important has occurred. For example, when a user clicks a control on a form, the form can raise a `Click` event and call a procedure that handles the event. Events also allow separate tasks to communicate. Say, for example, that your application performs a sort task separately from the main application. If a user cancels the sort, your application can send a cancel event instructing the sort process to stop.

Event Terms and Concepts

This section describes the terms and concepts used with events in Visual Basic.

Declaring Events

You declare events within classes, structures, modules, and interfaces using the `Event` keyword, as in the following example:

```
Event AnEvent(ByVal EventNumber As Integer)
```

Raising Events

An event is like a message announcing that something important has occurred. The act of broadcasting the message is called *raising* the event. In Visual Basic, you raise events with the `RaiseEvent` statement, as in the following example:

```
RaiseEvent AnEvent(EventNumber)
```

Events must be raised within the scope of the class, module, or structure where they are declared. For example, a derived class cannot raise events inherited from a base class.

Event Senders

Any object capable of raising an event is an *event sender*, also known as an *event source*. Forms, controls, and user-defined objects are examples of event senders.

Event Handlers

Event handlers are procedures that are called when a corresponding event occurs. You can use any valid subroutine with a matching signature as an event handler. You cannot use a function as an event handler, however, because it cannot return a value to the event source.

Visual Basic uses a standard naming convention for event handlers that combines the name of the event sender, an underscore, and the name of the event. For example, the `Click` event of a button named `button1` would be named `Sub button1_Click`.

NOTE

We recommend that you use this naming convention when defining event handlers for your own events, but it is not required; you can use any valid subroutine name.

Associating Events with Event Handlers

Before an event handler becomes usable, you must first associate it with an event by using either the `Handles` or `AddHandler` statement.

WithEvents and the Handles Clause

The `WithEvents` statement and `Handles` clause provide a declarative way of specifying event handlers. An event raised by an object declared with the `WithEvents` keyword can be handled by any procedure with a `Handles` statement for that event, as shown in the following example:

```
' Declare a WithEvents variable.  
Dim WithEvents EClass As New EventClass  
  
' Call the method that raises the object's events.  
Sub TestEvents()  
    EClass.RaiseEvents()  
End Sub  
  
' Declare an event handler that handles multiple events.  
Sub EClass_EventHandler() Handles EClass.XEvent, EClass.YEvent  
    MsgBox("Received Event.")  
End Sub  
  
Class EventClass  
    Public Event XEvent()  
    Public Event YEvent()  
    ' RaiseEvents raises both events.  
    Sub RaiseEvents()  
        RaiseEvent XEvent()  
        RaiseEvent YEvent()  
    End Sub  
End Class
```

The `WithEvents` statement and the `Handles` clause are often the best choice for event handlers because the declarative syntax they use makes event handling easier to code, read and debug. However, be aware of the following limitations on the use of `WithEvents` variables:

- You cannot use a `WithEvents` variable as an object variable. That is, you cannot declare it as `Object` —you must specify the class name when you declare the variable.
- Because shared events are not tied to class instances, you cannot use `WithEvents` to declaratively handle shared events. Similarly, you cannot use `WithEvents` or `Handles` to handle events from a `structure`. In both cases, you can use the `AddHandler` statement to handle those events.
- You cannot create arrays of `WithEvents` variables.

`WithEvents` variables allow a single event handler to handle one or more kind of event, or one or more event handlers to handle the same kind of event.

Although the `Handles` clause is the standard way of associating an event with an event handler, it is limited to associating events with event handlers at compile time.

In some cases, such as with events associated with forms or controls, Visual Basic automatically stubs out an

empty event handler and associates it with an event. For example, when you double-click a command button on a form in design mode, Visual Basic creates an empty event handler and a `WithEvents` variable for the command button, as in the following code:

```
Friend WithEvents Button1 As System.Windows.Forms.Button
Protected Sub Button1_Click() Handles Button1.Click
End Sub
```

AddHandler and RemoveHandler

The `AddHandler` statement is similar to the `Handles` clause in that both allow you to specify an event handler. However, `AddHandler`, used with `RemoveHandler`, provides greater flexibility than the `Handles` clause, allowing you to dynamically add, remove, and change the event handler associated with an event. If you want to handle shared events or events from a structure, you must use `AddHandler`.

`AddHandler` takes two arguments: the name of an event from an event sender such as a control, and an expression that evaluates to a delegate. You do not need to explicitly specify the delegate class when using `AddHandler`, since the `AddressOf` statement always returns a reference to the delegate. The following example associates an event handler with an event raised by an object:

```
AddHandler Obj.XEvent, AddressOf Me.XEventHandler
```

`RemoveHandler`, which disconnects an event from an event handler, uses the same syntax as `AddHandler`. For example:

```
RemoveHandler Obj.XEvent, AddressOf Me.XEventHandler
```

In the following example, an event handler is associated with an event, and the event is raised. The event handler catches the event and displays a message.

Then the first event handler is removed and a different event handler is associated with the event. When the event is raised again, a different message is displayed.

Finally, the second event handler is removed and the event is raised for a third time. Because there is no longer an event handler associated with the event, no action is taken.

```

Module Module1

    Sub Main()
        Dim c1 As New Class1
        ' Associate an event handler with an event.
        AddHandler c1.AnEvent, AddressOf EventHandler1
        ' Call a method to raise the event.
        c1.CauseTheEvent()
        ' Stop handling the event.
        RemoveHandler c1.AnEvent, AddressOf EventHandler1
        ' Now associate a different event handler with the event.
        AddHandler c1.AnEvent, AddressOf EventHandler2
        ' Call a method to raise the event.
        c1.CauseTheEvent()
        ' Stop handling the event.
        RemoveHandler c1.AnEvent, AddressOf EventHandler2
        ' This event will not be handled.
        c1.CauseTheEvent()
    End Sub

    Sub EventHandler1()
        ' Handle the event.
        MsgBox("EventHandler1 caught event.")
    End Sub

    Sub EventHandler2()
        ' Handle the event.
        MsgBox("EventHandler2 caught event.")
    End Sub

    Public Class Class1
        ' Declare an event.
        Public Event AnEvent()
        Sub CauseTheEvent()
            ' Raise an event.
            RaiseEvent AnEvent()
        End Sub
    End Class

End Module

```

Handling Events Inherited from a Base Class

Derived classes—classes that inherit characteristics from a base class—can handle events raised by their base class using the `Handles MyBase` statement.

To handle events from a base class

- Declare an event handler in the derived class by adding a `Handles MyBase. eventname` statement to the declaration line of your event-handler procedure, where `eventname` is the name of the event in the base class you are handling. For example:

```

Public Class BaseClass
    Public Event BaseEvent(ByVal i As Integer)
    ' Place methods and properties here.
End Class

Public Class DerivedClass
    Inherits BaseClass
    Sub EventHandler(ByVal x As Integer) Handles MyBase.BaseEvent
        ' Place code to handle events from BaseClass here.
    End Sub
End Class

```

Interfaces (Visual Basic)

2/28/2019 • 5 minutes to read • [Edit Online](#)

Interfaces define the properties, methods, and events that classes can implement. Interfaces allow you to define features as small groups of closely related properties, methods, and events; this reduces compatibility problems because you can develop enhanced implementations for your interfaces without jeopardizing existing code. You can add new features at any time by developing additional interfaces and implementations.

There are several other reasons why you might want to use interfaces instead of class inheritance:

- Interfaces are better suited to situations in which your applications require many possibly unrelated object types to provide certain functionality.
- Interfaces are more flexible than base classes because you can define a single implementation that can implement multiple interfaces.
- Interfaces are better in situations in which you do not have to inherit implementation from a base class.
- Interfaces are useful when you cannot use class inheritance. For example, structures cannot inherit from classes, but they can implement interfaces.

Declaring Interfaces

Interface definitions are enclosed within the `Interface` and `End Interface` statements. Following the `Interface` statement, you can add an optional `Inherits` statement that lists one or more inherited interfaces. The `Inherits` statements must precede all other statements in the declaration except comments. The remaining statements in the interface definition should be `Event`, `Sub`, `Function`, `Property`, `Interface`, `Class`, `Structure`, and `Enum` statements. Interfaces cannot contain any implementation code or statements associated with implementation code, such as `End Sub` or `End Property`.

In a namespace, interface statements are `Friend` by default, but they can also be explicitly declared as `Public` or `Friend`. Interfaces defined within classes, modules, interfaces, and structures are `Public` by default, but they can also be explicitly declared as `Public`, `Friend`, `Protected`, or `Private`.

NOTE

The `Shadows` keyword can be applied to all interface members. The `overloads` keyword can be applied to `Sub`, `Function`, and `Property` statements declared in an interface definition. In addition, `Property` statements can have the `Default`, `ReadOnly`, or `WriteOnly` modifiers. None of the other modifiers—`Public`, `Private`, `Friend`, `Protected`, `Shared`, `Overrides`, `MustOverride`, or `Overridable`—are allowed. For more information, see [Declaration Contexts and Default Access Levels](#).

For example, the following code defines an interface with one function, one property, and one event.

```
Interface IAsset
    Event CommittedChange(ByVal Success As Boolean)
    Property Division() As String
    Function GetID() As Integer
End Interface
```

Implementing Interfaces

The Visual Basic reserved word `Implements` is used in two ways. The `Implements` statement signifies that a class or structure implements an interface. The `Implements` keyword signifies that a class member or structure member implements a specific interface member.

Implements Statement

If a class or structure implements one or more interfaces, it must include the `Implements` statement immediately after the `Class` or `Structure` statement. The `Implements` statement requires a comma-separated list of interfaces to be implemented by a class. The class or structure must implement all interface members using the `Implements` keyword.

Implements Keyword

The `Implements` keyword requires a comma-separated list of interface members to be implemented. Generally, only a single interface member is specified, but you can specify multiple members. The specification of an interface member consists of the interface name, which must be specified in an `Implements` statement within the class; a period; and the name of the member function, property, or event to be implemented. The name of a member that implements an interface member can use any legal identifier, and it is not limited to the `InterfaceName_MethodName` convention used in earlier versions of Visual Basic.

For example, the following code shows how to declare a subroutine named `Sub1` that implements a method of an interface:

```
Class Class1
    Implements interfaceclass.interface2

    Sub Sub1(ByVal i As Integer) Implements interfaceclass.interface2.Sub1
    End Sub
End Class
```

The parameter types and return types of the implementing member must match the interface property or member declaration in the interface. The most common way to implement an element of an interface is with a member that has the same name as the interface, as shown in the previous example.

To declare the implementation of an interface method, you can use any attributes that are legal on instance method declarations, including `Overloads`, `Overrides`, `Overridable`, `Public`, `Private`, `Protected`, `Friend`, `Protected Friend`, `MustOverride`, `Default`, and `Static`. The `Shared` attribute is not legal since it defines a class rather than an instance method.

Using `Implements`, you can also write a single method that implements multiple methods defined in an interface, as in the following example:

```
Class Class2
    Implements I1, I2

    Protected Sub M1() Implements I1.M1, I1.M2, I2.M3, I2.M4
    End Sub
End Class
```

You can use a private member to implement an interface member. When a private member implements a member of an interface, that member becomes available by way of the interface even though it is not available directly on object variables for the class.

Interface Implementation Examples

Classes that implement an interface must implement all its properties, methods, and events.

The following example defines two interfaces. The second interface, `Interface2`, inherits `Interface1` and defines an additional property and method.

```

Interface Interface1
    Sub sub1(ByVal i As Integer)
End Interface

' Demonstrates interface inheritance.
Interface Interface2
    Inherits Interface1
    Sub M1(ByVal y As Integer)
    ReadOnly Property Num() As Integer
End Interface

```

The next example implements `Interface1`, the interface defined in the previous example:

```

Public Class ImplementationClass1
    Implements Interface1
    Sub Sub1(ByVal i As Integer) Implements Interface1.sub1
        ' Insert code here to implement this method.
    End Sub
End Class

```

The final example implements `Interface2`, including a method inherited from `Interface1`:

```

Public Class ImplementationClass2
    Implements Interface2
    Dim INum As Integer = 0
    Sub sub1(ByVal i As Integer) Implements Interface2.sub1
        ' Insert code here that implements this method.
    End Sub
    Sub M1(ByVal x As Integer) Implements Interface2.M1
        ' Insert code here to implement this method.
    End Sub

    ReadOnly Property Num() As Integer Implements Interface2.Num
        Get
            Num = INum
        End Get
    End Property
End Class

```

You can implement a readonly property with a readwrite property (that is, you do not have to declare it readonly in the implementing class). Implementing an interface promises to implement at least the members that the interface declares, but you can offer more functionality, such as allowing your property to be writable.

Walkthrough: Creating and Implementing Interfaces (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

Interfaces describe the characteristics of properties, methods, and events, but leave the implementation details up to structures or classes.

This walkthrough demonstrates how to declare and implement an interface.

NOTE

This walkthrough doesn't provide information about how to create a user interface.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To define an interface

1. Open a new Visual Basic Windows Application project.
2. Add a new module to the project by clicking **Add Module** on the **Project** menu.
3. Name the new module `Module1.vb` and click **Add**. The code for the new module is displayed.
4. Define an interface named `TestInterface` within `Module1` by typing `Interface TestInterface` between the `Module` and `End Module` statements, and then pressing ENTER. The **Code Editor** indents the `Interface` keyword and adds an `End Interface` statement to form a code block.
5. Define a property, method, and event for the interface by placing the following code between the `Interface` and `End Interface` statements:

```
Property Prop1() As Integer  
Sub Method1(ByVal X As Integer)  
Event Event1()
```

Implementation

You may notice that the syntax used to declare interface members is different from the syntax used to declare class members. This difference reflects the fact that interfaces cannot contain implementation code.

To implement the interface

1. Add a class named `ImplementationClass` by adding the following statement to `Module1`, after the `End Interface` statement but before the `End Module` statement, and then pressing ENTER:

```
Class ImplementationClass
```

If you are working within the integrated development environment, the **Code Editor** supplies a matching `End Class` statement when you press ENTER.

2. Add the following `Implements` statement to `ImplementationClass`, which names the interface the class implements:

```
Implements TestInterface
```

When listed separately from other items at the top of a class or structure, the `Implements` statement indicates that the class or structure implements an interface.

If you are working within the integrated development environment, the **Code Editor** implements the class members required by `TestInterface` when you press ENTER, and you can skip the next step.

3. If you are not working within the integrated development environment, you must implement all the members of the interface `MyInterface`. Add the following code to `ImplementationClass` to implement `Event1`, `Method1`, and `Prop1`:

```
Event Event1() Implements TestInterface.Event1

Public Sub Method1(ByVal X As Integer) Implements TestInterface.Method1
End Sub

Public Property Prop1() As Integer Implements TestInterface.Prop1
    Get
    End Get
    Set(ByVal value As Integer)
    End Set
End Property
```

The `Implements` statement names the interface and interface member being implemented.

4. Complete the definition of `Prop1` by adding a private field to the class that stored the property value:

```
' Holds the value of the property.
Private pval As Integer
```

Return the value of the `pval` from the property get accessor.

```
Return pval
```

Set the value of `pval` in the property set accessor.

```
pval = value
```

5. Complete the definition of `Method1` by adding the following code.

```
MsgBox("The X parameter for Method1 is " & X)
RaiseEvent Event1()
```

To test the implementation of the interface

1. Right-click the startup form for your project in the **Solution Explorer**, and click **View Code**. The editor displays the class for your startup form. By default, the startup form is called `Form1`.

2. Add the following `testInstance` field to the `Form1` class:

```
Dim WithEvents testInstance As TestInterface
```

By declaring `testInstance` as `WithEvents`, the `Form1` class can handle its events.

3. Add the following event handler to the `Form1` class to handle events raised by `testInstance`:

```
Sub EventHandler() Handles testInstance.Event1
    MsgBox("The event handler caught the event.")
End Sub
```

4. Add a subroutine named `Test` to the `Form1` class to test the implementation class:

```
Sub Test()
    ' Create an instance of the class.
    Dim T As New ImplementationClass
    ' Assign the class instance to the interface.
    ' Calls to the interface members are
    ' executed through the class instance.
    testInstance = T
    ' Set a property.
    testInstance.Prop1 = 9
    ' Read the property.
    MsgBox("Prop1 was set to " & testInstance.Prop1)
    ' Test the method and raise an event.
    testInstance.Method1(5)
End Sub
```

The `Test` procedure creates an instance of the class that implements `MyInterface`, assigns that instance to the `testInstance` field, sets a property, and runs a method through the interface.

5. Add code to call the `Test` procedure from the `Form1 Load` procedure of your startup form:

```
Private Sub Form1_Load(ByVal sender As System.Object,
                      ByVal e As System.EventArgs) Handles MyBase.Load
    Test() ' Test the class.
End Sub
```

6. Run the `Test` procedure by pressing F5. The message "Prop1 was set to 9" is displayed. After you click OK, the message "The X parameter for Method1 is 5" is displayed. Click OK, and the message "The event handler caught the event" is displayed.

Objects and classes in Visual Basic

5/4/2018 • 11 minutes to read • [Edit Online](#)

An *object* is a combination of code and data that can be treated as a unit. An object can be a piece of an application, like a control or a form. An entire application can also be an object.

When you create an application in Visual Basic, you constantly work with objects. You can use objects provided by Visual Basic, such as controls, forms, and data access objects. You can also use objects from other applications within your Visual Basic application. You can even create your own objects and define additional properties and methods for them. Objects act like prefabricated building blocks for programs — they let you write a piece of code once and reuse it over and over.

This topic discusses objects in detail.

Objects and classes

Each object in Visual Basic is defined by a *class*. A class describes the variables, properties, procedures, and events of an object. Objects are instances of classes; you can create as many objects you need once you have defined a class.

To understand the relationship between an object and its class, think of cookie cutters and cookies. The cookie cutter is the class. It defines the characteristics of each cookie, for example size and shape. The class is used to create objects. The objects are the cookies.

You must create an object before you can access its members.

To create an object from a class

1. Determine from which class you want to create an object.
2. Write a [Dim Statement](#) to create a variable to which you can assign a class instance. The variable should be of the type of the desired class.

```
Dim nextCustomer As customer
```

3. Add the [New Operator](#) keyword to initialize the variable to a new instance of the class.

```
Dim nextCustomer As New customer
```

4. You can now access the members of the class through the object variable.

```
nextCustomer.accountNumber = lastAccountNumber + 1
```

NOTE

Whenever possible, you should declare the variable to be of the class type you intend to assign to it. This is called *early binding*. If you don't know the class type at compile time, you can invoke *late binding* by declaring the variable to be of the [Object Data Type](#). However, late binding can make performance slower and limit access to the run-time object's members. For more information, see [Object Variable Declaration](#).

Multiple instances

Objects newly created from a class are often identical to each other. Once they exist as individual objects, however, their variables and properties can be changed independently of the other instances. For example, if you add three check boxes to a form, each check box object is an instance of the [CheckBox](#) class. The individual [CheckBox](#) objects share a common set of characteristics and capabilities (properties, variables, procedures, and events) defined by the class. However, each has its own name, can be separately enabled and disabled, and can be placed in a different location on the form.

Object members

An object is an element of an application, representing an *instance* of a class. Fields, properties, methods, and events are the building blocks of objects and constitute their *members*.

Member Access

You access a member of an object by specifying, in order, the name of the object variable, a period (.), and the name of the member. The following example sets the [Text](#) property of a [Label](#) object.

```
warningLabel.Text = "Data not saved"
```

IntelliSense listing of members

IntelliSense lists members of a class when you invoke its List Members option, for example when you type a period (.) as a member-access operator. If you type the period following the name of a variable declared as an instance of that class, IntelliSense lists all the instance members and none of the shared members. If you type the period following the class name itself, IntelliSense lists all the shared members and none of the instance members. For more information, see [Using IntelliSense](#).

Fields and properties

Fields and *properties* represent information stored in an object. You retrieve and set their values with assignment statements the same way you retrieve and set local variables in a procedure. The following example retrieves the [Width](#) property and sets the [ForeColor](#) property of a [Label](#) object.

```
Dim warningWidth As Integer = warningLabel.Width  
warningLabel.ForeColor = System.Drawing.Color.Red
```

Note that a field is also called a *member variable*.

Use property procedures when:

- You need to control when and how a value is set or retrieved.
- The property has a well-defined set of values that need to be validated.
- Setting the value causes some perceptible change in the object's state, such as an [IsVisible](#) property.
- Setting the property causes changes to other internal variables or to the values of other properties.
- A set of steps must be performed before the property can be set or retrieved.

Use fields when:

- The value is of a self-validating type. For example, an error or automatic data conversion occurs if a value other than [True](#) or [False](#) is assigned to a [Boolean](#) variable.
- Any value in the range supported by the data type is valid. This is true of many properties of type [Single](#) or [Double](#).
- The property is a [String](#) data type, and there is no constraint on the size or value of the string.

- For more information, see [Property Procedures](#).

Methods

A *method* is an action that an object can perform. For example, [Add](#) is a method of the [ComboBox](#) object that adds a new entry to a combo box.

The following example demonstrates the [Start](#) method of a [Timer](#) object.

```
Dim safetyTimer As New System.Windows.Forms.Timer  
safetyTimer.Start()
```

Note that a method is simply a *procedure* that is exposed by an object.

For more information, see [Procedures](#).

Events

An event is an action recognized by an object, such as clicking the mouse or pressing a key, and for which you can write code to respond. Events can occur as a result of a user action or program code, or they can be caused by the system. Code that signals an event is said to *raise* the event, and code that responds to it is said to *handle* it.

You can also develop your own custom events to be raised by your objects and handled by other objects. For more information, see [Events](#).

Instance members and shared members

When you create an object from a class, the result is an instance of that class. Members that are not declared with the [Shared](#) keyword are *instance members*, which belong strictly to that particular instance. An instance member in one instance is independent of the same member in another instance of the same class. An instance member variable, for example, can have different values in different instances.

Members declared with the [Shared](#) keyword are *shared members*, which belong to the class as a whole and not to any particular instance. A shared member exists only once, no matter how many instances of its class you create, or even if you create no instances. A shared member variable, for example, has only one value, which is available to all code that can access the class.

Accessing nonshared members

To access a nonshared member of an object

1. Make sure the object has been created from its class and assigned to an object variable.

```
Dim secondForm As New System.Windows.Forms.Form
```

2. In the statement that accesses the member, follow the object variable name with the *member-access operator* (`.`) and then the member name.

```
secondForm.Show()
```

Accessing shared members

To access a shared member of an object

- Follow the class name with the *member-access operator* (`.`) and then the member name. You should always access a [Shared](#) member of the object directly through the class name.

```
MsgBox("This computer is called " & Environment.MachineName)
```

- If you have already created an object from the class, you can alternatively access a [Shared](#) member

through the object's variable.

Differences between classes and modules

The main difference between classes and modules is that classes can be instantiated as objects while standard modules cannot. Because there is only one copy of a standard module's data, when one part of your program changes a public variable in a standard module, any other part of the program gets the same value if it then reads that variable. In contrast, object data exists separately for each instantiated object. Another difference is that unlike standard modules, classes can implement interfaces.

NOTE

When the `Shared` modifier is applied to a class member, it is associated with the class itself instead of a particular instance of the class. The member is accessed directly by using the class name, the same way module members are accessed.

Classes and modules also use different scopes for their members. Members defined within a class are scoped within a specific instance of the class and exist only for the lifetime of the object. To access class members from outside a class, you must use fully qualified names in the format of `Object.Member`.

On the other hand, members declared within a module are publicly accessible by default, and can be accessed by any code that can access the module. This means that variables in a standard module are effectively global variables because they are visible from anywhere in your project, and they exist for the life of the program.

Reusing classes and objects

Objects let you declare variables and procedures once and then reuse them whenever needed. For example, if you want to add a spelling checker to an application you could define all the variables and support functions to provide spell-checking functionality. If you create your spelling checker as a class, you can then reuse it in other applications by adding a reference to the compiled assembly. Better yet, you may be able to save yourself some work by using a spelling checker class that someone else has already developed.

The .NET Framework provides many examples of components that are available for use. The following example uses the `TimeZone` class in the `System` namespace. `TimeZone` provides members that allow you to retrieve information about the time zone of the current computer system.

```
Public Sub examineTimeZone()
    Dim tz As System.TimeZone = System.TimeZone.CurrentTimeZone
    Dim s As String = "Current time zone is "
    s &= CStr(tz.GetUtcOffset(Now).Hours) & " hours and "
    s &= CStr(tz.GetUtcOffset(Now).Minutes) & " minutes "
    s &= "different from UTC (coordinated universal time)"
    s &= vbCrLf & "and is currently "
    If tz.IsDaylightSavingTime(Now) = False Then s &= "not "
    s &= "on ""summer time""."
    MsgBox(s)
End Sub
```

In the preceding example, the first `Dim Statement` declares an object variable of type `TimeZone` and assigns to it a `TimeZone` object returned by the `CurrentTimeZone` property.

Relationships among objects

Objects can be related to each other in several ways. The principal kinds of relationship are *hierarchical* and *containment*.

Hierarchical relationship

When classes are derived from more fundamental classes, they are said to have a *hierarchical relationship*. Class hierarchies are useful when describing items that are a subtype of a more general class.

In the following example, suppose you want to define a special kind of [Button](#) that acts like a normal [Button](#) but also exposes a method that reverses the foreground and background colors.

To define a class is derived from an already existing class

1. Use a [Class Statement](#) to define a class from which to create the object you need.

```
Public Class reversibleButton
```

Be sure an [End Class](#) statement follows the last line of code in your class. By default, the integrated development environment (IDE) automatically generates an [End Class](#) when you enter a [Class](#) statement.

2. Follow the [Class](#) statement immediately with an [Inherits Statement](#). Specify the class from which your new class derives.

```
Inherits System.Windows.Forms.Button
```

Your new class inherits all the members defined by the base class.

3. Add the code for the additional members your derived class exposes. For example, you might add a [reverseColors](#) method, and your derived class might look as follows:

```
Public Class reversibleButton
    Inherits System.Windows.Forms.Button
    Public Sub reverseColors()
        Dim saveColor As System.Drawing.Color = Me.BackColor
        Me.BackColor = Me.ForeColor
        Me.ForeColor = saveColor
    End Sub
End Class
```

If you create an object from the [reversibleButton](#) class, it can access all the members of the [Button](#) class, as well as the [reverseColors](#) method and any other new members you define on [reversibleButton](#).

Derived classes inherit members from the class they are based on, allowing you to add complexity as you progress in a class hierarchy. For more information, see [Inheritance Basics](#).

Compiling the code

Be sure the compiler can access the class from which you intend to derive your new class. This might mean fully qualifying its name, as in the preceding example, or identifying its namespace in an [Imports Statement \(.NET Namespace and Type\)](#). If the class is in a different project, you might need to add a reference to that project. For more information, see [Managing references in a project](#).

Containment relationship

Another way that objects can be related is a *containment relationship*. Container objects logically encapsulate other objects. For example, the [OperatingSystem](#) object logically contains a [Version](#) object, which it returns through its [Version](#) property. Note that the container object does not physically contain any other object.

Collections

One particular type of object containment is represented by *collections*. Collections are groups of similar objects that can be enumerated. Visual Basic supports a specific syntax in the [For Each...Next Statement](#) that allows you to iterate through the items of a collection. Additionally, collections often allow you to use an [Item\[String\]](#) to retrieve elements by their index or by associating them with a unique string. Collections can be

easier to use than arrays because they allow you to add or remove items without using indexes. Because of their ease of use, collections are often used to store forms and controls.

Operators and Expressions in Visual Basic

2/28/2019 • 2 minutes to read • [Edit Online](#)

An *operator* is a code element that performs an operation on one or more code elements that hold values. Value elements include variables, constants, literals, properties, returns from `Function` and `Operator` procedures, and expressions.

An *expression* is a series of value elements combined with operators, which yields a new value. The operators act on the value elements by performing calculations, comparisons, or other operations.

Types of Operators

Visual Basic provides the following types of operators:

- [Arithmetic Operators](#) perform familiar calculations on numeric values, including shifting their bit patterns.
- [Comparison Operators](#) compare two expressions and return a `Boolean` value representing the result of the comparison.
- [Concatenation Operators](#) join multiple strings into a single string.
- [Logical and Bitwise Operators in Visual Basic](#) combine `Boolean` or numeric values and return a result of the same data type as the values.

The value elements that are combined with an operator are called *operands* of that operator. Operators combined with value elements form expressions, except for the assignment operator, which forms a *statement*. For more information, see [Statements](#).

Evaluation of Expressions

The end result of an expression represents a value, which is typically of a familiar data type such as `Boolean`, `String`, or a numeric type.

The following are examples of expressions.

```
5 + 4
```

' The preceding expression evaluates to 9.

```
15 * System.Math.Sqrt(9) + x
```

' The preceding expression evaluates to 45 plus the value of x.

```
"Concat" & "ena" & "tion"
```

' The preceding expression evaluates to "Concatenation".

```
763 < 23
```

' The preceding expression evaluates to False.

Several operators can perform actions in a single expression or statement, as the following example illustrates.

```
x = 45 + y * z ^ 2
```

In the preceding example, Visual Basic performs the operations in the expression on the right side of the assignment operator (`=`), then assigns the resulting value to the variable `x` on the left. There is no practical limit to the number of operators that can be combined into an expression, but an understanding of [Operator Precedence in Visual Basic](#) is necessary to ensure that you get the results you expect.

Procedures in Visual Basic

1/23/2019 • 3 minutes to read • [Edit Online](#)

A *procedure* is a block of Visual Basic statements enclosed by a declaration statement (`Function`, `Sub`, `Operator`, `Get`, `Set`) and a matching `End` declaration. All executable statements in Visual Basic must be within some procedure.

Calling a Procedure

You invoke a procedure from some other place in the code. This is known as a *procedure call*. When the procedure is finished running, it returns control to the code that invoked it, which is known as the *calling code*. The calling code is a statement, or an expression within a statement, that specifies the procedure by name and transfers control to it.

Returning from a Procedure

A procedure returns control to the calling code when it has finished running. To do this, it can use a [Return Statement](#), the appropriate [Exit Statement](#) statement for the procedure, or the procedure's [End <keyword> Statement](#). Control then passes to the calling code following the point of the procedure call.

- With a `Return` statement, control returns immediately to the calling code. Statements following the `Return` statement do not run. You can have more than one `Return` statement in the same procedure.
- With an `Exit Sub` or `Exit Function` statement, control returns immediately to the calling code. Statements following the `Exit` statement do not run. You can have more than one `Exit` statement in the same procedure, and you can mix `Return` and `Exit` statements in the same procedure.
- If a procedure has no `Return` or `Exit` statements, it concludes with an `End Sub` or `End Function`, `End Get`, or `End Set` statement following the last statement of the procedure body. The `End` statement returns control immediately to the calling code. You can have only one `End` statement in a procedure.

Parameters and Arguments

In most cases, a procedure needs to operate on different data each time you call it. You can pass this information to the procedure as part of the procedure call. The procedure defines zero or more *parameters*, each of which represents a value it expects you to pass to it. Corresponding to each parameter in the procedure definition is an *argument* in the procedure call. An argument represents the value you pass to the corresponding parameter in a given procedure call.

Types of Procedures

Visual Basic uses several types of procedures:

- [Sub Procedures](#) perform actions but do not return a value to the calling code.
- Event-handling procedures are `Sub` procedures that execute in response to an event raised by user action or by an occurrence in a program.
- [Function Procedures](#) return a value to the calling code. They can perform other actions before returning.

Some functions written in C# return a *reference return value*. Function callers can modify the return value, and this modification is reflected in the state of the called object. Starting with Visual Basic 2017, Visual

Basic code can consume reference return values, although it cannot return a value by reference. For more information, see [Reference return values](#).

- [Property Procedures](#) return and assign values of properties on objects or modules.
- [Operator Procedures](#) define the behavior of a standard operator when one or both of the operands is a newly-defined class or structure.
- [Generic Procedures in Visual Basic](#) define one or more *type parameters* in addition to their normal parameters, so the calling code can pass specific data types each time it makes a call.

Procedures and Structured Code

Every line of executable code in your application must be inside some procedure, such as `Main`, `calculate`, or `Button1_Click`. If you subdivide large procedures into smaller ones, your application is more readable.

Procedures are useful for performing repeated or shared tasks, such as frequently used calculations, text and control manipulation, and database operations. You can call a procedure from many different places in your code, so you can use procedures as building blocks for your application.

Structuring your code with procedures gives you the following benefits:

- Procedures allow you to break your programs into discrete logical units. You can debug separate units more easily than you can debug an entire program without procedures.
- After you develop procedures for use in one program, you can use them in other programs, often with little or no modification. This helps you avoid code duplication.

Statements in Visual Basic

8/24/2018 • 12 minutes to read • [Edit Online](#)

A statement in Visual Basic is a complete instruction. It can contain keywords, operators, variables, constants, and expressions. Each statement belongs to one of the following categories:

- **Declaration Statements**, which name a variable, constant, or procedure, and can also specify a data type.
- **Executable Statements**, which initiate actions. These statements can call a method or function, and they can loop or branch through blocks of code. Executable statements include **Assignment Statements**, which assign a value or expression to a variable or constant.

This topic describes each category. Also, this topic describes how to combine multiple statements on a single line and how to continue a statement over multiple lines.

Declaration statements

You use declaration statements to name and define procedures, variables, properties, arrays, and constants. When you declare a programming element, you can also define its data type, access level, and scope. For more information, see [Declared Element Characteristics](#).

The following example contains three declarations.

```
Public Sub applyFormat()
    Const limit As Integer = 33
    Dim thisWidget As New widget
    ' Insert code to implement the procedure.
End Sub
```

The first declaration is the `Sub` statement. Together with its matching `End Sub` statement, it declares a procedure named `applyFormat`. It also specifies that `applyFormat` is `Public`, which means that any code that can refer to it can call it.

The second declaration is the `Const` statement, which declares the constant `limit`, specifying the `Integer` data type and a value of 33.

The third declaration is the `Dim` statement, which declares the variable `thisWidget`. The data type is a specific object, namely an object created from the `widget` class. You can declare a variable to be of any elementary data type or of any object type that is exposed in the application you are using.

Initial Values

When the code containing a declaration statement runs, Visual Basic reserves the memory required for the declared element. If the element holds a value, Visual Basic initializes it to the default value for its data type. For more information, see "Behavior" in [Dim Statement](#).

You can assign an initial value to a variable as part of its declaration, as the following example illustrates.

```
Dim m As Integer = 45
' The preceding declaration creates m and assigns the value 45 to it.
```

If a variable is an object variable, you can explicitly create an instance of its class when you declare it by using

the [New Operator](#) keyword, as the following example illustrates.

```
Dim f As New System.Windows.Forms.Form()
```

Note that the initial value you specify in a declaration statement is not assigned to a variable until execution reaches its declaration statement. Until that time, the variable contains the default value for its data type.

Executable statements

An executable statement performs an action. It can call a procedure, branch to another place in the code, loop through several statements, or evaluate an expression. An assignment statement is a special case of an executable statement.

The following example uses an `If...Then...Else` control structure to run different blocks of code based on the value of a variable. Within each block of code, a `For...Next` loop runs a specified number of times.

```
Public Sub startWidget(ByVal aWidget As widget,
    ByVal clockwise As Boolean, ByVal revolutions As Integer)
    Dim counter As Integer
    If clockwise = True Then
        For counter = 1 To revolutions
            aWidget.spinClockwise()
        Next counter
    Else
        For counter = 1 To revolutions
            aWidget.spinCounterClockwise()
        Next counter
    End If
End Sub
```

The `If` statement in the preceding example checks the value of the parameter `clockwise`. If the value is `True`, it calls the `spinClockwise` method of `aWidget`. If the value is `False`, it calls the `spinCounterClockwise` method of `aWidget`. The `If...Then...Else` control structure ends with `End If`.

The `For...Next` loop within each block calls the appropriate method a number of times equal to the value of the `revolutions` parameter.

Assignment statements

Assignment statements carry out assignment operations, which consist of taking the value on the right side of the assignment operator (`=`) and storing it in the element on the left, as in the following example.

```
v = 42
```

In the preceding example, the assignment statement stores the literal value 42 in the variable `v`.

Eligible programming elements

The programming element on the left side of the assignment operator must be able to accept and store a value. This means it must be a variable or property that is not [ReadOnly](#), or it must be an array element. In the context of an assignment statement, such an element is sometimes called an *lvalue*, for "left value."

The value on the right side of the assignment operator is generated by an expression, which can consist of any combination of literals, constants, variables, properties, array elements, other expressions, or function calls. The following example illustrates this.

```
x = y + z + findResult(3)
```

The preceding example adds the value held in variable `y` to the value held in variable `z`, and then adds the value returned by the call to function `findResult`. The total value of this expression is then stored in variable `x`.

Data types in assignment statements

In addition to numeric values, the assignment operator can also assign `String` values, as the following example illustrates.

```
Dim a, b As String
a = "String variable assignment"
b = "Con" & "cat" & "enation"
' The preceding statement assigns the value "Concatenation" to b.
```

You can also assign `Boolean` values, using either a `Boolean` literal or a `Boolean` expression, as the following example illustrates.

```
Dim r, s, t As Boolean
r = True
s = 45 > 1003
t = 45 > 1003 Or 45 > 17
' The preceding statements assign False to s and True to t.
```

Similarly, you can assign appropriate values to programming elements of the `Char`, `Date`, or `Object` data type. You can also assign an object instance to an element declared to be of the class from which that instance is created.

Compound assignment statements

Compound assignment statements first perform an operation on an expression before assigning it to a programming element. The following example illustrates one of these operators, `+=`, which increments the value of the variable on the left side of the operator by the value of the expression on the right.

```
n += 1
```

The preceding example adds 1 to the value of `n`, and then stores that new value in `n`. It is a shorthand equivalent of the following statement:

```
n = n + 1
```

A variety of compound assignment operations can be performed using operators of this type. For a list of these operators and more information about them, see [Assignment Operators](#).

The concatenation assignment operator (`&=`) is useful for adding a string to the end of already existing strings, as the following example illustrates.

```
Dim q As String = "Sample "
q &= "String"
' q now contains "Sample String".
```

Type Conversions in Assignment Statements

The value you assign to a variable, property, or array element must be of a data type appropriate to that

destination element. In general, you should try to generate a value of the same data type as that of the destination element. However, some types can be converted to other types during assignment.

For information on converting between data types, see [Type Conversions in Visual Basic](#). In brief, Visual Basic automatically converts a value of a given type to any other type to which it widens. A *widening conversion* is one in that always succeeds at run time and does not lose any data. For example, Visual Basic converts an `Integer` value to `Double` when appropriate, because `Integer` widens to `Double`. For more information, see [Widening and Narrowing Conversions](#).

Narrowing conversions (those that are not widening) carry a risk of failure at run time, or of data loss. You can perform a narrowing conversion explicitly by using a type conversion function, or you can direct the compiler to perform all conversions implicitly by setting `Option Strict Off`. For more information, see [Implicit and Explicit Conversions](#).

Putting multiple statements on one line

You can have multiple statements on a single line separated by the colon (`:`) character. The following example illustrates this.

```
Dim sampleString As String = "Hello World" : MsgBox(sampleString)
```

Though occasionally convenient, this form of syntax makes your code hard to read and maintain. Thus, it is recommended that you keep one statement to a line.

Continuing a statement over multiple lines

A statement usually fits on one line, but when it is too long, you can continue it onto the next line using a line-continuation sequence, which consists of a space followed by an underscore character (`_`) followed by a carriage return. In the following example, the `MsgBox` executable statement is continued over two lines.

```
Public Sub demoBox()
    Dim nameVar As String
    nameVar = "John"
    MsgBox("Hello " & nameVar _
        & ". How are you?")
End Sub
```

Implicit line continuation

In many cases, you can continue a statement on the next consecutive line without using the underscore character (`_`). The following syntax elements implicitly continue the statement on the next line of code.

- After a comma (`,`). For example:

```
Public Function GetUsername(ByVal username As String,
                           ByVal delimiter As Char,
                           ByVal position As Integer) As String

    Return username.Split(delimiter)(position)
End Function
```

- After an open parenthesis (`(`) or before a closing parenthesis (`)`). For example:

```
Dim username = GetUsername()
    Security.Principal.WindowsIdentity.GetCurrent().Name,
    CChar("\"),
    1
)
```

- After an open curly brace (`{`) or before a closing curly brace (`}`). For example:

```
Dim customer = New Customer With {
    .Name = "Terry Adams",
    .Company = "Adventure Works",
    .Email = "terry@www.adventure-works.com"
}
```

For more information, see [Object Initializers: Named and Anonymous Types](#) or [Collection Initializers](#).

- After an open embedded expression (`<%=`) or before the close of an embedded expression (`%>`) within an XML literal. For example:

```
Dim customerXml = <Customer>
    <Name>
        <%= customer.Name
    %>
    </Name>
    <Email>
        <%= customer.Email
    %>
    </Email>
</Customer>
```

For more information, see [Embedded Expressions in XML](#).

- After the concatenation operator (`&`). For example:

```
cmd.CommandText =
    "SELECT * FROM Titles JOIN Publishers " &
    "ON Publishers.PubId = Titles.PubID " &
    "WHERE Publishers.State = 'CA'"
```

For more information, see [Operators Listed by Functionality](#).

- After assignment operators (`=`, `&=`, `:=`, `+=`, `-=`, `*=`, `/=`, `\=`, `^=`, `<<=`, `>>=`). For example:

```
Dim fileStream =
    My.Computer.FileSystem.
    OpenTextFileReader(filePath)
```

For more information, see [Operators Listed by Functionality](#).

- After binary operators (`+`, `-`, `/`, `*`, `Mod`, `<>`, `<`, `>`, `<=`, `>=`, `^`, `>>`, `<<`, `And`, `AndAlso`, `Or`, `OrElse`, `Like`, `Xor`) within an expression. For example:

```
Dim memoryInUse =
    My.Computer.Info.TotalPhysicalMemory +
    My.Computer.Info.TotalVirtualMemory -
    My.Computer.Info.AvailablePhysicalMemory -
    My.Computer.Info.AvailableVirtualMemory
```

For more information, see [Operators Listed by Functionality](#).

- After the `Is` and `IsNot` operators. For example:

```
If TypeOf inStream Is
    IO.FileStream AndAlso
    inStream IsNot
    Nothing Then

    ReadFile(inStream)

End If
```

For more information, see [Operators Listed by Functionality](#).

- After a member qualifier character (`.`) and before the member name. For example:

```
Dim fileStream =
    My.Computer.FileSystem.
        OpenTextFileReader(filePath)
```

However, you must include a line-continuation character (`_`) following a member qualifier character when you are using the `With` statement or supplying values in the initialization list for a type. Consider breaking the line after the assignment operator (for example, `=`) when you are using `With` statements or object initialization lists. For example:

```
' Not allowed:
' Dim aType = New With { .
'     PropertyName = "Value"

' Allowed:
Dim aType = New With {.PropertyName =
    "Value"}
```

```
Dim log As New EventLog()
```

```
' Not allowed:
' With log
'
'
'     Source = "Application"
' End With

' Allowed:
With log
    .Source =
        "Application"
End With
```

For more information, see [With...End With Statement](#) or [Object Initializers: Named and Anonymous Types](#).

- After an XML axis property qualifier (`.` or `.@` or `...`). However, you must include a line-continuation character (`_`) when you specify a member qualifier when you are using the `With` keyword. For example:

```
Dim customerName = customerXml.  
    <Name>.Value  
  
Dim customerEmail = customerXml...  
    <Email>.Value
```

For more information, see [XML Axis Properties](#).

- After a less-than sign (`<`) or before a greater-than sign (`>`) when you specify an attribute. Also after a greater-than sign (`>`) when you specify an attribute. However, you must include a line-continuation character (`_`) when you specify assembly-level or module-level attributes. For example:

```
<  
Serializable()  
>  
Public Class Customer  
    Public Property Name As String  
    Public Property Company As String  
    Public Property Email As String  
End Class
```

For more information, see [Attributes overview](#).

- Before and after query operators (`Aggregate` , `Distinct` , `From` , `Group By` , `Group Join` , `Join` , `Let` , `Order By` , `Select` , `Skip` , `Skip While` , `Take` , `Take While` , `Where` , `In` , `Into` , `On` , `Ascending` , and `Descending`). You cannot break a line between the keywords of query operators that are made up of multiple keywords (`Order By` , `Group Join` , `Take While` , and `Skip While`). For example:

```
Dim vsProcesses = From proc In  
                    Process.GetProcesses  
                    Where proc.MainWindowTitle.Contains("Visual Studio")  
                    Select proc.ProcessName, proc.Id,  
                           proc.MainWindowTitle
```

For more information, see [Queries](#).

- After the `In` keyword in a `For Each` statement. For example:

```
For Each p In  
    vsProcesses  
  
        Console.WriteLine("{0}" & vbTab & "{1}" & vbTab & "{2}",  
                          p.ProcessName,  
                          p.Id,  
                          p.MainWindowTitle)  
    Next
```

For more information, see [For Each...Next Statement](#).

- After the `From` keyword in a collection initializer. For example:

```
Dim days = New List(Of String) From
{
    "Mo", "Tu", "We", "Th", "F", "Sa", "Su"
}
```

For more information, see [Collection Initializers](#).

Adding comments

Source code is not always self-explanatory, even to the programmer who wrote it. To help document their code, therefore, most programmers make liberal use of embedded comments. Comments in code can explain a procedure or a particular instruction to anyone reading or working with it later. Visual Basic ignores comments during compilation, and they do not affect the compiled code.

Comment lines begin with an apostrophe (') or REM followed by a space. They can be added anywhere in code, except within a string. To append a comment to a statement, insert an apostrophe or REM after the statement, followed by the comment. Comments can also go on their own separate line. The following example demonstrates these possibilities.

```
' This is a comment on a separate code line.
REM This is another comment on a separate code line.
x += a(i) * b(i) ' Add this amount to total.
MsgBox(statusMessage) REM Inform operator of status.
```

Checking compilation errors

If, after you type a line of code, the line is displayed with a wavy blue underline (an error message may appear as well), there is a syntax error in the statement. You must find out what is wrong with the statement (by looking in the task list, or hovering over the error with the mouse pointer and reading the error message) and correct it. Until you have fixed all syntax errors in your code, your program will fail to compile correctly.

Variables in Visual Basic

2/28/2019 • 2 minutes to read • [Edit Online](#)

You often have to store values when you perform calculations with Visual Basic. For example, you might want to calculate several values, compare them, and perform different operations on them, depending on the result of the comparison. You have to retain the values if you want to compare them.

Usage

Visual Basic, just like most programming languages, uses variables for storing values. A *variable* has a name (the word that you use to refer to the value that the variable contains). A variable also has a data type (which determines the kind of data that the variable can store). A variable can represent an array if it has to store an indexed set of closely related data items.

Local type inference enables you to declare variables without explicitly stating a data type. Instead, the compiler infers the type of the variable from the type of the initialization expression. For more information, see [Local Type Inference](#) and [Option Infer Statement](#).

Assigning Values

You use assignment statements to perform calculations and assign the result to a variable, as the following example shows.

```
' The following statement assigns the value 10 to the variable.  
applesSold = 10  
' The following statement increments the variable.  
applesSold = applesSold + 1  
' The variable now holds the value 11.
```

NOTE

The equal sign (`=`) in this example is an assignment operator, not an equality operator. The value is being assigned to the variable `applesSold`.

For more information, see [How to: Move Data Into and Out of a Variable](#).

Variables and Properties

Like a variable, a *property* represents a value that you can access. However, it is more complex than a variable. A property uses code blocks that control how to set and retrieve its value. For more information, see [Differences Between Properties and Variables in Visual Basic](#).

COM Interop (Visual Basic)

9/7/2018 • 2 minutes to read • [Edit Online](#)

The Component Object Model (COM) allows an object to expose its functionality to other components and to host applications. Most of today's software includes COM objects. Although .NET assemblies are the best choice for new applications, you may at times need to employ COM objects. Introduction to COM Interop (Visual Basic)

2/23/2019 • 2 minutes to read • [Edit Online](#)

The Component Object Model (COM) lets an object expose its functionality to other components and to host applications. While COM objects have been fundamental to Windows programming for many years, applications designed for the common language runtime (CLR) offer many advantages.

.NET Framework applications will eventually replace those developed with COM. Until then, you may have to use or create COM objects by using Visual Studio. Interoperability with COM, or *COM interop*, enables you to use existing COM objects while transitioning to the .NET Framework at your own pace.

By using the .NET Framework to create COM components, you can use registration-free COM interop. This lets you control which DLL version is enabled when more than one version is installed on a computer, and lets end users use XCOPY or FTP to copy your application to an appropriate directory on their computer where it can be run. For more information, see [Registration-Free COM Interop](#).

Managed Code and Data

Code developed for the .NET Framework is referred to as *managed code*, and contains metadata that is used by the CLR. Data used by .NET Framework applications is called *managed data* because the runtime manages data-related tasks such as allocating and reclaiming memory and performing type checking. By default, Visual Basic .NET uses managed code and data, but you can access the unmanaged code and data of COM objects using interop assemblies (described later on this page).

Assemblies

An assembly is the primary building block of a .NET Framework application. It is a collection of functionality that is built, versioned, and deployed as a single implementation unit containing one or more files. Each assembly contains an assembly manifest.

Type Libraries and Assembly Manifests

Type libraries describe characteristics of COM objects, such as member names and data types. Assembly manifests perform the same function for .NET Framework applications. They include information about the following:

- Assembly identity, version, culture, and digital signature.
- Files that make up the assembly implementation.
- Types and resources that make up the assembly. This includes those that are exported from it.
- Compile-time dependencies on other assemblies.
- Permissions required for the assembly to run correctly.

For more information about assemblies and assembly manifests, see [Assemblies in .NET](#).

Importing and Exporting Type Libraries

Visual Studio contains a utility, Tlbimp, that lets you import information from a type library into a .NET Framework application. You can generate type libraries from assemblies by using the Tlbexp utility.

For information about Tlbimp and Tlbexp, see [Tlbimp.exe \(Type Library Importer\)](#) and [Tlbexp.exe \(Type Library Exporter\)](#).

Interop Assemblies

Interop assemblies are .NET Framework assemblies that bridge between managed and unmanaged code, mapping COM object members to equivalent .NET Framework managed members. Interop assemblies created by Visual Basic .NET handle many of the details of working with COM objects, such as interoperability marshaling.

Interoperability Marshaling

All .NET Framework applications share a set of common types that enable interoperability of objects, regardless of the programming language that is used. The parameters and return values of COM objects sometimes use data types that differ from those used in managed code. *Interoperability marshaling* is the process of packaging parameters and return values into equivalent data types as they move to and from COM objects. For more information, see [Interop Marshaling](#).

How to: Reference COM Objects from Visual Basic

2/28/2019 • 2 minutes to read • [Edit Online](#)

In Visual Basic, adding references to COM objects that have type libraries requires the creation of an interop assembly for the COM library. References to the members of the COM object are routed to the interop assembly and then forwarded to the actual COM object. Responses from the COM object are routed to the interop assembly and forwarded to your .NET Framework application.

You can reference a COM object without using an interop assembly by embedding the type information for the COM object in a .NET assembly. To embed type information, set the `Embed Interop Types` property to `True` for the reference to the COM object. If you are compiling by using the command-line compiler, use the `/link` option to reference the COM library. For more information, see [/link \(Visual Basic\)](#).

Visual Basic automatically creates interop assemblies when you add a reference to a type library from the integrated development environment (IDE). When working from the command line, you can use the Tlbimp utility to manually create interop assemblies.

To add references to COM objects

1. On the **Project** menu, choose **Add Reference** and then click the **COM** tab in the dialog box.
2. Select the component you want to use from the list of COM objects.
3. To simplify access to the interop assembly, add an `Imports` statement to the top of the class or module in which you will use the COM object. For example, the following code example imports the namespace `INKEDLib` for objects referenced in the `Microsoft InkEdit Control 1.0` library.

```
Imports INKEDLib

Class Sample
    Private s As IIInkCursor

End Class
```

To create an interop assembly using Tlbimp

1. Add the location of Tlbimp to the search path, if it is not already part of the search path and you are not currently in the directory where it is located.
2. Call Tlbimp from a command prompt, providing the following information:
 - Name and location of the DLL that contains the type library
 - Name and location of the namespace where the information should be placed
 - Name and location of the target interop assembly

The following code provides an example:

```
Tlbimp test3.dll /out:NameSpace1 /out:Interop1.dll
```

You can use Tlbimp to create interop assemblies for type libraries, even for unregistered COM objects. However, the COM objects referred to by interop assemblies must be properly registered on the computer where they are to be used. You can register a COM object by using the Regsvr32 utility included with the Windows operating system.

How to: Work with ActiveX Controls (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

ActiveX controls are COM components or objects you can insert into a Web page or other application to reuse packaged functionality someone else has programmed. You can use ActiveX controls developed for Visual Basic 6.0 and earlier versions to add features to the **Toolbox** of Visual Studio.

To add ActiveX controls to the toolbox

1. On the **Tools** menu, click **Choose Toolbox Items**.

The **Choose Toolbox** dialog box appears.

2. Click the **COM Components** tab.
3. Select the check box next to the ActiveX control you want to use, and then click **OK**.

The new control appears with the other tools in the **Toolbox**.

NOTE

You can use the Aximp utility to manually create an interop assembly for ActiveX controls. For more information, see [Aximp.exe \(Windows Forms ActiveX Control Importer\)](#).

Walkthrough: Calling Windows APIs (Visual Basic)

2/28/2019 • 9 minutes to read • [Edit Online](#)

Windows APIs are dynamic-link libraries (DLLs) that are part of the Windows operating system. You use them to perform tasks when it is difficult to write equivalent procedures of your own. For example, Windows provides a function named `FlashWindowEx` that lets you make the title bar for an application alternate between light and dark shades.

The advantage of using Windows APIs in your code is that they can save development time because they contain dozens of useful functions that are already written and waiting to be used. The disadvantage is that Windows APIs can be difficult to work with and unforgiving when things go wrong.

Windows APIs represent a special category of interoperability. Windows APIs do not use managed code, do not have built-in type libraries, and use data types that are different than those used with Visual Studio. Because of these differences, and because Windows APIs are not COM objects, interoperability with Windows APIs and the .NET Framework is performed using platform invoke, or PInvoke. Platform invoke is a service that enables managed code to call unmanaged functions implemented in DLLs. For more information, see [Consuming Unmanaged DLL Functions](#). You can use PInvoke in Visual Basic by using either the `Declare` statement or applying the `DllImport` attribute to an empty procedure.

Windows API calls were an important part of Visual Basic programming in the past, but are seldom necessary with Visual Basic .NET. Whenever possible, you should use managed code from the .NET Framework to perform tasks, instead of Windows API calls. This walkthrough provides information for those situations in which using Windows APIs is necessary.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

API Calls Using Declare

The most common way to call Windows APIs is by using the `Declare` statement.

To declare a DLL procedure

1. Determine the name of the function you want to call, plus its arguments, argument types, and return value, as well as the name and location of the DLL that contains it.

NOTE

For complete information about the Windows APIs, see the Win32 SDK documentation in the Platform SDK Windows API. For more information about the constants that Windows APIs use, examine the header files such as Windows.h included with the Platform SDK.

2. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
3. Select **Windows Application** from the list of Visual Basic project templates. The new project is displayed.
4. Add the following `Declare` function either to the class or module in which you want to use the DLL:

```
Declare Auto Function MBox Lib "user32.dll" Alias "MessageBox" (
    ByVal hWnd As Integer,
    ByVal txt As String,
    ByVal caption As String,
    ByVal Typ As Integer) As Integer
```

Parts of the Declare Statement

The `Declare` statement includes the following elements.

Auto modifier

The `Auto` modifier instructs the runtime to convert the string based on the method name according to common language runtime rules (or alias name if specified).

Lib and Alias keywords

The name following the `Function` keyword is the name your program uses to access the imported function. It can be the same as the real name of the function you are calling, or you can use any valid procedure name and then employ the `Alias` keyword to specify the real name of the function you are calling.

Specify the `Lib` keyword, followed by the name and location of the DLL that contains the function you are calling. You do not need to specify the path for files located in the Windows system directories.

Use the `Alias` keyword if the name of the function you are calling is not a valid Visual Basic procedure name, or conflicts with the name of other items in your application. `Alias` indicates the true name of the function being called.

Argument and Data Type Declarations

Declare the arguments and their data types. This part can be challenging because the data types that Windows uses do not correspond to Visual Studio data types. Visual Basic does a lot of the work for you by converting arguments to compatible data types, a process called *marshaling*. You can explicitly control how arguments are marshaled by using the `MarshalAsAttribute` attribute defined in the `System.Runtime.InteropServices` namespace.

NOTE

Previous versions of Visual Basic allowed you to declare parameters `As Any`, meaning that data of any data type could be used. Visual Basic requires that you use a specific data type for all `Declare` statements.

Windows API Constants

Some arguments are combinations of constants. For example, the `MessageBox` API shown in this walkthrough accepts an integer argument called `Typ` that controls how the message box is displayed. You can determine the numeric value of these constants by examining the `#define` statements in the file WinUser.h. The numeric values are generally shown in hexadecimal, so you may want to use a calculator to add them and convert to decimal. For example, if you want to combine the constants for the exclamation style `MB_ICONEXCLAMATION` 0x00000030 and the Yes/No style `MB_YESNO` 0x00000004, you can add the numbers and get a result of 0x00000034, or 52 decimal.

Although you can use the decimal result directly, it is better to declare these values as constants in your application and combine them using the `Or` operator.

To declare constants for Windows API calls

1. Consult the documentation for the Windows function you are calling. Determine the name of the constants it uses and the name of the .h file that contains the numeric values for these constants.
2. Use a text editor, such as Notepad, to view the contents of the header (.h) file, and find the values associated with the constants you are using. For example, the `MessageBox` API uses the constant `MB_ICONQUESTION` to show a question mark in the message box. The definition for `MB_ICONQUESTION` is in WinUser.h and appears as follows:

```
#define MB_ICONQUESTION 0x00000020L
```

3. Add equivalent `Const` statements to your class or module to make these constants available to your application. For example:

```
Const MB_ICONQUESTION As Integer = &H20
Const MB_YESNO As Integer = &H4
Const IDYES As Integer = 6
Const IDNO As Integer = 7
```

To call the DLL procedure

1. Add a button named `Button1` to the startup form for your project, and then double-click it to view its code. The event handler for the button is displayed.
2. Add code to the `Click` event handler for the button you added, to call the procedure and provide the appropriate arguments:

```
Private Sub Button1_Click(ByVal sender As System.Object,
    ByVal e As System.EventArgs) Handles Button1.Click

    ' Stores the return value.
    Dim RetVal As Integer
    RetVal = MBox(0, "Declare DLL Test", "Windows API MessageBox",
        MB_ICONQUESTION Or MB_YESNO)

    ' Check the return value.
    If RetVal = IDYES Then
        MsgBox("You chose Yes")
    Else
        MsgBox("You chose No")
    End If
End Sub
```

3. Run the project by pressing F5. The message box is displayed with both **Yes** and **No** response buttons. Click either one.

Data Marshaling

Visual Basic automatically converts the data types of parameters and return values for Windows API calls, but you can use the `MarshalAs` attribute to explicitly specify unmanaged data types that an API expects. For more information about interop marshaling, see [Interop Marshaling](#).

To use `Declare` and `MarshalAs` in an API call

1. Determine the name of the function you want to call, plus its arguments, data types, and return value.
2. To simplify access to the `MarshalAs` attribute, add an `Imports` statement to the top of the code for the class or module, as in the following example:

```
Imports System.Runtime.InteropServices
```

3. Add a function prototype for the imported function to the class or module you are using, and apply the `MarshalAs` attribute to the parameters or return value. In the following example, an API call that expects the type `void*` is marshaled as `AsAny`:

```
Declare Sub SetData Lib "..\LIB\UnmgdLib.dll" (
    ByVal x As Short,
    <MarshalAsAttribute(UnmanagedType.AsAny)>
    ByVal o As Object)
```

API Calls Using DllImport

The `DllImport` attribute provides a second way to call functions in DLLs without type libraries. `DllImport` is roughly equivalent to using a `Declare` statement but provides more control over how functions are called.

You can use `DllImport` with most Windows API calls as long as the call refers to a shared (sometimes called *static*) method. You cannot use methods that require an instance of a class. Unlike `Declare` statements, `DllImport` calls cannot use the `MarshalAs` attribute.

To call a Windows API using the `DllImport` attribute

1. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**.
The **New Project** dialog box appears.
2. Select **Windows Application** from the list of Visual Basic project templates. The new project is displayed.
3. Add a button named `Button2` to the startup form.
4. Double-click `Button2` to open the code view for the form.
5. To simplify access to `DllImport`, add an `Imports` statement to the top of the code for the startup form class:

```
Imports System.Runtime.InteropServices
```

6. Declare an empty function preceding the `End Class` statement for the form, and name the function `MoveFile`.

7. Apply the `Public` and `Shared` modifiers to the function declaration and set parameters for `MoveFile` based on the arguments the Windows API function uses:

```
Public Shared Function MoveFile(  
    ByVal src As String,  
    ByVal dst As String) As Boolean  
    ' Leave the body of the function empty.  
End Function
```

Your function can have any valid procedure name; the `DllImport` attribute specifies the name in the DLL. It also handles interoperability marshaling for the parameters and return values, so you can choose Visual Studio data types that are similar to the data types the API uses.

8. Apply the `DllImport` attribute to the empty function. The first parameter is the name and location of the DLL containing the function you are calling. You do not need to specify the path for files located in the Windows system directories. The second parameter is a named argument that specifies the name of the function in the Windows API. In this example, the `DllImport` attribute forces calls to `MoveFile` to be forwarded to `MoveFileW` in KERNEL32.DLL. The `MoveFileW` method copies a file from the path `src` to the path `dst`.

```
<DllImport("KERNEL32.DLL", EntryPoint:="MoveFileW", SetLastError:=True,  
    CharSet:=CharSet.Unicode, ExactSpelling:=True,  
    CallingConvention:=CallingConvention.StdCall)>  
Public Shared Function MoveFile(  
    ByVal src As String,  
    ByVal dst As String) As Boolean  
    ' Leave the body of the function empty.  
End Function
```

9. Add code to the `Button2_Click` event handler to call the function:

```
Private Sub Button2_Click(ByVal sender As System.Object,
    ByVal e As System.EventArgs) Handles Button2.Click

    Dim RetVal As Boolean = MoveFile("c:\tmp\Test.txt", "c:\Test.txt")
    If RetVal = True Then
        MsgBox("The file was moved successfully.")
    Else
        MsgBox("The file could not be moved.")
    End If
End Sub
```

10. Create a file named Test.txt and place it in the C:\Tmp directory on your hard drive. Create the Tmp directory if necessary.

11. Press F5 to start the application. The main form appears.

12. Click **Button2**. The message "The file was moved successfully" is displayed if the file can be moved.

How to: Call Windows APIs (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

This example defines and calls the `MessageBox` function in user32.dll and then passes a string to it.

Example

```
' Defines the MessageBox function.  
Public Class Win32  
    Declare Auto Function MessageBox Lib "user32.dll" (  
        ByVal hWnd As Integer, ByVal txt As String,  
        ByVal caption As String, ByVal Type As Integer  
    ) As Integer  
End Class  
  
' Calls the MessageBox function.  
Public Class DemoMessageBox  
    Public Shared Sub Main()  
        Win32.MessageBox(0, "Here's a MessageBox", "Platform Invoke Sample", 0)  
    End Sub  
End Class
```

Compiling the Code

How to: Call a Windows Function that Takes Unsigned Types (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

If you are consuming a class, module, or structure that has members of unsigned integer types, you can access these members with Visual Basic.

To call a Windows function that takes an unsigned type

1. Use a [Declare Statement](#) to tell Visual Basic which library holds the function, what its name is in that library, what its calling sequence is, and how to convert strings when calling it.
2. In the `Declare` statement, use `UInteger`, `ULong`, `UShort`, or `Byte` as appropriate for each parameter with an unsigned type.
3. Consult the documentation for the Windows function you are calling to find the names and values of the constants it uses. Many of these are defined in the WinUser.h file.
4. Declare the necessary constants in your code. Many Windows constants are 32-bit unsigned values, and you should declare these `As UInteger`.
5. Call the function in the normal way. The following example calls the Windows function `MessageBox`, which takes an unsigned integer argument.

```
Public Class windowsMessage
    Private Declare Auto Function mb Lib "user32.dll" Alias "MessageBox" (
        ByVal hWnd As Integer,
        ByVal lpText As String,
        ByVal lpCaption As String,
        ByVal uType As UInteger) As Integer
    Private Const MB_OK As UInteger = 0
    Private Const MB_ICONEXCLAMATION As UInteger = &H30
    Private Const IDOK As UInteger = 1
    Private Const IDCLOSE As UInteger = 8
    Private Const c As UInteger = MB_OK Or MB_ICONEXCLAMATION
    Public Function messageThroughWindows() As String
        Dim r As Integer = mb(0, "Click OK if you see this!",
            "Windows API call", c)
        Dim s As String = "Windows API MessageBox returned " &
            CStr(r)& vbCrLf & "(IDOK = " & CStr(IDOK) &
            ", IDCLOSE = " & CStr(IDCLOSE) & ")"
        Return s
    End Function
End Class
```

You can test the function `messageThroughWindows` with the following code.

```
Public Sub consumeWindowsMessage()
    Dim w As New windowsMessage
    w.messageThroughWindows()
End Sub
```

Caution

The `UInteger`, `ULong`, `UShort`, and `SByte` data types are not part of the [Language Independence and Language-Independent Components](#) (CLS), so CLS-compliant code cannot consume a component that

uses them.

IMPORTANT

Making a call to unmanaged code, such as the Windows application programming interface (API), exposes your code to potential security risks.

IMPORTANT

Calling the Windows API requires unmanaged code permission, which might affect its execution in partial-trust situations. For more information, see [SecurityPermission](#) and [Code Access Permissions](#).

Walkthrough: Creating COM Objects with Visual Basic

2/28/2019 • 4 minutes to read • [Edit Online](#)

When creating new applications or components, it is best to create .NET Framework assemblies. However, Visual Basic also makes it easy to expose a .NET Framework component to COM. This enables you to provide new components for earlier application suites that require COM components. This walkthrough demonstrates how to use Visual Basic to expose .NET Framework objects as COM objects, both with and without the COM class template.

The easiest way to expose COM objects is by using the COM class template. The COM class template creates a new class, and then configures your project to generate the class and interoperability layer as a COM object and register it with the operating system.

NOTE

Although you can also expose a class created in Visual Basic as a COM object for unmanaged code to use, it is not a true COM object and cannot be used by Visual Basic. For more information, see [COM Interoperability in .NET Framework Applications](#).

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To create a COM object by using the COM class template

1. Open a new Windows Application project from the **File** menu by clicking **New Project**.
2. In the **New Project** dialog box under the **Project Types** field, check that Windows is selected. Select **Class Library** from the **Templates** list, and then click **OK**. The new project is displayed.
3. Select **Add New Item** from the **Project** menu. The **Add New Item** dialog box is displayed.
4. Select **COM Class** from the **Templates** list, and then click **Add**. Visual Basic adds a new class and configures the new project for COM interop.
5. Add code such as properties, methods, and events to the COM class.
6. Select **Build ClassLibrary1** from the **Build** menu. Visual Basic builds the assembly and registers the COM object with the operating system.

Creating COM Objects without the COM Class Template

You can also create a COM class manually instead of using the COM class template. This procedure is helpful when you are working from the command line or when you want more control over how COM objects are defined.

To set up your project to generate a COM object

1. Open a new Windows Application project from the **File** menu by clicking **NewProject**.
2. In the **New Project** dialog box under the **Project Types** field, check that Windows is selected. Select **Class**

Library from the **Templates** list, and then click **OK**. The new project is displayed.

3. In **Solution Explorer**, right-click your project, and then click **Properties**. The **Project Designer** is displayed.
4. Click the **Compile** tab.
5. Select the **Register for COM Interop** check box.

To set up the code in your class to create a COM object

1. In **Solution Explorer**, double-click **Class1.vb** to display its code.
2. Rename the class to `ComClass1`.
3. Add the following constants to `ComClass1`. They will store the Globally Unique Identifier (GUID) constants that the COM objects are required to have.

```
Public Const ClassId As String = ""  
Public Const InterfaceId As String = ""  
Public Const EventsId As String = ""
```

4. On the **Tools** menu, click **Create Guid**. In the **Create GUID** dialog box, click **Registry Format** and then click **Copy**. Click **Exit**.
5. Replace the empty string for the `classId` with the GUID, removing the leading and trailing braces. For example, if the GUID provided by Guidgen is `"{2C8B0AEE-02C9-486e-B809-C780A11530FE}"` then your code should appear as follows.

```
Public Const ClassId As String = "2C8B0AEE-02C9-486e-B809-C780A11530FE"
```

6. Repeat the previous steps for the `InterfaceId` and `EventsId` constants, as in the following example.

```
Public Const InterfaceId As String = "3D8B5BA4-FB8C-5ff8-8468-11BF6BD5CF91"  
Public Const EventsId As String = "2B691787-6ED7-401e-90A4-B3B9C0360E31"
```

NOTE

Make sure that the GUIDs are new and unique; otherwise, your COM component could conflict with other COM components.

7. Add the `ComClass` attribute to `ComClass1`, specifying the GUIDs for the Class ID, Interface ID, and Events ID as in the following example:

```
<ComClass(ComClass1.ClassId, ComClass1.InterfaceId, ComClass1.EventsId)>  
Public Class ComClass1
```

8. COM classes must have a parameterless `Public Sub New()` constructor, or the class will not register correctly. Add a parameterless constructor to the class:

```
Public Sub New()  
    MyBase.New()  
End Sub
```

9. Add properties, methods, and events to the class, ending it with an `End Class` statement. Select **Build**

Solution from the **Build** menu. Visual Basic builds the assembly and registers the COM object with the operating system.

NOTE

The COM objects you generate with Visual Basic cannot be used by other Visual Basic applications because they are not true COM objects. Attempts to add references to such COM objects will raise an error. For details, see [COM Interoperability in .NET Framework Applications](#).

Troubleshooting Interoperability (Visual Basic)

3/5/2019 • 9 minutes to read • [Edit Online](#)

When you interoperate between COM and the managed code of the .NET Framework, you may encounter one or more of the following common issues.

Interop Marshaling

At times, you may have to use data types that are not part of the .NET Framework. Interop assemblies handle most of the work for COM objects, but you may have to control the data types that are used when managed objects are exposed to COM. For example, structures in class libraries must specify the `BStr` unmanaged type on strings sent to COM objects created by Visual Basic 6.0 and earlier versions. In such cases, you can use the [MarshalAsAttribute](#) attribute to cause managed types to be exposed as unmanaged types.

Exporting Fixed-Length Strings to Unmanaged Code

In Visual Basic 6.0 and earlier versions, strings are exported to COM objects as sequences of bytes without a null termination character. For compatibility with other languages, Visual Basic .NET includes a termination character when exporting strings. The best way to address this incompatibility is to export strings that lack the termination character as arrays of `Byte` or `Char`.

Exporting Inheritance Hierarchies

Managed class hierarchies flatten out when exposed as COM objects. For example, if you define a base class with a member, and then inherit the base class in a derived class that is exposed as a COM object, clients that use the derived class in the COM object will not be able to use the inherited members. Base class members can be accessed from COM objects only as instances of a base class, and then only if the base class is also created as a COM object.

Overloaded Methods

Although you can create overloaded methods with Visual Basic, they are not supported by COM. When a class that contains overloaded methods is exposed as a COM object, new method names are generated for the overloaded methods.

For example, consider a class that has two overloads of the `Synch` method. When the class is exposed as a COM object, the new generated method names could be `Synch` and `Synch_2`.

The renaming can cause two problems for consumers of the COM object.

1. Clients might not expect the generated method names.
2. The generated method names in the class exposed as a COM object can change when new overloads are added to the class or its base class. This can cause versioning problems.

To solve both problems, give each method a unique name, instead of using overloading, when you develop objects that will be exposed as COM objects.

Use of COM Objects Through Interop Assemblies

You use interop assemblies almost as if they are managed code replacements for the COM objects they represent.

However, because they are wrappers and not actual COM objects, there are some differences between using interop assemblies and standard assemblies. These areas of difference include the exposure of classes, and data types for parameters and return values.

Classes Exposed as Both Interfaces and Classes

Unlike classes in standard assemblies, COM classes are exposed in interop assemblies as both an interface and a class that represents the COM class. The interface's name is identical to that of the COM class. The name of the interop class is the same as that of the original COM class, but with the word "Class" appended. For example, suppose you have a project with a reference to an interop assembly for a COM object. If the COM class is named `MyComClass`, IntelliSense and the Object Browser show an interface named `MyComClass` and a class named `MyComClassClass`.

Creating Instances of a .NET Framework Class

Generally, you create an instance of a .NET Framework class using the `New` statement with a class name. Having a COM class represented by an interop assembly is the one case in which you can use the `New` statement with an interface. Unless you are using the COM class with an `Inherits` statement, you can use the interface just as you would a class. The following code demonstrates how to create a `Command` object in a project that has a reference to the Microsoft ActiveX Data Objects 2.8 Library COM object:

```
Dim cmd As New ADODB.Command
```

However, if you are using the COM class as the base for a derived class, you must use the interop class that represents the COM class, as in the following code:

```
Class DerivedCommand  
    Inherits ADODB.CommandClass  
End Class
```

NOTE

Interop assemblies implicitly implement interfaces that represent COM classes. You should not try to use the `Implements` statement to implement these interfaces or an error will result.

Data Types for Parameters and Return Values

Unlike members of standard assemblies, interop assembly members may have data types that differ from those used in the original object declaration. Although interop assemblies implicitly convert COM types to compatible common language runtime types, you should pay attention to the data types that are used by both sides to prevent runtime errors. For example, in COM objects created in Visual Basic 6.0 and earlier versions, values of type `Integer` assume the .NET Framework equivalent type, `Short`. It is recommended that you use the Object Browser to examine the characteristics of imported members before you use them.

Module level COM methods

Most COM objects are used by creating an instance of a COM class using the `New` keyword and then calling methods of the object. One exception to this rule involves COM objects that contain `AppObj` or `GlobalMultiUse` COM classes. Such classes resemble module level methods in Visual Basic .NET classes. Visual Basic 6.0 and earlier versions implicitly create instances of such objects for you the first time that you call one of their methods. For example, in Visual Basic 6.0 you can add a reference to the Microsoft DAO 3.6 Object Library and call the

`DBEngine` method without first creating an instance:

```
Dim db As DAO.Database
' Open the database.
Set db = DBEngine.OpenDatabase("C:\nwind.mdb")
' Use the database object.
```

Visual Basic .NET requires that you always create instances of COM objects before you can use their methods. To use these methods in Visual Basic, declare a variable of the desired class and use the new keyword to assign the object to the object variable. The `Shared` keyword can be used when you want to make sure that only one instance of the class is created.

```
' Class level variable.
Shared DBEngine As New DAO.DBEngine

Sub DAOOpenRecordset()
    Dim db As DAO.Database
    Dim rst As DAO.Recordset
    Dim fld As DAO.Field
    ' Open the database.
    db = DBEngine.OpenDatabase("C:\nwind.mdb")

    ' Open the Recordset.
    rst = db.OpenRecordset(
        "SELECT * FROM Customers WHERE Region = 'WA'", 
        DAO.RecordsetTypeEnum.dbOpenForwardOnly,
        DAO.RecordsetOptionEnum.dbReadOnly)
    ' Print the values for the fields in the debug window.
    For Each fld In rst.Fields
        Debug.WriteLine(fld.Value.ToString & ";")
    Next
    Debug.WriteLine("")
    ' Close the Recordset.
    rst.Close()
End Sub
```

Unhandled Errors in Event Handlers

One common interop problem involves errors in event handlers that handle events raised by COM objects. Such errors are ignored unless you specifically check for errors using `On Error` or `Try...Catch...Finally` statements. For example, the following example is from a Visual Basic .NET project that has a reference to the Microsoft ActiveX Data Objects 2.8 Library COM object.

```

' To use this example, add a reference to the
'   Microsoft ActiveX Data Objects 2.8 Library
' from the COM tab of the project references page.
Dim WithEvents cn As New ADODB.Connection
Sub ADODBConnect()
    cn.ConnectionString =
        "Provider=Microsoft.Jet.OLEDB.4.0;" &
        "Data Source=C:\NWIND.MDB"
    cn.Open()
    MsgBox(cn.ConnectionString)
End Sub

Private Sub Form1_Load(ByVal sender As System.Object,
    ByVal e As System.EventArgs) Handles MyBase.Load

    ADODBConnect()
End Sub

Private Sub cn_ConnectComplete(
    ByVal pError As ADODB.Error,
    ByRef adStatus As ADODB.EventStatusEnum,
    ByVal pConnection As ADODB.Connection) Handles cn.ConnectComplete

    ' This is the event handler for the cn_ConnectComplete event raised
    ' by the ADODB.Connection object when a database is opened.
    Dim x As Integer = 6
    Dim y As Integer = 0
    Try
        x = CInt(x / y) ' Attempt to divide by zero.
        ' This procedure would fail silently without exception handling.
    Catch ex As Exception
        MsgBox("There was an error: " & ex.Message)
    End Try
End Sub

```

This example raises an error as expected. However, if you try the same example without the `Try...Catch...Finally` block, the error is ignored as if you used the `On Error Resume Next` statement. Without error handling, the division by zero silently fails. Because such errors never raise unhandled exception errors, it is important that you use some form of exception handling in event handlers that handle events from COM objects.

Understanding COM interop errors

Without error handling, interop calls often generate errors that provide little information. Whenever possible, use structured error handling to provide more information about problems when they occur. This can be especially helpful when you debug applications. For example:

```

Try
    ' Place call to COM object here.
Catch ex As Exception
    ' Display information about the failed call.
End Try

```

You can find information such as the error description, HRESULT, and the source of COM errors by examining the contents of the exception object.

ActiveX Control Issues

Most ActiveX controls that work with Visual Basic 6.0 work with Visual Basic .NET without trouble. The main exceptions are container controls, or controls that visually contain other controls. Some examples of older controls that do not work correctly with Visual Studio are as follows:

- Microsoft Forms 2.0 Frame control
- Up-Down control, also known as the spin control
- Sheridan Tab Control

There are only a few workarounds for unsupported ActiveX control problems. You can migrate existing controls to Visual Studio if you own the original source code. Otherwise, you can check with software vendors for updated .NET-compatible versions of controls to replace unsupported ActiveX controls.

Passing ReadOnly Properties of Controls ByRef

Visual Basic .NET sometimes raises COM errors such as, "Error 0x800A017F CTL\_E\_SETNOTSUPPORTED", when you pass `ReadOnly` properties of some older ActiveX controls as `ByRef` parameters to other procedures. Similar procedure calls from Visual Basic 6.0 do not raise an error, and the parameters are treated as if you passed them by value. The Visual Basic .NET error message indicates that you are trying to change a property that does not have a property `Set` procedure.

If you have access to the procedure being called, you can prevent this error by using the `ByVal` keyword to declare parameters that accept `ReadOnly` properties. For example:

```
Sub ProcessParams(ByVal c As Object)
    'Use the arguments here.
End Sub
```

If you do not have access to the source code for the procedure being called, you can force the property to be passed by value by adding an extra set of brackets around the calling procedure. For example, in a project that has a reference to the Microsoft ActiveX Data Objects 2.8 Library COM object, you can use:

```
Sub PassByVal(ByVal pError As ADODB.Error)
    ' The extra set of parentheses around the arguments
    ' forces them to be passed by value.
    ProcessParams((pError.Description))
End Sub
```

Deploying Assemblies That Expose Interop

Deploying assemblies that expose COM interfaces presents some unique challenges. For example, a potential problem occurs when separate applications reference the same COM assembly. This situation is common when a new version of an assembly is installed and another application is still using the old version of the assembly. If you uninstall an assembly that shares a DLL, you can unintentionally make it unavailable to the other assemblies.

To avoid this problem, you should install shared assemblies to the Global Assembly Cache (GAC) and use a MergeModule for the component. If you cannot install the application in the GAC, it should be installed to CommonFilesFolder in a version-specific subdirectory.

Assemblies that are not shared should be located side by side in the directory with the calling application.

COM Interoperability in .NET Framework Applications (Visual Basic)

5/4/2018 • 2 minutes to read • [Edit Online](#)

When you want to use COM objects and .NET Framework objects in the same application, you need to address the differences in how the objects exist in memory. A .NET Framework object is located in managed memory—the memory controlled by the common language runtime—and may be moved by the runtime as needed. A COM object is located in unmanaged memory and is not expected to move to another memory location. Visual Studio and the .NET Framework provide tools to control the interaction of these managed and unmanaged components. For more information about managed code, see [Common Language Runtime](#).

In addition to using COM objects in .NET applications, you may also want to use Visual Basic to develop objects accessible from unmanaged code through COM.

The links on this page provide details on the interactions between COM and .NET Framework objects.

Walkthrough: Implementing Inheritance with COM Objects (Visual Basic)

2/28/2019 • 5 minutes to read • [Edit Online](#)

You can derive Visual Basic classes from `Public` classes in COM objects, even those created in earlier versions of Visual Basic. The properties and methods of classes inherited from COM objects can be overridden or overloaded just as properties and methods of any other base class can be overridden or overloaded. Inheritance from COM objects is useful when you have an existing class library that you do not want to recompile.

The following procedure shows how to use Visual Basic 6.0 to create a COM object that contains a class, and then use it as a base class.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To build the COM object that is used in this walkthrough

1. In Visual Basic 6.0, open a new ActiveX DLL project. A project named `Project1` is created. It has a class named `Class1`.
2. In the **Project Explorer**, right-click **Project1**, and then click **Project1 Properties**. The **Project Properties** dialog box is displayed.
3. On the **General** tab of the **Project Properties** dialog box, change the project name by typing `ComObject1` in the **Project Name** field.
4. In the **Project Explorer**, right-click `Class1`, and then click **Properties**. The **Properties** window for the class is displayed.
5. Change the `Name` property to `MathFunctions`.
6. In the **Project Explorer**, right-click `MathFunctions`, and then click **View Code**. The **Code Editor** is displayed.
7. Add a local variable to hold the property value:

```
' Local variable to hold property value  
Private mvarProp1 As Integer
```

8. Add Property `Let` and Property `Get` property procedures:

```
Public Property Let Prop1(ByVal vData As Integer)  
    'Used when assigning a value to the property.  
    mvarProp1 = vData  
End Property  
Public Property Get Prop1() As Integer  
    'Used when retrieving a property's value.  
    Prop1 = mvarProp1  
End Property
```

9. Add a function:

```
Function AddNumbers(  
    ByVal SomeNumber As Integer,  
    ByVal AnotherNumber As Integer) As Integer  
  
    AddNumbers = SomeNumber + AnotherNumber  
End Function
```

10. Create and register the COM object by clicking **Make ComObject1.dll** on the **File** menu.

NOTE

Although you can also expose a class created with Visual Basic as a COM object, it is not a true COM object and cannot be used in this walkthrough. For details, see [COM Interoperability in .NET Framework Applications](#).

Interop Assemblies

In the following procedure, you will create an interop assembly, which acts as a bridge between unmanaged code (such as a COM object) and the managed code Visual Studio uses. The interop assembly that Visual Basic creates handles many of the details of working with COM objects, such as *interop marshaling*, the process of packaging parameters and return values into equivalent data types as they move to and from COM objects. The reference in the Visual Basic application points to the interop assembly, not the actual COM object.

To use a COM object with Visual Basic 2005 and later versions

1. Open a new Visual Basic Windows Application project.

2. On the **Project** menu, click **Add Reference**.

The **Add Reference** dialog box is displayed.

3. On the **COM** tab, double-click **ComObject1** in the **Component Name** list and click **OK**.

4. On the **Project** menu, click **Add New Item**.

The **Add New Item** dialog box is displayed.

5. In the **Templates** pane, click **Class**.

The default file name, **Class1.vb**, appears in the **Name** field. Change this field to **MathClass.vb** and click **Add**. This creates a class named **MathClass**, and displays its code.

6. Add the following code to the top of **MathClass** to inherit from the COM class.

```
' The inherited class is called MathFunctions in the base class,  
' but the interop assembly appends the word Class to the name.  
Inherits ComObject1.MathFunctionsClass
```

7. Overload the public method of the base class by adding the following code to **MathClass**:

```
' This method overloads the method AddNumbers from the base class.  
Overloads Function AddNumbers(  
    ByVal SomeNumber As Integer,  
    ByVal AnotherNumber As Integer) As Integer  
  
    Return SomeNumber + AnotherNumber  
End Function
```

8. Extend the inherited class by adding the following code to `MathClass` :

```
' The following function extends the inherited class.  
Function SubtractNumbers(  
    ByVal SomeNumber As Integer,  
    ByVal AnotherNumber As Integer) As Integer  
  
    Return AnotherNumber - SomeNumber  
End Function
```

The new class inherits the properties of the base class in the COM object, overloads a method, and defines a new method to extend the class.

To test the inherited class

1. Add a button to your startup form, and then double-click it to view its code.

2. In the button's `Click` event handler procedure, add the following code to create an instance of `MathClass` and call the overloaded methods:

```
Dim Result1 As Short  
Dim Result2 As Integer  
Dim Result3 As Integer  
Dim MathObject As New MathClass  
Result1 = MathObject.AddNumbers(4S, 2S) ' Add two Shorts.  
Result2 = MathObject.AddNumbers(4, 2) 'Add two Integers.  
Result3 = MathObject.SubtractNumbers(2, 4) ' Subtract 2 from 4.  
MathObject.Prop1 = 6 ' Set an inherited property.  
  
MsgBox("Calling the AddNumbers method in the base class " &  
    "using Short type numbers 4 and 2 = " & Result1)  
MsgBox("Calling the overloaded AddNumbers method using " &  
    "Integer type numbers 4 and 2 = " & Result2)  
MsgBox("Calling the SubtractNumbers method " &  
    "subtracting 2 from 4 = " & Result3)  
MsgBox("The value of the inherited property is " &  
    MathObject.Prop1)
```

3. Run the project by pressing F5.

When you click the button on the form, the `AddNumbers` method is first called with `Short` data type numbers, and Visual Basic chooses the appropriate method from the base class. The second call to `AddNumbers` is directed to the overload method from `MathClass`. The third call calls the `SubtractNumbers` method, which extends the class. The property in the base class is set, and the value is displayed.

Next Steps

You may have noticed that the overloaded `AddNumbers` function appears to have the same data type as the method inherited from the base class of the COM object. This is because the arguments and parameters of the base class method are defined as 16-bit integers in Visual Basic 6.0, but they are exposed as 16-bit integers of type `Short` in later versions of Visual Basic. The new function accepts 32-bit integers, and overloads the base class function.

When working with COM objects, make sure that you verify the size and data types of parameters. For example, when you are using a COM object that accepts a Visual Basic 6.0 collection object as an argument, you cannot provide a collection from a later version of Visual Basic.

Properties and methods inherited from COM classes can be overridden, meaning that you can declare a local property or method that replaces a property or method inherited from a base COM class. The rules for overriding

inherited COM properties are similar to the rules for overriding other properties and methods with the following exceptions:

- If you override any property or method inherited from a COM class, you must override all the other inherited properties and methods.
- Properties that use `ByRef` parameters cannot be overridden.

Select the Visual Basic language version

1/19/2019 • 2 minutes to read • [Edit Online](#)

The Visual Basic compiler defaults to the latest major version of the language that has been released. You may choose to compile any project using a new point release of the language. Choosing a newer version of the language enables your project to make use of the latest language features. In other scenarios, you may need to validate that a project compiles cleanly when using an older version of the language.

This capability decouples the decision to install new versions of the SDK and tools in your development environment from the decision to incorporate new language features in a project. You can install the latest SDK and tools on your build machine. Each project can be configured to use a specific version of the language for its build.

There are three ways to set the language version:

- Manually edit your [.vbproj](#) file
- Set the language version [for multiple projects in a subdirectory](#)
- Configure the [-langversion](#) compiler option

Edit the vbproj file

You can set the language version in your [.vbproj](#) file. Add the following element:

```
<PropertyGroup>
  <LangVersion>latest</LangVersion>
</PropertyGroup>
```

The value `latest` uses the latest minor version of the Visual Basic language. Valid values are:

VALUE	MEANING
default	The compiler accepts all valid language syntax from the latest major version that it can support.
9	The compiler accepts only syntax that is included in Visual Basic 9.0 or lower.
10	The compiler accepts only syntax that is included in Visual Basic 10.0 or lower.
11	The compiler accepts only syntax that is included in Visual Basic 11.0 or lower.
12	The compiler accepts only syntax that is included in Visual Basic 12.0 or lower.
14	The compiler accepts only syntax that is included in Visual Basic 14.0 or lower.
15	The compiler accepts only syntax that is included in Visual Basic 15.0 or lower.

VALUE	MEANING
15.3	The compiler accepts only syntax that is included in Visual Basic 15.3 or lower.
15.5	The compiler accepts only syntax that is included in Visual Basic 15.5 or lower.
latest	The compiler accepts all valid language syntax that it can support.

The special strings `default` and `latest` resolve to the latest major and minor language versions installed on the build machine, respectively.

Configure multiple projects

You can create a **Directory.build.props** file that contains the `<LangVersion>` element to configure multiple directories. You typically do that in your solution directory. Add the following to a **Directory.build.props** file in your solution directory:

```
<Project>
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
</Project>
```

Now, builds in every subdirectory of the directory containing that file will use Visual Basic version 15.5 syntax. For more information, see the article on [Customize your build](#).

Set the langversion compiler option

You can use the `-langversion` command-line option. For more information, see the article on the [-langversion](#) compiler option. You can see a list of the valid values by typing `vbc -langversion:?`.

Typographic and Code Conventions (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Visual Basic documentation uses the following typographic and code conventions.

Typographic Conventions

EXAMPLE	DESCRIPTION
<code>Sub</code> , <code>If</code> , <code>ChDir</code> , <code>Print</code> , <code>True</code> , <code>Debug</code>	Language-specific keywords and runtime members have initial uppercase letters and are formatted as shown in this example.
SmallProject , ButtonCollection	Words and phrases you are instructed to type are formatted as shown in this example.
Module Statement	Links you can click to go to another Help page are formatted as shown in this example.
<i>object</i> , <i>variableName</i> , <code>argumentList</code>	Placeholders for information that you supply are formatted as shown in this example.
<code>[Shadows]</code> , <code>[expressionList]</code>	In syntax, optional items are enclosed in brackets.
{ <code>Public</code> <code>Friend</code> <code>Private</code> }	In syntax, when you must make a choice between two or more items, the items are enclosed in braces and separated by vertical bars. You must select one, and only one, of the items.
[<code>Protected</code> <code>Friend</code>]	In syntax, when you have the option of selecting between two or more items, the items are enclosed in square brackets and separated by vertical bars. You can select any combination of the items, or no item.
{[<code>ByVal</code> <code>ByRef</code>]}	In syntax, when you can select no more than one item, but you can also omit the items completely, the items are enclosed in square brackets surrounded by braces and separated by vertical bars.
<i>memberName1</i> , <i>memberName2</i> , <i>memberName3</i>	Multiple instances of the same placeholder are differentiated by subscripts, as shown in the example.
<i>memberName1</i> ... <i>memberNameN</i>	In syntax, an ellipsis (...) is used to indicate an indefinite number of items of the kind immediately in front of the ellipsis. In code, ellipses signify code omitted for the sake of clarity.
<code>ESC</code> , <code>ENTER</code>	Key names and key sequences on the keyboard appear in all uppercase letters.

EXAMPLE	DESCRIPTION
ALT+F1	When plus signs (+) appear between key names, you must hold down one key while pressing the other. For example, ALT+F1 means hold down the ALT key while pressing the F1 key.

Code Conventions

EXAMPLE	DESCRIPTION
<code>sampleString = "Hello, world!"</code>	Code samples appear in a fixed-pitch font and are formatted as shown in this example.
The previous statement sets the value of <code>sampleString</code> to "Hello, world!"	Code elements in explanatory text appear in a fixed-pitch font, as shown in this example.
<code>' This is a comment.</code> <code>REM This is also a comment.</code>	Code comments are introduced by an apostrophe ('') or the REM keyword.
<code>sampleVar = "This is an " _</code> <code>& "example" _</code> <code>& " of how to continue code."</code>	A space followed by an underscore (_) at the end of a line indicates that the statement continues on the following line.

Keywords (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

The following tables list all Visual Basic language keywords.

Reserved Keywords

The following keywords are *reserved*, which means that you cannot use them as names for programming elements such as variables or procedures. You can bypass this restriction by enclosing the name in brackets (`[]`). For more information, see "Escaped Names" in [Declared Element Names](#).

NOTE

We do not recommend that you use escaped names, because it can make your code hard to read, and it can lead to subtle errors that can be difficult to find.

#If	=	&	&=
*	*=	/	/=
\	\=	^	^=
+	+ =	-	- =
>> Operator	>> = Operator	<<	<< =

NOTE

`EndIf`, `GoSub`, `Variant`, and `Wend` are retained as reserved keywords, although they are no longer used in Visual Basic. The meaning of the `Let` keyword has changed. `Let` is now used in LINQ queries. For more information, see [Let Clause](#).

Unreserved Keywords

The following keywords are not reserved, which means you can use them as names for your programming elements. However, doing this is not recommended, because it can make your code hard to read and can lead to subtle errors that can be difficult to find.

The following table shows non-intrinsic math functions that can be derived from the intrinsic math functions of the `System.Math` object. You can access the intrinsic math functions by adding `Imports System.Math` to your file or project.

FUNCTION	DERIVED EQUIVALENTS
Secant (Sec(x))	$1 / \text{Cos}(x)$
Cosecant (Csc(x))	$1 / \text{Sin}(x)$
Cotangent (Ctan(x))	$1 / \text{Tan}(x)$
Inverse sine (Asin(x))	$\text{Atan}(x / \text{Sqrt}(-x * x + 1))$
Inverse cosine (Acos(x))	$\text{Atan}(-x / \text{Sqrt}(-x * x + 1)) + 2 * \text{Atan}(1)$
Inverse secant (Asec(x))	$2 * \text{Atan}(1) - \text{Atan}(\text{Sign}(x) / \text{Sqrt}(x * x - 1))$
Inverse cosecant (Acsc(x))	$\text{Atan}(\text{Sign}(x) / \text{Sqrt}(x * x - 1))$
Inverse cotangent (Acot(x))	$2 * \text{Atan}(1) - \text{Atan}(x)$
Hyperbolic sine (Sinh(x))	$(\text{Exp}(x) - \text{Exp}(-x)) / 2$
Hyperbolic cosine (Cosh(x))	$(\text{Exp}(x) + \text{Exp}(-x)) / 2$
Hyperbolic tangent (Tanh(x))	$(\text{Exp}(x) - \text{Exp}(-x)) / (\text{Exp}(x) + \text{Exp}(-x))$
Hyperbolic secant (Sech(x))	$2 / (\text{Exp}(x) + \text{Exp}(-x))$
Hyperbolic cosecant (Csch(x))	$2 / (\text{Exp}(x) - \text{Exp}(-x))$
Hyperbolic cotangent (Coth(x))	$(\text{Exp}(x) + \text{Exp}(-x)) / (\text{Exp}(x) - \text{Exp}(-x))$

Visual Basic provides several attributes that allow objects interoperate with unmanaged code, and one attribute that enables module members to be accessed without the module name. The following table lists the attributes used by Visual Basic.

ComClassAttribute	Instructs the compiler to add metadata that allows a class to be exposed as a COM object.
HideModuleNameAttribute	Allows the module members to be accessed using only the qualification needed for the module.
VBFixedArrayAttribute	Indicates that an array in a structure or non-local variable should be treated as a fixed-length array.
VBFixedStringAttribute	Indicates that a string should be treated as if it were fixed length.

Constants and Enumerations (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

Visual Basic supplies a number of predefined constants and enumerations for developers. Constants store values that remain constant throughout the execution of an application. Enumerations provide a convenient way to work with sets of related constants, and to associate constant values with names.

Constants

Conditional Compilation Constants

The following table lists the predefined constants available for conditional compilation.

CONSTANT	DESCRIPTION
CONFIG	A string that corresponds to the current setting of the Active Solution Configuration box in the Configuration Manager .
DEBUG	A <code>Boolean</code> value that can be set in the Project Properties dialog box. By default, the Debug configuration for a project defines <code>DEBUG</code> . When <code>DEBUG</code> is defined, <code>Debug</code> class methods generate output to the Output window. When it is not defined, <code>Debug</code> class methods are not compiled and no Debug output is generated.
TARGET	A string representing the output type for the project or the setting of the command-line <code>/target</code> option. The possible values of <code>TARGET</code> are: <ul style="list-style-type: none">- "winexe" for a Windows application.- "exe" for a console application.- "library" for a class library.- "module" for a module.- The <code>/target</code> option may be set in the Visual Studio integrated development environment. For more information, see /target (Visual Basic).
TRACE	A <code>Boolean</code> value that can be set in the Project Properties dialog box. By default, all configurations for a project define <code>TRACE</code> . When <code>TRACE</code> is defined, <code>Trace</code> class methods generate output to the Output window. When it is not defined, <code>Trace</code> class methods are not compiled and no <code>Trace</code> output is generated.
VBC_VER	A number representing the Visual Basic version, in <i>major.minor</i> format. The version number for Visual Basic 2005 is 8.0.

Print and Display Constants

When you call print and display functions, you can use the following constants in your code in place of the actual values.

CONSTANT	DESCRIPTION
<code>vbCrLf</code>	Carriage return/linefeed character combination.
<code>vbCr</code>	Carriage return character.
<code>vbLf</code>	Linefeed character.
<code>vbNewLine</code>	Newline character.
<code>vbNullChar</code>	Null character.
<code>vbNullString</code>	Not the same as a zero-length string (""); used for calling external procedures.
<code>vbObjectError</code>	Error number. User-defined error numbers should be greater than this value. For example: <code>Err.Raise(Number) = vbObjectError + 1000</code>
<code>vbTab</code>	Tab character.
<code>vbBack</code>	Backspace character.
<code>vbFormFeed</code>	Not used in Microsoft Windows.
<code>vbVerticalTab</code>	Not useful in Microsoft Windows.

Enumerations

The following table lists and describes the enumerations provided by Visual Basic.

ENUMERATION	DESCRIPTION
<code>AppWinStyle</code>	Indicates the window style to use for the invoked program when calling the <code>Shell</code> function.
<code>AudioPlayMode</code>	Indicates how to play sounds when calling audio methods.
<code>BuiltInRole</code>	Indicates the type of role to check when calling the <code>IsInRole</code> method.
<code>CallType</code>	Indicates the type of procedure being invoked when calling the <code>CallByName</code> function.
<code>CompareMethod</code>	Indicates how to compare strings when calling comparison functions.
<code>DateFormat</code>	Indicates how to display dates when calling the <code>FormatDateTime</code> function.
<code>DateInterval</code>	Indicates how to determine and format date intervals when calling date-related functions.

ENUMERATION	DESCRIPTION
DeleteDirectoryOption	Specifies what should be done when a directory that is to be deleted contains files or directories.
DueDate	Indicates when payments are due when calling financial methods.
FieldType	Indicates whether text fields are delimited or fixed-width.
FileAttribute	Indicates the file attributes to use when calling file-access functions.
FirstDayOfWeek	Indicates the first day of the week to use when calling date-related functions.
FirstWeekOfYear	Indicates the first week of the year to use when calling date-related functions.
MsgBoxResult	Indicates which button was pressed on a message box, returned by the MsgBox function.
MsgBoxStyle	Indicates which buttons to display when calling the MsgBox function.
OpenAccess	Indicates how to open a file when calling file-access functions.
OpenMode	Indicates how to open a file when calling file-access functions.
OpenShare	Indicates how to open a file when calling file-access functions.
RecycleOption	Specifies whether a file should be deleted permanently or placed in the Recycle Bin.
SearchOption	Specifies whether to search all or only top-level directories.
TriState	Indicates a Boolean value or whether the default should be used when calling number-formatting functions.
UICancelOption	Specifies what should be done if the user clicks Cancel during an operation.
UIOption	Specifies whether or not to show a progress dialog when copying, deleting, or moving files or directories.
VariantType	Indicates the type of a variant object, returned by the VarType function.
VbStrConv	Indicates which type of conversion to perform when calling the StrConv function.

Data Type Summary (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

The following table shows the Visual Basic data types, their supporting common language runtime types, their nominal storage allocation, and their value ranges.

VISUAL BASIC TYPE	COMMON LANGUAGE RUNTIME TYPE STRUCTURE	NOMINAL STORAGE ALLOCATION	VALUE RANGE
Boolean	Boolean	Depends on implementing platform	<code>True</code> or <code>False</code>
Byte	Byte	1 byte	0 through 255 (unsigned)
Char (single character)	Char	2 bytes	0 through 65535 (unsigned)
Date	DateTime	8 bytes	0:00:00 (midnight) on January 1, 0001 through 11:59:59 PM on December 31, 9999
Decimal	Decimal	16 bytes	0 through +/- 79,228,162,514,264,337,593,543,950,335 (+/- 7.9...E+28) <sup>†</sup> with no decimal point; 0 through +/- 7.9228162514264337593543950335 with 28 places to the right of the decimal; smallest nonzero number is +/- 0.00000000000000000000000000000001 (+/-1E-28) <sup>†</sup>
Double (double-precision floating-point)	Double	8 bytes	-1.79769313486231570E+308 through -4.94065645841246544E-324 <sup>†</sup> for negative values; 4.94065645841246544E-324 through 1.79769313486231570E+308 <sup>†</sup> for positive values
Integer	Int32	4 bytes	-2,147,483,648 through 2,147,483,647 (signed)

VISUAL BASIC TYPE	COMMON LANGUAGE RUNTIME TYPE STRUCTURE	NOMINAL STORAGE ALLOCATION	VALUE RANGE
Long (long integer)	Int64	8 bytes	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807 (9.2...E+18 <sup>†</sup>) (signed)
Object	Object (class)	4 bytes on 32-bit platform 8 bytes on 64-bit platform	Any type can be stored in a variable of type Object
SByte	SByte	1 byte	-128 through 127 (signed)
Short (short integer)	Int16	2 bytes	-32,768 through 32,767 (signed)
Single (single-precision floating-point)	Single	4 bytes	-3.4028235E+38 through -1.401298E-45 <sup>†</sup> for negative values; 1.401298E-45 through 3.4028235E+38 <sup>†</sup> for positive values
String (variable-length)	String (class)	Depends on implementing platform	0 to approximately 2 billion Unicode characters
UInteger	UInt32	4 bytes	0 through 4,294,967,295 (unsigned)
ULong	UInt64	8 bytes	0 through 18,446,744,073,709,551,615 (1.8...E+19 <sup>†</sup>) (unsigned)
User-Defined (structure)	(inherits from ValueType)	Depends on implementing platform	Each member of the structure has a range determined by its data type and independent of the ranges of the other members
UShort	UInt16	2 bytes	0 through 65,535 (unsigned)

<sup>†</sup> In *scientific notation*, "E" refers to a power of 10. So 3.56E+2 signifies 3.56×10^2 or 356, and 3.56E-2 signifies $3.56 / 10^2$ or 0.0356.

NOTE

For strings containing text, use the [StrConv](#) function to convert from one text format to another.

In addition to specifying a data type in a declaration statement, you can force the data type of some programming elements by using a type character. See [Type Characters](#).

Memory Consumption

When you declare an elementary data type, it is not safe to assume that its memory consumption is the same as its nominal storage allocation. This is due to the following considerations:

- **Storage Assignment.** The common language runtime can assign storage based on the current characteristics of the platform on which your application is executing. If memory is nearly full, it might pack your declared elements as closely together as possible. In other cases it might align their memory addresses to natural hardware boundaries to optimize performance.
- **Platform Width.** Storage assignment on a 64-bit platform is different from assignment on a 32-bit platform.

Composite Data Types

The same considerations apply to each member of a composite data type, such as a structure or an array. You cannot rely on simply adding together the nominal storage allocations of the type's members. Furthermore, there are other considerations, such as the following:

- **Overhead.** Some composite types have additional memory requirements. For example, an array uses extra memory for the array itself and also for each dimension. On a 32-bit platform, this overhead is currently 12 bytes plus 8 bytes for each dimension. On a 64-bit platform this requirement is doubled.
- **Storage Layout.** You cannot safely assume that the order of storage in memory is the same as your order of declaration. You cannot even make assumptions about byte alignment, such as a 2-byte or 4-byte boundary. If you are defining a class or structure and you need to control the storage layout of its members, you can apply the [StructLayoutAttribute](#) attribute to the class or structure.

Object Overhead

An `Object` referring to any elementary or composite data type uses 4 bytes in addition to the data contained in the data type.

Boolean Data Type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds values that can be only `True` or `False`. The keywords `True` and `False` correspond to the two states of `Boolean` variables.

Remarks

Use the [Boolean Data Type \(Visual Basic\)](#) to contain two-state values such as true/false, yes/no, or on/off.

The default value of `Boolean` is `False`.

`Boolean` values are not stored as numbers, and the stored values are not intended to be equivalent to numbers. You should never write code that relies on equivalent numeric values for `True` and `False`. Whenever possible, you should restrict usage of `Boolean` variables to the logical values for which they are designed.

Type Conversions

When Visual Basic converts numeric data type values to `Boolean`, 0 becomes `False` and all other values become `True`. When Visual Basic converts `Boolean` values to numeric types, `False` becomes 0 and `True` becomes -1.

When you convert between `Boolean` values and numeric data types, keep in mind that the .NET Framework conversion methods do not always produce the same results as the Visual Basic conversion keywords. This is because the Visual Basic conversion retains behavior compatible with previous versions. For more information, see "Boolean Type Does Not Convert to Numeric Type Accurately" in [Troubleshooting Data Types](#).

Programming Tips

- **Negative Numbers.** `Boolean` is not a numeric type and cannot represent a negative value. In any case, you should not use `Boolean` to hold numeric values.
- **Type Characters.** `Boolean` has no literal type character or identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.Boolean](#) structure.

Example

In the following example, `runningVB` is a `Boolean` variable, which stores a simple yes/no setting.

```
Dim runningVB As Boolean
' Check to see if program is running on Visual Basic engine.
If scriptEngine = "VB" Then
    runningVB = True
End If
```

Byte data type (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Holds unsigned 8-bit (1-byte) integers that range in value from 0 through 255.

Remarks

Use the `Byte` data type to contain binary data.

The default value of `Byte` is 0.

Literal assignments

You can declare and initialize a `Byte` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integral literal is outside the range of a `Byte` (that is, if it is less than `Byte.MinValue` or greater than `Byte.MaxValue`), a compilation error occurs.

In the following example, integers equal to 201 that are represented as decimal, hexadecimal, and binary literals are implicitly converted from `Integer` to `byte` values.

```
Dim byteValue1 As Byte = 201
Console.WriteLine(byteValue1)

Dim byteValue2 As Byte = &H00C9
Console.WriteLine(byteValue2)

Dim byteValue3 As Byte = &B1100_1001
Console.WriteLine(byteValue3)
' The example displays the following output:
'      201
'      201
'      201
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```
Dim byteValue3 As Byte = &B1100_1001
Console.WriteLine(byteValue3)
' The example displays the following output:
'      201
```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As Byte = &H_6A
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Programming tips

- **Negative Numbers.** Because `Byte` is an unsigned type, it cannot represent a negative number. If you use the unary minus (`-`) operator on an expression that evaluates to type `Byte`, Visual Basic converts the expression to `Short` first.
- **Format Conversions.** When Visual Basic reads or writes files, or when it calls DLLs, methods, and properties, it can automatically convert between data formats. Binary data stored in `Byte` variables and arrays is preserved during such format conversions. You should not use a `String` variable for binary data, because its contents can be corrupted during conversion between ANSI and Unicode formats.
- **Widening.** The `Byte` data type widens to `Short`, `UShort`, `Integer`, `UInteger`, `Long`, `ULong`, `Decimal`, `Single`, or `Double`. This means you can convert `Byte` to any of these types without encountering a `System.OverflowException` error.
- **Type Characters.** `Byte` has no literal type character or identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.Byte` structure.

Example

In the following example, `b` is a `Byte` variable. The statements demonstrate the range of the variable and the application of bit-shift operators to it.

```
' The valid range of a Byte variable is 0 through 255.
Dim b As Byte
b = 30
' The following statement causes an error because the value is too large.
'b = 256
' The following statement causes an error because the value is negative.
'b = -5
' The following statement sets b to 6.
b = CByte(5.7)

' The following statements apply bit-shift operators to b.
' The initial value of b is 6.
Console.WriteLine(b)
' Bit shift to the right divides the number in half. In this
' example, binary 110 becomes 11.
b >>= 1
' The following statement displays 3.
Console.WriteLine(b)
' Now shift back to the original position, and then one more bit
' to the left. Each shift to the left doubles the value. In this
' example, binary 11 becomes 1100.
b <<= 2
' The following statement displays 12.
Console.WriteLine(b)
```

Char Data Type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds unsigned 16-bit (2-byte) code points ranging in value from 0 through 65535. Each *code point*, or character code, represents a single Unicode character.

Remarks

Use the `Char` data type when you need to hold only a single character and do not need the overhead of `String`. In some cases you can use `Char()`, an array of `Char` elements, to hold multiple characters.

The default value of `Char` is the character with a code point of 0.

Unicode Characters

The first 128 code points (0–127) of Unicode correspond to the letters and symbols on a standard U.S. keyboard. These first 128 code points are the same as those the ASCII character set defines. The second 128 code points (128–255) represent special characters, such as Latin-based alphabet letters, accents, currency symbols, and fractions. Unicode uses the remaining code points (256–65535) for a wide variety of symbols, including worldwide textual characters, diacritics, and mathematical and technical symbols.

You can use methods like `IsDigit` and `IsPunctuation` on a `Char` variable to determine its Unicode classification.

Type Conversions

Visual Basic does not convert directly between `Char` and the numeric types. You can use the `Asc` or `AscW` function to convert a `Char` value to an `Integer` that represents its code point. You can use the `Chr` or `ChrW` function to convert an `Integer` value to a `Char` that has that code point.

If the type checking switch ([Option Strict Statement](#)) is on, you must append the literal type character to a single-character string literal to identify it as the `Char` data type. The following example illustrates this.

```
Option Strict On
Dim charVar As Char
' The following statement attempts to convert a String literal to Char.
' Because Option Strict is On, it generates a compiler error.
charVar = "Z"
' The following statement succeeds because it specifies a Char literal.
charVar = "Z"C
```

Programming Tips

- Negative Numbers.** `Char` is an unsigned type and cannot represent a negative value. In any case, you should not use `Char` to hold numeric values.
- Interop Considerations.** If you interface with components not written for the .NET Framework, for example Automation or COM objects, remember that character types have a different data width (8 bits) in other environments. If you pass an 8-bit argument to such a component, declare it as `Byte` instead of `Char` in your new Visual Basic code.
- Widening.** The `Char` data type widens to `String`. This means you can convert `Char` to `String` and will

not encounter a [System.OverflowException](#) error.

- **Type Characters.** Appending the literal type character `c` to a single-character string literal forces it to the `Char` data type. `char` has no identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.Char](#) structure.

Date Data Type (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

Holds IEEE 64-bit (8-byte) values that represent dates ranging from January 1 of the year 0001 through December 31 of the year 9999, and times from 12:00:00 AM (midnight) through 11:59:59.9999999 PM. Each increment represents 100 nanoseconds of elapsed time since the beginning of January 1 of the year 1 in the Gregorian calendar. The maximum value represents 100 nanoseconds before the beginning of January 1 of the year 10000.

Remarks

Use the `Date` data type to contain date values, time values, or date and time values.

The default value of `Date` is 0:00:00 (midnight) on January 1, 0001.

You can get the current date and time from the [DateAndTime](#) class.

Format Requirements

You must enclose a `Date` literal within number signs (# #). You must specify the date value in the format M/d/yyyy, for example `#5/31/1993#`, or yyyy-MM-dd, for example `#1993-5-31#`. You can use slashes when specifying the year first. This requirement is independent of your locale and your computer's date and time format settings.

The reason for this restriction is that the meaning of your code should never change depending on the locale in which your application is running. Suppose you hard-code a `Date` literal of `#3/4/1998#` and intend it to mean March 4, 1998. In a locale that uses mm/dd/yyyy, 3/4/1998 compiles as you intend. But suppose you deploy your application in many countries. In a locale that uses dd/mm/yyyy, your hard-coded literal would compile to April 3, 1998. In a locale that uses yyyy/mm/dd, the literal would be invalid (April 1998, 0003) and cause a compiler error.

Workarounds

To convert a `Date` literal to the format of your locale, or to a custom format, supply the literal to the [Format](#) function, specifying either a predefined or user-defined date format. The following example demonstrates this.

```
MsgBox("The formatted date is " & Format(#5/31/1993#, "dddd, d MMM yyyy"))
```

Alternatively, you can use one of the overloaded constructors of the [DateTime](#) structure to assemble a date and time value. The following example creates a value to represent May 31, 1993 at 12:14 in the afternoon.

```
Dim dateInMay As New System.DateTime(1993, 5, 31, 12, 14, 0)
```

Hour Format

You can specify the time value in either 12-hour or 24-hour format, for example `#1:15:30 PM#` or `#13:15:30#`. However, if you do not specify either the minutes or the seconds, you must specify AM or PM.

Date and Time Defaults

If you do not include a date in a date/time literal, Visual Basic sets the date part of the value to January 1, 0001. If you do not include a time in a date/time literal, Visual Basic sets the time part of the value to the start of the day, that is, midnight (0:00:00).

Type Conversions

If you convert a `Date` value to the `String` type, Visual Basic renders the date according to the short date format specified by the run-time locale, and it renders the time according to the time format (either 12-hour or 24-hour) specified by the run-time locale.

Programming Tips

- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, keep in mind that date/time types in other environments are not compatible with the Visual Basic `Date` type. If you are passing a date/time argument to such a component, declare it as `Double` instead of `Date` in your new Visual Basic code, and use the conversion methods `DateTime.FromOADate` and `DateTime.ToDateTime`.
- **Type Characters.** `Date` has no literal type character or identifier type character. However, the compiler treats literals enclosed within number signs (# #) as `Date`.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.DateTime` structure.

Example

A variable or constant of the `Date` data type holds both the date and the time. The following example illustrates this.

```
Dim someDateAndTime As Date = #8/13/2002 12:14 PM#
```

Decimal Data Type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds signed 128-bit (16-byte) values representing 96-bit (12-byte) integer numbers scaled by a variable power of 10. The scaling factor specifies the number of digits to the right of the decimal point; it ranges from 0 through 28. With a scale of 0 (no decimal places), the largest possible value is +/- 79,228,162,514,264,337,593,543,950,335 (+/-7.9228162514264337593543950335E+28). With 28 decimal places, the largest value is +/- 7.9228162514264337593543950335, and the smallest nonzero value is +/- 0.0000000000000000000000000000000001 (+/-1E-28).

Remarks

The `Decimal` data type provides the greatest number of significant digits for a number. It supports up to 29 significant digits and can represent values in excess of 7.9228×10^{28} . It is particularly suitable for calculations, such as financial, that require a large number of digits but cannot tolerate rounding errors.

The default value of `Decimal` is 0.

Programming Tips

- **Precision.** `Decimal` is not a floating-point data type. The `Decimal` structure holds a binary integer value, together with a sign bit and an integer scaling factor that specifies what portion of the value is a decimal fraction. Because of this, `Decimal` numbers have a more precise representation in memory than floating-point types (`Single` and `Double`).
- **Performance.** The `Decimal` data type is the slowest of all the numeric types. You should weigh the importance of precision against performance before choosing a data type.
- **Widening.** The `Decimal` data type widens to `Single` or `Double`. This means you can convert `Decimal` to either of these types without encountering a `System.OverflowException` error.
- **Trailing Zeros.** Visual Basic does not store trailing zeros in a `Decimal` literal. However, a `Decimal` variable preserves any trailing zeros acquired computationally. The following example illustrates this.

```
Dim d1, d2, d3, d4 As Decimal
d1 = 2.375D
d2 = 1.625D
d3 = d1 + d2
d4 = 4.000D
MsgBox("d1 = " & CStr(d1) & ", d2 = " & CStr(d2) &
      ", d3 = " & CStr(d3) & ", d4 = " & CStr(d4))
```

The output of `MsgBox` in the preceding example is as follows:

d1 = 2.375, d2 = 1.625, d3 = 4.000, d4 = 4

- **Type Characters.** Appending the literal type character `D` to a literal forces it to the `Decimal` data type. Appending the identifier type character `@` to any identifier forces it to `Decimal`.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.Decimal` structure.

Range

You might need to use the `D` type character to assign a large value to a `Decimal` variable or constant. This requirement is because the compiler interprets a literal as `Long` unless a literal type character follows the literal, as the following example shows.

```
Dim bigDec1 As Decimal = 9223372036854775807      ' No overflow.  
Dim bigDec2 As Decimal = 9223372036854775808      ' Overflow.  
Dim bigDec3 As Decimal = 9223372036854775808D    ' No overflow.
```

The declaration for `bigDec1` doesn't produce an overflow because the value that's assigned to it falls within the range for `Long`. The `Long` value can be assigned to the `Decimal` variable.

The declaration for `bigDec2` generates an overflow error because the value that's assigned to it is too large for `Long`. Because the numeric literal can't first be interpreted as a `Long`, it can't be assigned to the `Decimal` variable.

For `bigDec3`, the literal type character `D` solves the problem by forcing the compiler to interpret the literal as a `Decimal` instead of as a `Long`.

Double Data Type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds signed IEEE 64-bit (8-byte) double-precision floating-point numbers that range in value from -1.79769313486231570E+308 through -4.94065645841246544E-324 for negative values and from 4.94065645841246544E-324 through 1.79769313486231570E+308 for positive values. Double-precision numbers store an approximation of a real number.

Remarks

The `Double` data type provides the largest and smallest possible magnitudes for a number.

The default value of `Double` is 0.

Programming Tips

- **Precision.** When you work with floating-point numbers, remember that they do not always have a precise representation in memory. This could lead to unexpected results from certain operations, such as value comparison and the `Mod` operator. For more information, see [Troubleshooting Data Types](#).
- **Trailing Zeros.** The floating-point data types do not have any internal representation of trailing zero characters. For example, they do not distinguish between 4.2000 and 4.2. Consequently, trailing zero characters do not appear when you display or print floating-point values.
- **Type Characters.** Appending the literal type character `R` to a literal forces it to the `Double` data type. For example, if an integer value is followed by `R`, the value is changed to a `Double`.

```
' Visual Basic expands the 4 in the statement Dim dub As Double = 4.0:  
Dim dub As Double = 4.0R
```

Appending the identifier type character `#` to any identifier forces it to `Double`. In the following example, the variable `num#` is typed as a `Double`:

```
Dim num# = 3
```

- **Framework Type.** The corresponding type in the .NET Framework is the [System.Double](#) structure.

Integer data type (Visual Basic)

2/20/2019 • 3 minutes to read • [Edit Online](#)

Holds signed 32-bit (4-byte) integers that range in value from -2,147,483,648 through 2,147,483,647.

Remarks

The `Integer` data type provides optimal performance on a 32-bit processor. The other integral types are slower to load and store from and to memory.

The default value of `Integer` is 0.

Literal assignments

You can declare and initialize an `Integer` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integer literal is outside the range of `Integer` (that is, if it is less than `Int32.MinValue` or greater than `Int32.MaxValue`), a compilation error occurs.

In the following example, integers equal to 90,946 that are represented as decimal, hexadecimal, and binary literals are assigned to `Integer` values.

```
Dim intValue1 As Integer = 90946
Console.WriteLine(intValue1)
Dim intValue2 As Integer = &H16342
Console.WriteLine(intValue2)

Dim intValue3 As Integer = &B0001_0110_0011_0100_0010
Console.WriteLine(intValue3)
' The example displays the following output:
'      90946
'      90946
'      90946
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```

Dim intValue1 As Integer = 90_946
Console.WriteLine(intValue1)

Dim intValue2 As Integer = &H0001_6342
Console.WriteLine(intValue2)

Dim intValue3 As Integer = &B0001_0110_0011_0100_0010
Console.WriteLine(intValue3)
' The example displays the following output:
'      90946
'      90946
'      90946

```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As Integer = &H_C305_F860
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```

<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>

```

For more information see [setting the Visual Basic language version](#).

Numeric literals can also include the `I` type character to denote the `Integer` data type, as the following example shows.

```
Dim number = &H_035826I
```

Programming tips

- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, such as Automation or COM objects, remember that `Integer` has a different data width (16 bits) in other environments. If you are passing a 16-bit argument to such a component, declare it as `Short` instead of `Integer` in your new Visual Basic code.
- **Widening.** The `Integer` data type widens to `Long`, `Decimal`, `Single`, or `Double`. This means you can convert `Integer` to any one of these types without encountering a [System.OverflowException](#) error.
- **Type Characters.** Appending the literal type character `I` to a literal forces it to the `Integer` data type. Appending the identifier type character `%` to any identifier forces it to `Integer`.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.Int32](#) structure.

Range

If you try to set a variable of an integral type to a number outside the range for that type, an error occurs. If you try to set it to a fraction, the number is rounded up or down to the nearest integer value. If the number is equally close to two integer values, the value is rounded to the nearest even integer. This behavior minimizes rounding errors that result from consistently rounding a midpoint value in a single direction. The following code shows examples of rounding.

```
' The valid range of an Integer variable is -2147483648 through +2147483647.  
Dim k As Integer  
' The following statement causes an error because the value is too large.  
k = 2147483648  
' The following statement sets k to 6.  
k = 5.9  
' The following statement sets k to 4  
k = 4.5  
' The following statement sets k to 6  
' Note, Visual Basic uses banker's rounding (toward nearest even number)  
k = 5.5
```

Long data type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds signed 64-bit (8-byte) integers ranging in value from -9,223,372,036,854,775,808 through 9,223,372,036,854,775,807 (9.2...E+18).

Remarks

Use the `Long` data type to contain integer numbers that are too large to fit in the `Integer` data type.

The default value of `Long` is 0.

Literal assignments

You can declare and initialize a `Long` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integer literal is outside the range of `Long` (that is, if it is less than `Int64.MinValue` or greater than `Int64.MaxValue`, a compilation error occurs.

In the following example, integers equal to 4,294,967,296 that are represented as decimal, hexadecimal, and binary literals are assigned to `Long` values.

```
Dim longValue1 As Long = 4294967296
Console.WriteLine(longValue1)

Dim longValue2 As Long = &H100000000
Console.WriteLine(longValue2)

Dim longValue3 As Long = &B1_0000_0000_0000_0000_0000_0000_0000
Console.WriteLine(longValue3)
' The example displays the following output:
'      4294967296
'      4294967296
'      4294967296
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```

Dim longValue1 As Long = 4_294_967_296

Console.WriteLine(longValue2)

Dim longValue3 As Long = &B1_0000_0000_0000_0000_0000_0000_0000
Console.WriteLine(longValue3)
' The example displays the following output:
'      4294967296
'      4294967296
'      4294967296

```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As Long = &H_0FAC_0326_1489_D68C
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Numeric literals can also include the `L` type character to denote the `Long` data type, as the following example shows.

```
Dim number = &H_0FAC_0326_1489_D68CL
```

Programming tips

- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, remember that `Long` has a different data width (32 bits) in other environments. If you are passing a 32-bit argument to such a component, declare it as `Integer` instead of `Long` in your new Visual Basic code.
- **Widening.** The `Long` data type widens to `Decimal`, `Single`, or `Double`. This means you can convert `Long` to any one of these types without encountering a `System.OverflowException` error.
- **Type Characters.** Appending the literal type character `L` to a literal forces it to the `Long` data type. Appending the identifier type character `&` to any identifier forces it to `Long`.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.Int64` structure.

Object Data Type

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds addresses that refer to objects. You can assign any reference type (string, array, class, or interface) to an `Object` variable. An `Object` variable can also refer to data of any value type (numeric, `Boolean`, `Char`, `Date`, structure, or enumeration).

Remarks

The `Object` data type can point to data of any data type, including any object instance your application recognizes. Use `Object` when you do not know at compile time what data type the variable might point to.

The default value of `Object` is `Nothing` (a null reference).

Data Types

You can assign a variable, constant, or expression of any data type to an `Object` variable. To determine the data type an `Object` variable currently refers to, you can use the `GetTypeCode` method of the `System.Type` class. The following example illustrates this.

```
Dim myObject As Object
' Suppose myObject has now had something assigned to it.
Dim datTyp As Integer
datTyp = Type.GetTypeCode(myObject.GetType())
```

The `Object` data type is a reference type. However, Visual Basic treats an `Object` variable as a value type when it refers to data of a value type.

Storage

Whatever data type it refers to, an `Object` variable does not contain the data value itself, but rather a pointer to the value. It always uses four bytes in computer memory, but this does not include the storage for the data representing the value of the variable. Because of the code that uses the pointer to locate the data, `Object` variables holding value types are slightly slower to access than explicitly typed variables.

Programming Tips

- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, keep in mind that pointer types in other environments are not compatible with the Visual Basic `Object` type.
- **Performance.** A variable you declare with the `Object` type is flexible enough to contain a reference to any object. However, when you invoke a method or property on such a variable, you always incur *late binding* (at run time). To force *early binding* (at compile time) and better performance, declare the variable with a specific class name, or cast it to the specific data type.

When you declare an object variable, try to use a specific class type, for example `OperatingSystem`, instead of the generalized `Object` type. You should also use the most specific class available, such as `TextBox` instead of `Control`, so that you can access its properties and methods. You can usually use the **Classes** list in the **Object Browser** to find available class names.

- **Widening.** All data types and all reference types widen to the `Object` data type. This means you can convert any type to `Object` without encountering a `System.OverflowException` error.

However, if you convert between value types and `Object`, Visual Basic performs operations called *boxing* and *unboxing*, which make execution slower.

- **Type Characters.** `Object` has no literal type character or identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.Object` class.

Example

The following example illustrates an `Object` variable pointing to an object instance.

```
Dim objDb As Object
Dim myCollection As New Collection()
    ' Suppose myCollection has now been populated.
objDb = myCollection.Item(1)
```

SByte data type (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

Holds signed 8-bit (1-byte) integers that range in value from -128 through 127.

Remarks

Use the `SByte` data type to contain integer values that do not require the full data width of `Integer` or even the half data width of `Short`. In some cases, the common language runtime might be able to pack your `SByte` variables closely together and save memory consumption.

The default value of `SByte` is 0.

Literal assignments

You can declare and initialize an `SByte` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal.

In the following example, integers equal to -102 that are represented as decimal, hexadecimal, and binary literals are assigned to `SByte` values. This example requires that you compile with the `/removeintchecks` compiler switch.

```
Dim sbyteValue1 As SByte = -102
Console.WriteLine(sbyteValue1)

Dim sbyteValue4 As SByte = &H9A
Console.WriteLine(sbyteValue4)

Dim sbyteValue5 As SByte = &B1001_1010
Console.WriteLine(sbyteValue5)
' The example displays the following output:
'      -102
'      -102
'      -102
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```
Dim sbyteValue3 As SByte = &B1001_1010
Console.WriteLine(sbyteValue3)
' The example displays the following output:
'      -102
```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As SByte = &H_F9
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>

</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

If the integer literal is outside the range of `sbyte` (that is, if it is less than `SByte.MinValue` or greater than `SByte.MaxValue`), a compilation error occurs. When an integer literal has no suffix, an `Integer` is inferred. If the integer literal is outside the range of the `Integer` type, a `Long` is inferred. This means that, in the previous examples, the numeric literals `0x9A` and `0b10011010` are interpreted as 32-bit signed integers with a value of 156, which exceeds `SByte.MaxValue`. To successfully compile code like this that assigns a non-decimal integer to an `sbyte`, you can do either of the following:

- Disable integer bounds checks by compiling with the `/removeintchecks` compiler switch.
- Use a [type character](#) to explicitly define the literal value that you want to assign to the `sbyte`. The following example assigns a negative literal `Short` value to an `sbyte`. Note that, for negative numbers, the high-order bit of the high-order word of the numeric literal must be set. In the case of our example, this is bit 15 of the literal `Short` value.

```
Dim sByteValue1 As SByte = &HFF_9As
Dim sByteValue2 As SByte = &B1111_1111_1001_1010s
Console.WriteLine(sByteValue1)
Console.WriteLine(sByteValue2)
```

Programming tips

- **CLS Compliance.** The `sbyte` data type is not part of the [Common Language Specification \(CLS\)](#), so CLS-compliant code cannot consume a component that uses it.
- **Widening.** The `sbyte` data type widens to `Short`, `Integer`, `Long`, `Decimal`, `Single`, and `Double`. This means you can convert `sbyte` to any of these types without encountering a `System.OverflowException` error.
- **Type Characters.** `sbyte` has no literal type character or identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.SByte` structure.

Short data type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds signed 16-bit (2-byte) integers that range in value from -32,768 through 32,767.

Remarks

Use the `Short` data type to contain integer values that do not require the full data width of `Integer`. In some cases, the common language runtime can pack your `short` variables closely together and save memory consumption.

The default value of `Short` is 0.

Literal assignments

You can declare and initialize a `Short` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integer literal is outside the range of `Short` (that is, if it is less than `Int16.MinValue` or greater than `Int16.MaxValue`), a compilation error occurs.

In the following example, integers equal to 1,034 that are represented as decimal, hexadecimal, and binary literals are implicitly converted from `Integer` to `Short` values.

```
Dim shortValue1 As Short = 1034
Console.WriteLine(shortValue1)

Dim shortValue2 As Short = &H040A
Console.WriteLine(shortValue2)

Dim shortValue3 As Short = &B0100_00001010
Console.WriteLine(shortValue3)
' The example displays the following output:
'      1034
'      1034
'      1034
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```
Dim shortValue1 As Short = 1_034
Console.WriteLine(shortValue1)

Dim shortValue3 As Short = &B00000100_00001010
Console.WriteLine(shortValue3)
' The example displays the following output:
'      1034
'      1034
```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As Short = &H_3264
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Numeric literals can also include the `s` type character to denote the `Short` data type, as the following example shows.

```
Dim number = &H_3264S
```

Programming tips

- **Widening.** The `Short` data type widens to `Integer`, `Long`, `Decimal`, `Single`, or `Double`. This means you can convert `Short` to any one of these types without encountering a [System.OverflowException](#) error.
- **Type Characters.** Appending the literal type character `s` to a literal forces it to the `Short` data type. `Short` has no identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.Int16](#) structure.

Single Data Type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds signed IEEE 32-bit (4-byte) single-precision floating-point numbers ranging in value from -3.4028235E+38 through -1.401298E-45 for negative values and from 1.401298E-45 through 3.4028235E+38 for positive values. Single-precision numbers store an approximation of a real number.

Remarks

Use the `Single` data type to contain floating-point values that do not require the full data width of `Double`. In some cases the common language runtime might be able to pack your `Single` variables closely together and save memory consumption.

The default value of `Single` is 0.

Programming Tips

- **Precision.** When you work with floating-point numbers, keep in mind that they do not always have a precise representation in memory. This could lead to unexpected results from certain operations, such as value comparison and the `Mod` operator. For more information, see [Troubleshooting Data Types](#).
- **Widening.** The `Single` data type widens to `Double`. This means you can convert `Single` to `Double` without encountering a [System.OverflowException](#) error.
- **Trailing Zeros.** The floating-point data types do not have any internal representation of trailing 0 characters. For example, they do not distinguish between 4.2000 and 4.2. Consequently, trailing 0 characters do not appear when you display or print floating-point values.
- **Type Characters.** Appending the literal type character `F` to a literal forces it to the `Single` data type. Appending the identifier type character `!` to any identifier forces it to `Single`.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.Single](#) structure.

String Data Type (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

Holds sequences of unsigned 16-bit (2-byte) code points that range in value from 0 through 65535. Each *code point*, or character code, represents a single Unicode character. A string can contain from 0 to approximately two billion (2^{31}) Unicode characters.

Remarks

Use the `String` data type to hold multiple characters without the array management overhead of `Char()`, an array of `Char` elements.

The default value of `String` is `Nothing` (a null reference). Note that this is not the same as the empty string (value `""`).

Unicode Characters

The first 128 code points (0–127) of Unicode correspond to the letters and symbols on a standard U.S. keyboard. These first 128 code points are the same as those the ASCII character set defines. The second 128 code points (128–255) represent special characters, such as Latin-based alphabet letters, accents, currency symbols, and fractions. Unicode uses the remaining code points (256–65535) for a wide variety of symbols. This includes worldwide textual characters, diacritics, and mathematical and technical symbols.

You can use methods such as `IsDigit` and `IsPunctuation` on an individual character in a `String` variable to determine its Unicode classification.

Format Requirements

You must enclose a `String` literal within quotation marks (`" "`). If you must include a quotation mark as one of the characters in the string, you use two contiguous quotation marks (`""`). The following example illustrates this.

```
Dim j As String = "Joe said ""Hello"" to me."
Dim h As String = "Hello"
' The following messages all display the same thing:
' "Joe said "Hello" to me."
MsgBox(j)
MsgBox("Joe said " & " " & h & " " & " to me.")
MsgBox("Joe said "" & h & "" to me.")
```

Note that the contiguous quotation marks that represent a quotation mark in the string are independent of the quotation marks that begin and end the `String` literal.

String Manipulations

Once you assign a string to a `String` variable, that string is *immutable*, which means you cannot change its length or contents. When you alter a string in any way, Visual Basic creates a new string and abandons the previous one. The `String` variable then points to the new string.

You can manipulate the contents of a `String` variable by using a variety of string functions. The following example illustrates the `Left` function

```
Dim S As String = "Database"
' The following statement sets S to a new string containing "Data".
S = Microsoft.VisualBasic.Left(S, 4)
```

A string created by another component might be padded with leading or trailing spaces. If you receive such a string, you can use the [Trim](#), [LTrim](#), and [RTrim](#) functions to remove these spaces.

For more information about string manipulations, see [Strings](#).

Programming Tips

- **Negative Numbers.** Remember that the characters held by `String` are unsigned and cannot represent negative values. In any case, you should not use `String` to hold numeric values.
- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, remember that string characters have a different data width (8 bits) in other environments. If you are passing a string argument of 8-bit characters to such a component, declare it as `Byte()`, an array of `Byte` elements, instead of `string` in your new Visual Basic code.
- **Type Characters.** Appending the identifier type character `$` to any identifier forces it to the `String` data type. `String` has no literal type character. However, the compiler treats literals enclosed in quotation marks (" ") as `String`.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.String](#) class.

UInteger data type

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds unsigned 32-bit (4-byte) integers ranging in value from 0 through 4,294,967,295.

Remarks

The `UInteger` data type provides the largest unsigned value in the most efficient data width.

The default value of `UInteger` is 0.

Literal assignments

You can declare and initialize a `UInteger` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integer literal is outside the range of `UInteger` (that is, if it is less than `UInt32.MinValue` or greater than `UInt32.MaxValue`), a compilation error occurs.

In the following example, integers equal to 3,000,000,000 that are represented as decimal, hexadecimal, and binary literals are assigned to `UInteger` values.

```
Dim uintValue1 As UInteger = 3000000000ui
Console.WriteLine(uintValue1)

Dim uintValue2 As UInteger = &HB2D05E00ui
Console.WriteLine(uintValue2)

Dim uintValue3 As UInteger = &B1011_0010_1101_0000_0101_1110_0000_0000ui
Console.WriteLine(uintValue3)
' The example displays the following output:
'      3000000000
'      3000000000
'      3000000000
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```
Dim uintValue1 As UInteger = 3_000_000_000ui
Console.WriteLine(uintValue1)

Dim uintValue2 As UInteger = &HB2D0_5E00ui
Console.WriteLine(uintValue2)

Dim uintValue3 As UInteger = &B1011_0010_1101_0000_0101_1110_0000_0000ui
Console.WriteLine(uintValue3)
' The example displays the following output:
'      3000000000
'      3000000000
'      3000000000
```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As UInteger = &H_0F8C_0326
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Numeric literals can also include the `UI` or `ui` type character to denote the `UInteger` data type, as the following example shows.

```
Dim number = &H_0FAC_14D7ui
```

Programming tips

The `UInteger` and `Integer` data types provide optimal performance on a 32-bit processor, because the smaller integer types (`UShort`, `Short`, `Byte`, and `SByte`), even though they use fewer bits, take more time to load, store, and fetch.

- **Negative Numbers.** Because `UInteger` is an unsigned type, it cannot represent a negative number. If you use the unary minus (`-`) operator on an expression that evaluates to type `UInteger`, Visual Basic converts the expression to `Long` first.
- **CLS Compliance.** The `UInteger` data type is not part of the [Common Language Specification](#) (CLS), so CLS-compliant code cannot consume a component that uses it.
- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, keep in mind that types such as `uint` can have a different data width (16 bits) in other environments. If you are passing a 16-bit argument to such a component, declare it as `UShort` instead of `UInteger` in your managed Visual Basic code.
- **Widening.** The `UInteger` data type widens to `Long`, `ULong`, `Decimal`, `Single`, and `Double`. This means you can convert `UInteger` to any of these types without encountering a `System.OverflowException` error.
- **Type Characters.** Appending the literal type characters `UI` to a literal forces it to the `UInteger` data type. `UInteger` has no identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the `System.UInt32` structure.

ULong data type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds unsigned 64-bit (8-byte) integers ranging in value from 0 through 18,446,744,073,709,551,615 (more than 1.84 times 10<sup>19</sup>).

Remarks

Use the `ULong` data type to contain binary data too large for `UInteger`, or the largest possible unsigned integer values.

The default value of `ULong` is 0.

Literal assignments

You can declare and initialize a `ULong` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integer literal is outside the range of `ULong` (that is, if it is less than `UInt64.MinValue` or greater than `UInt64.MaxValue`), a compilation error occurs.

In the following example, integers equal to 7,934,076,125 that are represented as decimal, hexadecimal, and binary literals are assigned to `ULong` values.

```
Dim ulongValue1 As ULong = 7934076125
Console.WriteLine(ulongValue1)

Dim ulongValue2 As ULong = &H0001D8e864DD
Console.WriteLine(ulongValue2)

Dim ulongValue3 As ULong = &B0001_1101_1000_1110_1000_0110_0100_1101_1101
Console.WriteLine(ulongValue3)
' The example displays the following output:
'      7934076125
'      7934076125
'      7934076125
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```

Dim longValue1 As Long = 4_294_967_296
Console.WriteLine(longValue1)

Dim longValue2 As Long = &H1_0000_0000
Console.WriteLine(longValue2)

Dim longValue3 As Long = &B1_0000_0000_0000_0000_0000_0000_0000
Console.WriteLine(longValue3)
' The example displays the following output:
'      4294967296
'      4294967296
'      4294967296

```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As ULong = &H_F9AC_0326_1489_D68C
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Numeric literals can also include the `UL` or `ul` type character to denote the `ULong` data type, as the following example shows.

```
Dim number = &H_00_00_0A_96_2F_AC_14_D7ul
```

Programming tips

- Negative Numbers.** Because `ULong` is an unsigned type, it cannot represent a negative number. If you use the unary minus (`-`) operator on an expression that evaluates to type `ULong`, Visual Basic converts the expression to `Decimal` first.
- CLS Compliance.** The `ULong` data type is not part of the [Common Language Specification \(CLS\)](#), so CLS-compliant code cannot consume a component that uses it.
- Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, keep in mind that types such as `ulong` can have a different data width (32 bits) in other environments. If you are passing a 32-bit argument to such a component, declare it as `UInteger` instead of `ULong` in your managed Visual Basic code.

Furthermore, Automation does not support 64-bit integers on Windows 95, Windows 98, Windows ME, or Windows 2000. You cannot pass a Visual Basic `ULong` argument to an Automation component on these platforms.

- Widening.** The `ULong` data type widens to `Decimal`, `Single`, and `Double`. This means you can convert `ULong` to any of these types without encountering a [System.OverflowException](#) error.
- Type Characters.** Appending the literal type characters `UL` to a literal forces it to the `ULong` data type. `ULong` has no identifier type character.

- **Framework Type.** The corresponding type in the .NET Framework is the [System.UInt64](#) structure.

User-Defined Data Type

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds data in a format you define. The `Structure` statement defines the format.

Previous versions of Visual Basic support the user-defined type (UDT). The current version expands the UDT to a *structure*. A structure is a concatenation of one or more *members* of various data types. Visual Basic treats a structure as a single unit, although you can also access its members individually.

Remarks

Define and use a structure data type when you need to combine various data types into a single unit, or when none of the elementary data types serve your needs.

The default value of a structure data type consists of the combination of the default values of each of its members.

Declaration Format

A structure declaration starts with the [Structure Statement](#) and ends with the [End Structure](#) statement. The `Structure` statement supplies the name of the structure, which is also the identifier of the data type the structure is defining. Other parts of the code can use this identifier to declare variables, parameters, and function return values to be of this structure's data type.

The declarations between the `Structure` and `End Structure` statements define the members of the structure.

Member Access Levels

You must declare every member using a [Dim Statement](#) or a statement that specifies access level, such as [Public](#), [Friend](#), or [Private](#). If you use a `Dim` statement, the access level defaults to public.

Programming Tips

- **Memory Consumption.** As with all composite data types, you cannot safely calculate the total memory consumption of a structure by adding together the nominal storage allocations of its members. Furthermore, you cannot safely assume that the order of storage in memory is the same as your order of declaration. If you need to control the storage layout of a structure, you can apply the [StructLayoutAttribute](#) attribute to the `Structure` statement.
- **Interop Considerations.** If you are interfacing with components not written for the .NET Framework, for example Automation or COM objects, keep in mind that user-defined types in other environments are not compatible with Visual Basic structure types.
- **Widening.** There is no automatic conversion to or from any structure data type. You can define conversion operators on your structure using the [Operator Statement](#), and you can declare each conversion operator to be `Widening` or `Narrowing`.
- **Type Characters.** Structure data types have no literal type character or identifier type character.
- **Framework Type.** There is no corresponding type in the .NET Framework. All structures inherit from the .NET Framework class [System.ValueType](#), but no individual structure corresponds to [System.ValueType](#).

Example

The following paradigm shows the outline of the declaration of a structure.

```
[Public | Protected | Friend | Protected Friend | Private] Structure structname
    {Dim | Public | Friend | Private} member1 As datatype1
    ' ...
    {Dim | Public | Friend | Private} memberN As datatypeN
End Structure
```

UShort data type (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Holds unsigned 16-bit (2-byte) integers ranging in value from 0 through 65,535.

Remarks

Use the `ushort` data type to contain binary data too large for `Byte`.

The default value of `UShort` is 0.

Literal assignments

You can declare and initialize a `ushort` variable by assigning it a decimal literal, a hexadecimal literal, an octal literal, or (starting with Visual Basic 2017) a binary literal. If the integer literal is outside the range of `UShort` (that is, if it is less than `UInt16.MinValue` or greater than `UInt16.MaxValue`), a compilation error occurs.

In the following example, integers equal to 65,034 that are represented as decimal, hexadecimal, and binary literals are assigned to `ushort` values.

```
Dim ushortValue1 As UShort = 65034
Console.WriteLine(ushortValue1)

Dim ushortValue2 As UShort = &HFE0A
Console.WriteLine(ushortValue2)

Dim ushortValue3 As UShort = &B1111_1110_0000_1010
Console.WriteLine(ushortValue3)
' The example displays the following output:
'       65034
'       65034
'       65034
```

NOTE

You use the prefix `&h` or `&H` to denote a hexadecimal literal, the prefix `&b` or `&B` to denote a binary literal, and the prefix `&o` or `&O` to denote an octal literal. Decimal literals have no prefix.

Starting with Visual Basic 2017, you can also use the underscore character, `_`, as a digit separator to enhance readability, as the following example shows.

```
Dim ushortValue1 As UShort = 65_034
Console.WriteLine(ushortValue1)

Dim ushortValue3 As UShort = &B11111110_00001010
Console.WriteLine(ushortValue3)
' The example displays the following output:
'       65034
'       65034
```

Starting with Visual Basic 15.5, you can also use the underscore character (`_`) as a leading separator between the prefix and the hexadecimal, binary, or octal digits. For example:

```
Dim number As UShort = &H_FF8C
```

To use the underscore character as a leading separator, you must add the following element to your Visual Basic project (\*.vbproj) file:

```
<PropertyGroup>
  <LangVersion>15.5</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

Numeric literals can also include the `us` or `us` type character to denote the `UShort` data type, as the following example shows.

```
Dim number = &H_5826us
```

Programming tips

- **Negative Numbers.** Because `UShort` is an unsigned type, it cannot represent a negative number. If you use the unary minus (`-`) operator on an expression that evaluates to type `UShort`, Visual Basic converts the expression to `Integer` first.
- **CLS Compliance.** The `UShort` data type is not part of the [Common Language Specification](#) (CLS), so CLS-compliant code cannot consume a component that uses it.
- **Widening.** The `UShort` data type widens to `Integer`, `UInteger`, `Long`, `ULong`, `Decimal`, `Single`, and `Double`. This means you can convert `UShort` to any of these types without encountering a [System.OverflowException](#) error.
- **Type Characters.** Appending the literal type characters `us` to a literal forces it to the `UShort` data type. `UShort` has no identifier type character.
- **Framework Type.** The corresponding type in the .NET Framework is the [System.UInt16](#) structure.

Syntax

```
#Const constname = expression
```

Parts

constname

Required. Name of the constant being defined.

expression

Required. Literal, other conditional compiler constant, or any combination that includes any or all arithmetic or logical operators except `Is`.

Remarks

Conditional compiler constants are always private to the file in which they appear. You cannot create public compiler constants using the `#Const` directive; you can create them only in the user interface or with the `/define` compiler option.

You can use only conditional compiler constants and literals in `expression`. Using a standard constant defined with `Const` causes an error. Conversely, you can use constants defined with the `#Const` keyword only for conditional compilation. Constants can also be undefined, in which case they have a value of `Nothing`.

Example

This example uses the `#Const` directive.

```
#Const MyLocation = "USA"  
#Const Version = "8.0.0012"  
#Const CustomerNumber = 36
```

#ExternalSource Directive

1/23/2019 • 2 minutes to read • [Edit Online](#)

Indicates a mapping between specific lines of source code and text external to the source.

Syntax

```
#ExternalSource( StringLiteral , IntLiteral )
    [ LogicalLine+ ]
#End ExternalSource
```

Parts

`StringLiteral`

The path to the external source.

`IntLiteral`

The line number of the first line of the external source.

`LogicalLine`

The line where the error occurs in the external source.

`#End ExternalSource`

Terminates the `#ExternalSource` block.

Remarks

This directive is used only by the compiler and the debugger.

A source file may include external source directives, which indicate a mapping between specific lines of code in the source file and text external to the source, such as an .aspx file. If errors are encountered in the designated source code during compilation, they are identified as coming from the external source.

External source directives have no effect on compilation and cannot be nested. They are intended for internal use by the application only.

#If...Then...#Else Directives

2/28/2019 • 2 minutes to read • [Edit Online](#)

Conditionally compiles selected blocks of Visual Basic code.

Syntax

```
#If expression Then
    statements
[ #ElseIf expression Then
    [ statements ]
...
#ElseIf expression Then
    [ statements ] ]
[ #Else
    [ statements ] ]
#End If
```

Parts

`expression`

Required for `#If` and `#ElseIf` statements, optional elsewhere. Any expression, consisting exclusively of one or more conditional compiler constants, literals, and operators, that evaluates to `True` or `False`.

`statements`

Required for `#If` statement block, optional elsewhere. Visual Basic program lines or compiler directives that are compiled if the associated expression evaluates to `True`.

`#End If`

Terminates the `#If` statement block.

Remarks

On the surface, the behavior of the `#If...Then...#Else` directives appears the same as that of the `If...Then...Else` statements. However, the `#If...Then...#Else` directives evaluate what is compiled by the compiler, whereas the `If...Then...Else` statements evaluate conditions at run time.

Conditional compilation is typically used to compile the same program for different platforms. It is also used to prevent debugging code from appearing in an executable file. Code excluded during conditional compilation is completely omitted from the final executable file, so it has no effect on size or performance.

Regardless of the outcome of any evaluation, all expressions are evaluated using `Option Compare Binary`. The `Option Compare` statement does not affect expressions in `#If` and `#ElseIf` statements.

NOTE

No single-line form of the `#If`, `#Else`, `#ElseIf`, and `#End If` directives exists. No other code can appear on the same line as any of the directives.

The statements within a conditional compilation block must be complete logical statements. For example, you cannot conditionally compile only the attributes of a function, but you can conditionally declare the function

along with its attributes:

```
#If DEBUG Then
<WebMethod()
Public Function SomeFunction() As String
#Else
<WebMethod(CacheDuration:=86400)>
Public Function SomeFunction() As String
#End If
```

Example

This example uses the `#If...Then...#Else` construct to determine whether to compile certain statements.

```
#Const CustomerNumber = 36
#If CustomerNumber = 35 Then
    ' Insert code to be compiled for customer # 35.
#ElseIf CustomerNumber = 36 Then
    ' Insert code to be compiled for customer # 36.
#Else
    ' Insert code to be compiled for all other customers.
#End If
```

#Region Directive

2/28/2019 • 2 minutes to read • [Edit Online](#)

Collapses and hides sections of code in Visual Basic files.

Syntax

```
#Region "identifier_string"  
#End Region
```

Parts

TERM	DEFINITION
<code>identifier_string</code>	Required. String that acts as the title of a region when it is collapsed. Regions are collapsed by default.
<code>#End Region</code>	Terminates the <code>#Region</code> block.

Remarks

Use the `#Region` directive to specify a block of code to expand or collapse when using the outlining feature of the Visual Studio Code Editor. You can place, or *nest*, regions within other regions to group similar regions together.

Example

This example uses the `#Region` directive.

```
#Region "MathFunctions"  
    ' Insert code for the Math functions here.  
#End Region
```

Math Functions (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

The methods of the [System.Math](#) class provide trigonometric, logarithmic, and other common mathematical functions.

Remarks

The following table lists methods of the [System.Math](#) class. You can use these in a Visual Basic program.

.NET METHOD	DESCRIPTION
Abs	Returns the absolute value of a number.
Acos	Returns the angle whose cosine is the specified number.
Asin	Returns the angle whose sine is the specified number.
Atan	Returns the angle whose tangent is the specified number.
Atan2	Returns the angle whose tangent is the quotient of two specified numbers.
BigMul	Returns the full product of two 32-bit numbers.
Ceiling	Returns the smallest integral value that's greater than or equal to the specified <code>Decimal</code> or <code>Double</code> .
Cos	Returns the cosine of the specified angle.
Cosh	Returns the hyperbolic cosine of the specified angle.
DivRem	Returns the quotient of two 32-bit or 64-bit signed integers, and also returns the remainder in an output parameter.
Exp	Returns e (the base of natural logarithms) raised to the specified power.
Floor	Returns the largest integer that's less than or equal to the specified <code>Decimal</code> or <code>Double</code> number.
IEEERemainder	Returns the remainder that results from the division of a specified number by another specified number.
Log	Returns the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Log10	Returns the base 10 logarithm of a specified number.
Max	Returns the larger of two numbers.

.NET METHOD	DESCRIPTION
Min	Returns the smaller of two numbers.
Pow	Returns a specified number raised to the specified power.
Round	Returns a <code>Decimal</code> or <code>Double</code> value rounded to the nearest integral value or to a specified number of fractional digits.
Sign	Returns an <code>Integer</code> value indicating the sign of a number.
Sin	Returns the sine of the specified angle.
Sinh	Returns the hyperbolic sine of the specified angle.
Sqrt	Returns the square root of a specified number.
Tan	Returns the tangent of the specified angle.
Tanh	Returns the hyperbolic tangent of the specified angle.
Truncate	Calculates the integral part of a specified <code>Decimal</code> or <code>Double</code> number.

To use these functions without qualification, import the `System.Math` namespace into your project by adding the following code to the top of your source file:

```
Imports System.Math
```

Example

This example uses the `Abs` method of the `Math` class to compute the absolute value of a number.

```
' Returns 50.3.
Dim MyNumber1 As Double = Math.Abs(50.3)
' Returns 50.3.
Dim MyNumber2 As Double = Math.Abs(-50.3)
```

Example

This example uses the `Atan` method of the `Math` class to calculate the value of pi.

```
Public Function GetPi() As Double
    ' Calculate the value of pi.
    Return 4.0 * Math.Atan(1.0)
End Function
```

Example

This example uses the `Cos` method of the `Math` class to return the cosine of an angle.

```
Public Function Sec(ByVal angle As Double) As Double
    ' Calculate the secant of angle, in radians.
    Return 1.0 / Math.Cos(angle)
End Function
```

Example

This example uses the [Exp](#) method of the [Math](#) class to return e raised to a power.

```
Public Function Sinh(ByVal angle As Double) As Double
    ' Calculate hyperbolic sine of an angle, in radians.
    Return (Math.Exp(angle) - Math.Exp(-angle)) / 2.0
End Function
```

Example

This example uses the [Log](#) method of the [Math](#) class to return the natural logarithm of a number.

```
Public Function Asinh(ByVal value As Double) As Double
    ' Calculate inverse hyperbolic sine, in radians.
    Return Math.Log(value + Math.Sqrt(value * value + 1.0))
End Function
```

Example

This example uses the [Round](#) method of the [Math](#) class to round a number to the nearest integer.

```
' Returns 3.
Dim MyVar2 As Double = Math.Round(2.8)
```

Example

This example uses the [Sign](#) method of the [Math](#) class to determine the sign of a number.

```
' Returns 1.
Dim MySign1 As Integer = Math.Sign(12)
' Returns -1.
Dim MySign2 As Integer = Math.Sign(-2.4)
' Returns 0.
Dim MySign3 As Integer = Math.Sign(0)
```

Example

This example uses the [Sin](#) method of the [Math](#) class to return the sine of an angle.

```
Public Function Csc(ByVal angle As Double) As Double
    ' Calculate cosecant of an angle, in radians.
    Return 1.0 / Math.Sin(angle)
End Function
```

Example

This example uses the [Sqr](#) method of the [Math](#) class to calculate the square root of a number.

```
' Returns 2.  
Dim MySqr1 As Double = Math.Sqrt(4)  
' Returns 4.79583152331272.  
Dim MySqr2 As Double = Math.Sqrt(23)  
' Returns 0.  
Dim MySqr3 As Double = Math.Sqrt(0)  
' Returns NaN (not a number).  
Dim MySqr4 As Double = Math.Sqrt(-4)
```

Example

This example uses the [Tan](#) method of the [Math](#) class to return the tangent of an angle.

```
Public Function Ctan(ByVal angle As Double) As Double  
    ' Calculate cotangent of an angle, in radians.  
    Return 1.0 / Math.Tan(angle)  
End Function
```

String Functions (Visual Basic)

2/28/2019 • 5 minutes to read • [Edit Online](#)

The following table lists the functions that Visual Basic provides to search and manipulate strings.

.NET FRAMEWORK METHOD	DESCRIPTION
Asc, AscW	Returns an <code>Integer</code> value representing the character code corresponding to a character.
Chr, ChrW	Returns the character associated with the specified character code.
Filter	Returns a zero-based array containing a subset of a <code>String</code> array based on specified filter criteria.
Format	Returns a string formatted according to instructions contained in a format <code>String</code> expression.
FormatCurrency	Returns an expression formatted as a currency value using the currency symbol defined in the system control panel.
FormatDateTime	Returns a string expression representing a date/time value.
FormatNumber	Returns an expression formatted as a number.
FormatPercent	Returns an expression formatted as a percentage (that is, multiplied by 100) with a trailing % character.
InStr	Returns an integer specifying the start position of the first occurrence of one string within another.
InStrRev	Returns the position of the first occurrence of one string within another, starting from the right side of the string.
Join	Returns a string created by joining a number of substrings contained in an array.
LCase	Returns a string or character converted to lowercase.
Left	Returns a string containing a specified number of characters from the left side of a string.
Len	Returns an integer that contains the number of characters in a string.
LSet	Returns a left-aligned string containing the specified string adjusted to the specified length.
LTrim	Returns a string containing a copy of a specified string with no leading spaces.

.NET FRAMEWORK METHOD	DESCRIPTION
Mid	Returns a string containing a specified number of characters from a string.
Replace	Returns a string in which a specified substring has been replaced with another substring a specified number of times.
Right	Returns a string containing a specified number of characters from the right side of a string.
RSet	Returns a right-aligned string containing the specified string adjusted to the specified length.
RTrim	Returns a string containing a copy of a specified string with no trailing spaces.
Space	Returns a string consisting of the specified number of spaces.
Split	Returns a zero-based, one-dimensional array containing a specified number of substrings.
StrComp	Returns -1, 0, or 1, based on the result of a string comparison.
StrConv	Returns a string converted as specified.
StrDup	Returns a string or object consisting of the specified character repeated the specified number of times.
StrReverse	Returns a string in which the character order of a specified string is reversed.
Trim	Returns a string containing a copy of a specified string with no leading or trailing spaces.
UCase	Returns a string or character containing the specified string converted to uppercase.

You can use the [Option Compare](#) statement to set whether strings are compared using a case-insensitive text sort order determined by your system's locale (`Text`) or by the internal binary representations of the characters (`Binary`). The default text comparison method is `Binary`.

Example

This example uses the `UCase` function to return an uppercase version of a string.

```
' String to convert.
Dim LowerCase As String = "Hello World 1234"
' Returns "HELLO WORLD 1234".
Dim UpperCase As String = UCase(LowerCase)
```

Example

This example uses the `LTrim` function to strip leading spaces and the `RTrim` function to strip trailing spaces from

a string variable. It uses the `Trim` function to strip both types of spaces.

```
' Initializes string.  
Dim TestString As String = " <-Trim-> "  
Dim TrimString As String  
' Returns "<-Trim-> ".  
TrimString = LTrim(TestString)  
' Returns " <-Trim-> ".  
TrimString = RTrim(TestString)  
' Returns "<-Trim-> ".  
TrimString = LTrim(RTrim(TestString))  
' Using the Trim function alone achieves the same result.  
' Returns "<-Trim-> ".  
TrimString = Trim(TestString)
```

Example

This example uses the `Mid` function to return a specified number of characters from a string.

```
' Creates text string.  
Dim TestString As String = "Mid Function Demo"  
' Returns "Mid".  
Dim FirstWord As String = Mid(TestString, 1, 3)  
' Returns "Demo".  
Dim LastWord As String = Mid(TestString, 14, 4)  
' Returns "Function Demo".  
Dim MidWords As String = Mid(TestString, 5)
```

Example

This example uses `Len` to return the number of characters in a string.

```
' Initializes variable.  
Dim TestString As String = "Hello World"  
' Returns 11.  
Dim TestLen As Integer = Len(TestString)
```

Example

This example uses the `InStr` function to return the position of the first occurrence of one string within another.

```

' String to search in.
Dim SearchString As String = "XXpXXpXXPXXP"
' Search for "P".
Dim SearchChar As String = "P"

Dim TestPos As Integer
' A textual comparison starting at position 4. Returns 6.
TestPos = InStr(4, SearchString, SearchChar, CompareMethod.Text)

' A binary comparison starting at position 1. Returns 9.
TestPos = InStr(1, SearchString, SearchChar, CompareMethod.Binary)

' If Option Compare is not set, or set to Binary, return 9.
' If Option Compare is set to Text, returns 3.
TestPos = InStr(SearchString, SearchChar)

' Returns 0.
TestPos = InStr(1, SearchString, "W")

```

Example

This example shows various uses of the `Format` function to format values using both `string` formats and user-defined formats. For the date separator (`/`), time separator (`:`), and the AM/PM indicators (`t` and `tt`), the actual formatted output displayed by your system depends on the locale settings the code is using. When times and dates are displayed in the development environment, the short time format and short date format of the code locale are used.

NOTE

For locales that use a 24-hour clock, the AM/PM indicators (`t` and `tt`) display nothing.

```

Dim TestDateTime As Date = #1/27/2001 5:04:23 PM#
Dim TestStr As String
' Returns current system time in the system-defined long time format.
TestStr = Format(Now(), "Long Time")
' Returns current system date in the system-defined long date format.
TestStr = Format(Now(), "Long Date")
' Also returns current system date in the system-defined long date
' format, using the single letter code for the format.
TestStr = Format(Now(), "D")

' Returns the value of TestDateTime in user-defined date/time formats.
' Returns "5:4:23".
TestStr = Format(TestDateTime, "h:m:s")
' Returns "05:04:23 PM".
TestStr = Format(TestDateTime, "hh:mm:ss tt")
' Returns "Saturday, Jan 27 2001".
TestStr = Format(TestDateTime, "dddd, MMM d yyyy")
' Returns "17:04:23".
TestStr = Format(TestDateTime, "HH:mm:ss")
' Returns "23".
TestStr = Format(23)

' User-defined numeric formats.
' Returns "5,459.40".
TestStr = Format(5459.4, "##,##0.00")
' Returns "334.90".
TestStr = Format(334.9, "###0.00")
' Returns "500.00%".
TestStr = Format(5, "0.00%")

Type Conversion Functions (Visual Basic)

2/28/2019 • 12 minutes to read • [Edit Online](#)

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Sometimes there is no call to a procedure to accomplish the conversion, which improves performance. Each function coerces an expression to a specific data type.

Syntax

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CSByte(expression)
CShort(expression)
CSng(expression)
CStr(expression)
CUInt(expression)
CULng(expression)
CUShort(expression)
```

Part

`expression`

Required. Any expression of the source data type.

Return Value Data Type

The function name determines the data type of the value it returns, as shown in the following table.

FUNCTION NAME	RETURN DATA TYPE	RANGE FOR <small>EXPRESSION ARGUMENT</small>
<code>CBool</code>	Boolean Data Type	Any valid <code>Char</code> or <code>String</code> or numeric expression.

FUNCTION NAME	RETURN DATA TYPE	RANGE FOR EXPRESSION ARGUMENT
<code>CInt</code>	Integer Data Type	<p><code>Int32.MinValue</code> (-2,147,483,648) through <code>Int32.MaxValue</code> (2,147,483,647); fractional parts are rounded.<sup>1</sup></p> <p>Starting with Visual Basic 15.8, Visual Basic optimizes the performance of floating-point to integer conversion with the <code>CInt</code> function; see the Remarks section for more information. <code>CObj</code>	Object Data Type	Any valid expression.
<code>CSByte</code>	SByte Data Type	<p><code>SByte.MinValue</code> (-128) through <code>SByte.MaxValue</code> (127); fractional parts are rounded.<sup>1</sup></p> <p>Starting with Visual Basic 15.8, Visual Basic optimizes the performance of floating-point to signed byte conversion with the <code>csbyte</code> function; see the Remarks section for more information. See the CInt Example section for an example.</p>

FUNCTION NAME	RETURN DATA TYPE	RANGE FOR EXPRESSION ARGUMENT
<code>CShort</code>	Short Data Type	<p><code>Int16.MinValue</code> (-32,768) through <code>Int16.MaxValue</code> (32,767); fractional parts are rounded.<sup>1</sup></p> <p>Starting with Visual Basic 15.8, Visual Basic optimizes the performance of floating-point to 16-bit integer conversion with the <code>CShort</code> function; see the Remarks section for more information. See the CInt Example section for an example.</p>
<code>CSng</code>	Single Data Type	<p>-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.</p>
<code>CStr</code>	String Data Type	<p>Returns for <code>cstr</code> depend on the <code>expression</code> argument. See Return Values for the CStr Function.</p>
<code>CUInt</code>	UInteger Data Type	<p><code>UInt32.MinValue</code> (0) through <code>UInt32.MaxValue</code> (4,294,967,295) (unsigned); fractional parts are rounded.<sup>1</sup></p> <p>Starting with Visual Basic 15.8, Visual Basic optimizes the performance of floating-point to unsigned integer conversion with the <code>CUInt</code> function; see the Remarks section for more information. See the CInt Example section for an example.</p>
<code>CULng</code>	ULong Data Type	<p><code>UInt64.MinValue</code> (0) through <code>UInt64.MaxValue</code> (18,446,744,073,709,551,615) (unsigned); fractional parts are rounded.<sup>1</sup></p> <p>Starting with Visual Basic 15.8, Visual Basic optimizes the performance of floating-point to unsigned long integer conversion with the <code>CULng</code> function; see the Remarks section for more information. See the CInt Example section for an example.</p>

FUNCTION NAME	RETURN DATA TYPE	RANGE FOR EXPRESSION ARGUMENT
<code>CUShort</code>	UShort Data Type	<p><code>UInt16.MinValue</code> (0) through <code>UInt16.MaxValue</code> (65,535) (unsigned); fractional parts are rounded.<sup>1</sup></p> <p>Starting with Visual Basic 15.8, Visual Basic optimizes the performance of floating-point to unsigned 16-bit integer conversion with the <code>CUShort</code> function; see the Remarks section for more information. See the CInt Example section for an example.</p>

<sup>1</sup> Fractional parts can be subject to a special type of rounding called *banker's rounding*. See "Remarks" for more information.

Remarks

As a rule, you should use the Visual Basic type conversion functions in preference to the .NET Framework methods such as `ToString()`, either on the `Convert` class or on an individual type structure or class. The Visual Basic functions are designed for optimal interaction with Visual Basic code, and they also make your source code shorter and easier to read. In addition, the .NET Framework conversion methods do not always produce the same results as the Visual Basic functions, for example when converting `Boolean` to `Integer`. For more information, see [Troubleshooting Data Types](#).

Starting with Visual Basic 15.8, the performance of floating-point-to-integer conversion is optimized when you pass the `Single` or `Double` value returned by the following methods to one of the integer conversion functions (`CByte`, `CShort`, `CInt`, `CLng`, `CSByte`, `CUShort`, `CUInt`, `CULng`):

- [Conversion.Fix\(Double\)](#)
- [Conversion.Fix\(Object\)](#)
- [Conversion.Fix\(Single\)](#)
- [Conversion.Int\(Double\)](#)
- [Conversion.Int\(Object\)](#)
- [Conversion.Int\(Single\)](#)
- [Math.Ceiling\(Double\)](#)
- [Math.Floor\(Double\)](#)
- [Math.Round\(Double\)](#)
- [Math.Truncate\(Double\)](#)

This optimization allows code that does a large number of integer conversions to run up to twice as fast. The following example illustrates these optimized floating-point-to-integer conversions:

```

Dim s As Single = 173.7619
Dim d As Double = s

Dim i1 As Integer = CInt(Fix(s))           ' Result: 173
Dim b1 As Byte = CByte(Int(d))            ' Result: 173
Dim s1 AS Short = CShort(Math.Truncate(s)) ' Result: 173
Dim i2 As Integer = CInt(Math.Ceiling(d))   ' Result: 174
Dim i3 As Integer = CInt(Math.Round(s))     ' Result: 174

```

Behavior

- **Coercion.** In general, you can use the data type conversion functions to coerce the result of an operation to a particular data type rather than the default data type. For example, use `CDec` to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic would normally take place.
- **Failed Conversions.** If the `expression` passed to the function is outside the range of the data type to which it is to be converted, an `OverflowException` occurs.
- **Fractional Parts.** When you convert a nonintegral value to an integral type, the integer conversion functions (`CByte`, `CInt`, `CLng`, `CSByte`, `CShort`, `CUInt`, `CULng`, and `CUShort`) remove the fractional part and round the value to the closest integer.

If the fractional part is exactly 0.5, the integer conversion functions round it to the nearest even integer. For example, 0.5 rounds to 0, and 1.5 and 2.5 both round to 2. This is sometimes called *banker's rounding*, and its purpose is to compensate for a bias that could accumulate when adding many such numbers together.

`CInt` and `CLng` differ from the `Int` and `Fix` functions, which truncate, rather than round, the fractional part of a number. Also, `Fix` and `Int` always return a value of the same data type as you pass in.

- **Date/Time Conversions.** Use the `IsDate` function to determine if a value can be converted to a date and time. `CDate` recognizes date literals and time literals but not numeric values. To convert a Visual Basic 6.0 `Date` value to a `Date` value in Visual Basic 2005 or later versions, you can use the `DateTime.FromOADate` method.
- **Neutral Date/Time Values.** The `Date Data Type` always contains both date and time information. For purposes of type conversion, Visual Basic considers 1/1/0001 (January 1 of the year 1) to be a *neutral value* for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a `Date` value to a string, `cstr` does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original `Date` value and can be recovered with functions such as `DatePart` function.
- **Culture Sensitivity.** The type conversion functions involving strings perform conversions based on the current culture settings for the application. For example, `CDate` recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date might not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

If you need to convert to or from a string representation of a value in a format other than the one specified by your locale, you cannot use the Visual Basic type

conversion functions. To do this, use the `ToString(IFormatProvider)` and `Parse(String, IFormatProvider)` methods of that value's type. For example, use `Double.Parse` when converting a string to a `Double`, and use `Double.ToString` when converting a value of type `Double` to a string.

CType Function

The [CType Function](#) takes a second argument, `typename`, and coerces `expression` to `typename`, where `typename` can be any data type, structure, class, or interface to which there exists a valid conversion.

For a comparison of `cType` with the other type conversion keywords, see [DirectCast Operator](#) and [TryCast Operator](#).

CBool Example

The following example uses the `CBool` function to convert expressions to `Boolean` values. If an expression evaluates to a nonzero value, `CBool` returns `True`; otherwise, it returns `False`.

```
Dim a, b, c As Integer
Dim check As Boolean
a = 5
b = 5
' The following line of code sets check to True.
check = CBool(a = b)
c = 0
' The following line of code sets check to False.
check = CBool(c)
```

CByte Example

The following example uses the `CByte` function to convert an expression to a `Byte`.

```
Dim aDouble As Double
Dim aByte As Byte
aDouble = 125.5678
' The following line of code sets aByte to 126.
aByte = CByte(aDouble)
```

CChar Example

The following example uses the `CChar` function to convert the first character of a `String` expression to a `Char` type.

```
Dim aString As String
Dim aChar As Char
' CChar converts only the first character of the string.
aString = "BCD"
' The following line of code sets aChar to "B".
aChar = CChar(aString)
```

The input argument to `CChar` must be of data type `Char` or `String`. You cannot use `CChar` to convert a number to a character, because `CChar` cannot accept a numeric data type. The

following example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses the `InputBox` function to obtain the string of digits, `CInt` to convert the string to type `Integer`, and `ChrW` to convert the number to type `Char`.

```
Dim someDigits As String
Dim codePoint As Integer
Dim thisChar As Char
someDigits = InputBox("Enter code point of character:")
codePoint = CInt(someDigits)
' The following line of code sets thisChar to the Char value of codePoint.
thisChar = ChrW(codePoint)
```

CDate Example

The following example uses the `CDate` function to convert strings to `Date` values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim aDateString, aTimeString As String
Dim aDate, aTime As Date
aDateString = "February 12, 1969"
aTimeString = "4:35:47 PM"
' The following line of code sets aDate to a Date value.
aDate = CDate(aDateString)
' The following line of code sets aTime to Date value.
aTime = CDate(aTimeString)
```

CDbl Example

```
Dim aDec As Decimal
Dim aDbl As Double
' The following line of code uses the literal type character D to make aDec a Decimal.
aDec = 234.456784D
' The following line of code sets aDbl to 1.9225456288E+1.
aDbl = CDbl(aDec * 8.2D * 0.01D)
```

CDec Example

The following example uses the `CDec` function to convert a numeric value to `Decimal`.

```
Dim aDouble As Double
Dim aDecimal As Decimal
aDouble = 10000000.0587
' The following line of code sets aDecimal to 10000000.0587.
aDecimal = CDec(aDouble)
```

CInt Example

The following example uses the `CInt` function to convert a value to `Integer`.

```
Dim aDbl As Double
Dim anInt As Integer
aDbl = 2345.5678
' The following line of code sets anInt to 2346.
anInt = CInt(aDbl)
```

CLng Example

The following example uses the `cLng` function to convert values to `Long`.

```
Dim aDbl1, aDbl2 As Double
Dim aLng1, aLng2 As Long
aDbl1 = 25427.45
aDbl2 = 25427.55
' The following line of code sets aLng1 to 25427.
aLng1 = CLng(aDbl1)
' The following line of code sets aLng2 to 25428.
aLng2 = CLng(aDbl2)
```

CObj Example

The following example uses the `cObj` function to convert a numeric value to `Object`. The `Object` variable itself contains only a four-byte pointer, which points to the `Double` value assigned to it.

```
Dim aDouble As Double
Dim anObject As Object
aDouble = 2.7182818284
' The following line of code sets anObject to a pointer to aDouble.
anObject = CObj(aDouble)
```

CSByte Example

The following example uses the `csByte` function to convert a numeric value to `SByte`.

```
Dim aDouble As Double
Dim anSByte As SByte
aDouble = 39.501
' The following line of code sets anSByte to 40.
anSByte = CSByte(aDouble)
```

CShort Example

The following example uses the `cShort` function to convert a numeric value to `Short`.

```
Dim aByte As Byte
Dim aShort As Short
aByte = 100
' The following line of code sets aShort to 100.
aShort = CShort(aByte)
```

CSng Example

The following example uses the `CSng` function to convert values to `Single`.

```
Dim aDouble1, aDouble2 As Double
Dim aSingle1, aSingle2 As Single
aDouble1 = 75.3421105
aDouble2 = 75.3421567
' The following line of code sets aSingle1 to 75.34211.
aSingle1 = CSng(aDouble1)
' The following line of code sets aSingle2 to 75.34216.
aSingle2 = CSng(aDouble2)
```

CStr Example

The following example uses the `CStr` function to convert a numeric value to `String`.

```
Dim aDouble As Double
Dim aString As String
aDouble = 437.324
' The following line of code sets aString to "437.324".
aString = CStr(aDouble)
```

The following example uses the `CStr` function to convert `Date` values to `String` values.

```
Dim aDate As Date
Dim aString As String
' The following line of code generates a COMPILER ERROR because of invalid format.
' aDate = #February 12, 1969 00:00:00#
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' The following line of code sets the time component of aDate to midnight.
aDate = #2/12/1969#
' The following conversion suppresses the neutral time value of 00:00:00.
' The following line of code sets aString to "2/12/1969".
aString = CStr(aDate)
' The following line of code sets the time component of aDate to one second past
midnight.
aDate = #2/12/1969 12:00:01 AM#
' The time component becomes part of the converted value.
' The following line of code sets aString to "2/12/1969 12:00:01 AM".
aString = CStr(aDate)
```

`CStr` always renders a `Date` value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM". However, `CStr` suppresses the *neutral values* of 1/1/0001 for the date and 00:00:00 for the time.

For more detail on the values returned by `CStr`, see [Return Values for the CStr Function](#).

CUInt Example

The following example uses the `CUInt` function to convert a numeric value to `UInteger`.

```
Dim aDouble As Double
Dim aUInteger As UInteger
aDouble = 39.501
' The following line of code sets aUInteger to 40.
aUInteger = CUInt(aDouble)
```

CULng Example

The following example uses the `CULng` function to convert a numeric value to `ULong`.

```
Dim aDouble As Double
Dim aULong As ULong
aDouble = 39.501
' The following line of code sets aULong to 40.
aULong = CULng(aDouble)
```

CUShort Example

The following example uses the `cushort` function to convert a numeric value to `UShort`.

```
Dim aDouble As Double
Dim aUShort As UShort
aDouble = 39.501
' The following line of code sets aUShort to 40.
aUShort = CUShort(aDouble)
```

Return Values for the CStr Function (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The following table describes the return values for `cstr` for different data types of `expression`.

IF <code>expression</code> TYPE IS	<code>CSTR</code> RETURNS
Boolean Data Type	A string containing "True" or "False".
Date Data Type	A string containing a <code>Date</code> value (date and time) in the short date format of your system.
Numeric Data Types	A string representing the number.

CStr and Date

The `Date` type always contains both date and time information. For purposes of type conversion, Visual Basic considers 1/1/0001 (January 1 of the year 1) to be a *neutral value* for the date, and 00:00:00 (midnight) to be a neutral value for the time. `cstr` does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original `Date` value and can be recovered with functions such as [DatePart](#).

NOTE

The `cstr` function performs its conversion based on the current culture settings for the application. To get the string representation of a number in a particular culture, use the number's `ToString(IFormatProvider)` method. For example, use `Double.ToString` when converting a value of type `Double` to a `String`.

CType Function (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Returns the result of explicitly converting an expression to a specified data type, object, structure, class, or interface.

Syntax

```
CType(expression, typename)
```

Parts

`expression` Any valid expression. If the value of `expression` is outside the range allowed by `typename`, Visual Basic throws an exception.

`typename` Any expression that is legal within an `As` clause in a `Dim` statement, that is, the name of any data type, object, structure, class, or interface.

Remarks

TIP

You can also use the following functions to perform a type conversion:

- Type conversion functions such as `CByte`, `CDbl`, and `CInt` that perform a conversion to a specific data type. For more information, see [Type Conversion Functions](#).
- [DirectCast Operator](#) or [TryCast Operator](#). These operators require that one type inherit from or implement the other type. They can provide somewhat better performance than `CType` when converting to and from the `Object` data type.

`CType` is compiled inline, which means that the conversion code is part of the code that evaluates the expression. In some cases, the code runs faster because no procedures are called to perform the conversion.

If no conversion is defined from `expression` to `typename` (for example, from `Integer` to `Date`), Visual Basic displays a compile-time error message.

If a conversion fails at run time, the appropriate exception is thrown. If a narrowing conversion fails, an [OverflowException](#) is the most common result. If the conversion is undefined, an [InvalidOperationException](#) is thrown. For example, this can happen if `expression` is of type `Object` and its run-time type has no conversion to `typename`.

If the data type of `expression` or `typename` is a class or structure you've defined, you can define `CType` on that class or structure as a conversion operator. This makes `CType` act as an *overloaded operator*. If you do this, you can control the behavior of conversions to and from your class or structure, including the exceptions that can be thrown.

Overloading

The `CType` operator can also be overloaded on a class or structure defined outside your code. If your code

converts to or from such a class or structure, be sure you understand the behavior of its `CType` operator. For more information, see [Operator Procedures](#).

Converting Dynamic Objects

Type conversions of dynamic objects are performed by user-defined dynamic conversions that use the `TryConvert` or `BindConvert` methods. If you're working with dynamic objects, use the `CTypeDynamic` method to convert the dynamic object.

Example

The following example uses the `CType` function to convert an expression to the `Single` data type.

```
Dim testNumber As Long = 1000
' The following line of code sets testNewType to 1000.0.
Dim testNewType As Single = CType(testNumber, Single)
```

For additional examples, see [Implicit and Explicit Conversions](#).

Ansi (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that Visual Basic should marshal all strings to American National Standards Institute (ANSI) values regardless of the name of the external procedure being declared.

When you call a procedure defined outside your project, the Visual Basic compiler does not have access to the information it needs to call the procedure correctly. This information includes where the procedure is located, how it is identified, its calling sequence and return type, and the string character set it uses. The [Declare Statement](#) creates a reference to an external procedure and supplies this necessary information.

The `charsetmodifier` part in the `Declare` statement supplies the character set information for marshaling strings during a call to the external procedure. It also affects how Visual Basic searches the external file for the external procedure name. The `Ansi` modifier specifies that Visual Basic should marshal all strings to ANSI values and should look up the procedure without modifying its name during the search.

If no character set modifier is specified, `Ansi` is the default.

Remarks

The `Ansi` modifier can be used in this context:

Assembly (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that an attribute at the beginning of a source file applies to the entire assembly.

Remarks

Many attributes pertain to an individual programming element, such as a class or property. You apply such an attribute by attaching the attribute block, within angle brackets (`<>`), directly to the declaration statement.

If an attribute pertains not only to the following element but to the entire assembly, you place the attribute block at the beginning of the source file and identify the attribute with the `Assembly` keyword. If it applies to the current assembly module, you use the `Module` keyword.

You can also apply an attribute to an assembly in the `AssemblyInfo.vb` file, in which case you do not have to use an attribute block in your main source-code file.

Async (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

The `Async` modifier indicates that the method or [lambda expression](#) that it modifies is asynchronous. Such methods are referred to as *async methods*.

An `async` method provides a convenient way to do potentially long-running work without blocking the caller's thread. The caller of an `async` method can resume its work without waiting for the `async` method to finish.

NOTE

The `Async` and `Await` keywords were introduced in Visual Studio 2012. For an introduction to `async` programming, see [Asynchronous Programming with Async and Await](#).

The following example shows the structure of an `async` method. By convention, `async` method names end in "Async."

```
Public Async Function ExampleMethodAsync() As Task(Of Integer)
    ' ...
    ' At the Await expression, execution in this method is suspended and,
    ' if AwaitedProcessAsync has not already finished, control returns
    ' to the caller of ExampleMethodAsync. When the awaited task is
    ' completed, this method resumes execution.
    Dim exampleInt As Integer = Await AwaitedProcessAsync()
    ' ...
    ' The return statement completes the task. Any method that is
    ' awaiting ExampleMethodAsync can now get the integer result.
    Return exampleInt
End Function
```

Typically, a method modified by the `Async` keyword contains at least one `Await` expression or statement. The method runs synchronously until it reaches the first `Await`, at which point it suspends until the awaited task completes. In the meantime, control is returned to the caller of the method. If the method doesn't contain an `Await` expression or statement, the method isn't suspended and executes as a synchronous method does. A compiler warning alerts you to any `async` methods that don't contain `Await` because that situation might indicate an error. For more information, see the [compiler error](#).

The `Async` keyword is an unreserved keyword. It is a keyword when it modifies a method or a lambda expression. In all other contexts, it is interpreted as an identifier.

Return Types

An `async` method is either a `Sub` procedure, or a `Function` procedure that has a return type of `Task` or `Task<TResult>`. The method cannot declare any `ByRef` parameters.

You specify `Task(Of TResult)` for the return type of an `async` method if the `Return` statement of the method has an operand of type `TResult`. You use `Task` if no meaningful value is returned when the method is completed. That is, a call to the method returns a `Task`, but when the `Task` is completed, any `Await` statement that's awaiting the `Task` doesn't produce a result value.

Async subroutines are used primarily to define event handlers where a `Sub` procedure is required. The caller of an async subroutine can't await it and can't catch exceptions that the method throws.

For more information and examples, see [Async Return Types](#).

Example

The following examples show an async event handler, an async lambda expression, and an async method. For a full example that uses these elements, see [Walkthrough: Accessing the Web by Using Async and Await](#). You can download the walkthrough code from [Developer Code Samples](#).

```
' An event handler must be a Sub procedure.
Async Sub button1_Click(sender As Object, e As RoutedEventArgs) Handles button1.Click
    textBox1.Clear()
    ' SumPageSizesAsync is a method that returns a Task.
    Await SumPageSizesAsync()
    textBox1.Text = vbCrLf & "Control returned to button1_Click."
End Sub

' The following async lambda expression creates an equivalent anonymous
' event handler.
AddHandler button1.Click, Async Sub(sender, e)
    textBox1.Clear()
    ' SumPageSizesAsync is a method that returns a Task.
    Await SumPageSizesAsync()
    textBox1.Text = vbCrLf & "Control returned to button1_Click."
End Sub

' The following async method returns a Task(Of T).
' A typical call awaits the Byte array result:
'     Dim result As Byte() = Await GetURLContents("http://msdn.com")
Private Async Function GetURLContentsAsync(url As String) As Task(Of Byte())

    ' The downloaded resource ends up in the variable named content.
    Dim content = New MemoryStream()

    ' Initialize an HttpWebRequest for the current URL.
    Dim webReq = CType(WebRequest.Create(url), HttpWebRequest)

    ' Send the request to the Internet resource and wait for
    ' the response.
    Using response AsWebResponse = Await webReq.GetResponseAsync()
        ' Get the data stream that is associated with the specified URL.
        Using responseStream As Stream = response.GetResponseStream()
            ' Read the bytes in responseStream and copy them to content.
            ' CopyToAsync returns a Task, not a Task<T>.
            Await responseStream.CopyToAsync(content)
        End Using
    End Using

    ' Return the result as a byte array.
    Return content.ToArray()
End Function
```

Auto (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that Visual Basic should marshal strings according to .NET Framework rules based on the external name of the external procedure being declared.

When you call a procedure defined outside your project, the Visual Basic compiler does not have access to the information it must have to call the procedure correctly. This information includes where the procedure is located, how it is identified, its calling sequence and return type, and the string character set it uses. The [Declare Statement](#) creates a reference to an external procedure and supplies this necessary information.

The `charsetmodifier` part in the `Declare` statement supplies the character set information for marshaling strings during a call to the external procedure. It also affects how Visual Basic searches the external file for the external procedure name. The `Auto` modifier specifies that Visual Basic should marshal strings according to .NET Framework rules, and that it should determine the base character set of the run-time platform and possibly modify the external procedure name if the initial search fails. For more information, see "Character Sets" in [Declare Statement](#).

If no character set modifier is specified, `Ansi` is the default.

Remarks

The `Auto` modifier can be used in this context:

ByVal (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies that an argument is passed in such a way that the called procedure or property cannot change the value of a variable underlying the argument in the calling code.

Remarks

The `ByVal` modifier can be used in these contexts:

[Declare Statement](#)

[Function Statement](#)

[Operator Statement](#)

[Property Statement](#)

[Sub Statement](#)

Example

The following example demonstrates the use of the `ByVal` parameter passing mechanism with a reference type argument. In the example, the argument is `c1`, an instance of class `Class1`. `ByVal` prevents the code in the procedures from changing the underlying value of the reference argument, `c1`, but does not protect the accessible fields and properties of `c1`.

```
Module Module1

    Sub Main()

        ' Declare an instance of the class and assign a value to its field.
        Dim c1 As Class1 = New Class1()
        c1.Field = 5
        Console.WriteLine(c1.Field)
        ' Output: 5

        ' ByVal does not prevent changing the value of a field or property.
        ChangeFieldValue(c1)
        Console.WriteLine(c1.Field)
        ' Output: 500

        ' ByVal does prevent changing the value of c1 itself.
        ChangeClassReference(c1)
        Console.WriteLine(c1.Field)
        ' Output: 500

        Console.ReadKey()
    End Sub

    Public Sub ChangeFieldValue(ByVal cls As Class1)
        cls.Field = 500
    End Sub

    Public Sub ChangeClassReference(ByVal cls As Class1)
        cls = New Class1()
        cls.Field = 1000
    End Sub

    Public Class Class1
        Public Field As Integer
    End Class

End Module

Default (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Identifies a property as the default property of its class, structure, or interface.

Remarks

A class, structure, or interface can designate at most one of its properties as the *default property*, provided that property takes at least one parameter. If code makes a reference to a class or structure without specifying a member, Visual Basic resolves that reference to the default property.

Default properties can result in a small reduction in source code-characters, but they can make your code more difficult to read. If the calling code is not familiar with your class or structure, when it makes a reference to the class or structure name it cannot be certain whether that reference accesses the class or structure itself, or a default property. This can lead to compiler errors or subtle run-time logic errors.

You can somewhat reduce the chance of default property errors by always using the [Option Strict Statement](#) to set compiler type checking to `On`.

If you are planning to use a predefined class or structure in your code, you must determine whether it has a default property, and if so, what its name is.

Because of these disadvantages, you should consider not defining default properties. For code readability, you should also consider always referring to all properties explicitly, even default properties.

The `Default` modifier can be used in this context:

[Property Statement](#)

See also

- [How to: Declare and Call a Default Property in Visual Basic](#)
- [Keywords](#)

Friend (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

Specifies that one or more declared programming elements are accessible only from within the assembly that contains their declaration.

Remarks

In many cases, you want programming elements such as classes and structures to be used by the entire assembly, not only by the component that declares them. However, you might not want them to be accessible by code outside the assembly (for example, if the application is proprietary). If you want to limit access to an element in this way, you can declare it by using the `Friend` modifier.

Code in other classes, structures, and modules that are compiled to the same assembly can access all the `Friend` elements in that assembly.

`Friend` access is often the preferred level for an application's programming elements, and `Friend` is the default access level of an interface, a module, a class, or a structure.

You can use `Friend` only at the module, interface, or namespace level. Therefore, the declaration context for a `Friend` element must be a source file, a namespace, an interface, a module, a class, or a structure; it can't be a procedure.

NOTE

You can also use the `Protected Friend` access modifier, which makes a class member accessible from within that class, from derived classes, and from the same assembly in which the class is defined. To restrict access to a member from within its class and from derived classes in the same assembly, you use the `Private Protected` access modifier.

For a comparison of `Friend` and the other access modifiers, see [Access levels in Visual Basic](#).

NOTE

You can specify that another assembly is a friend assembly, which allows it to access all types and members that are marked as `Friend`. For more information, see [Friend Assemblies](#).

Example

The following class uses the `Friend` modifier to allow other programming elements within the same assembly to access certain members.

```

Class CustomerInfo

    Private p_CustomerID As Integer

    Public ReadOnly Property CustomerID() As Integer
        Get
            Return p_CustomerID
        End Get
    End Property

    ' Allow friend access to the empty constructor.
    Friend Sub New()

    End Sub

    ' Require that a customer identifier be specified for the public constructor.
    Public Sub New(ByVal customerID As Integer)
        p_CustomerID = customerID
    End Sub

    ' Allow friend programming elements to set the customer identifier.
    Friend Sub SetCustomerID(ByVal customerID As Integer)
        p_CustomerID = customerID
    End Sub
End Class

```

Usage

In (Generic Modifier) (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

For generic type parameters, the `In` keyword specifies that the type parameter is contravariant.

Remarks

Contravariance enables you to use a less derived type than that specified by the generic parameter. This allows for implicit conversion of classes that implement variant interfaces and implicit conversion of delegate types.

For more information, see [Covariance and Contravariance](#).

Rules

You can use the `In` keyword in generic interfaces and delegates.

A type parameter can be declared contravariant in a generic interface or delegate if it is used only as a type of method arguments and not used as a method return type. `ByRef` parameters cannot be covariant or contravariant.

Covariance and contravariance are supported for reference types and not supported for value types.

In Visual Basic, you cannot declare events in contravariant interfaces without specifying the delegate type. Also, contravariant interfaces cannot have nested classes, enums, or structures, but they can have nested interfaces.

Behavior

An interface that has a contravariant type parameter allows its methods to accept arguments of less derived types than those specified by the interface type parameter. For example, because in .NET Framework 4, in the `IComparer<T>` interface, type `T` is contravariant, you can assign an object of the `IComparer(Of Person)` type to an object of the `IComparer(Of Employee)` type without using any special conversion methods if `Person` inherits `Employee`.

A contravariant delegate can be assigned another delegate of the same type, but with a less derived generic type parameter.

Example

The following example shows how to declare, extend, and implement a contravariant generic interface. It also shows how you can use implicit conversion for classes that implement this interface.

```

' Contravariant interface.
Interface IContravariant(Of In A)
End Interface

' Extending contravariant interface.
Interface IExtContravariant(Of In A)
    Inherits IContravariant(Of A)
End Interface

' Implementing contravariant interface.
Class Sample(Of A)
    Implements IContravariant(Of A)
End Class

Sub Main()
    Dim iobj As IContravariant(Of Object) = New Sample(Of Object)()
    Dim istr As IContravariant(Of String) = New Sample(Of String)()

    ' You can assign iobj to istr, because
    ' the IContravariant interface is contravariant.
    istr = iobj
End Sub

```

Example

The following example shows how to declare, instantiate, and invoke a contravariant generic delegate. It also shows how you can implicitly convert a delegate type.

```

' Contravariant delegate.
Public Delegate Sub DContravariant(Of In A)(ByVal argument As A)

' Methods that match the delegate signature.
Public Shared Sub SampleControl(ByVal control As Control)
End Sub

Public Shared Sub SampleButton(ByVal control As Button)
End Sub

Private Sub Test()

    ' Instantiating the delegates with the methods.
    Dim dControl As DContravariant(Of Control) =
        AddressOf SampleControl
    Dim dButton As DContravariant(Of Button) =
        AddressOf SampleButton

    ' You can assign dControl to dButton
    ' because the DContravariant delegate is contravariant.
    dButton = dControl

    ' Invoke the delegate.
    dButton(New Button())
End Sub

```

Iterator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a function or `Get` accessor is an iterator.

Remarks

An *iterator* performs a custom iteration over a collection. An iterator uses the `Yield` statement to return each element in the collection one at a time. When a `Yield` statement is reached, the current location in code is retained. Execution is restarted from that location the next time that the iterator function is called.

An iterator can be implemented as a function or as a `Get` accessor of a property definition. The `Iterator` modifier appears in the declaration of the iterator function or `Get` accessor.

You call an iterator from client code by using a [For Each...Next Statement](#).

The return type of an iterator function or `Get` accessor can be `IEnumerable`, `IEnumerable<T>`, `IEnumerator`, or `IEnumerator<T>`.

An iterator cannot have any `ByRef` parameters.

An iterator cannot occur in an event, instance constructor, static constructor, or static destructor.

An iterator can be an anonymous function. For more information, see [Iterators](#).

Usage

The `Iterator` modifier can be used in these contexts:

- [Function Statement](#)
- [Property Statement](#)

Example

The following example demonstrates an iterator function. The iterator function has a `yield` statement that is inside a `For...Next` loop. Each iteration of the `For Each` statement body in `Main` creates a call to the `Power` iterator function. Each call to the iterator function proceeds to the next execution of the `Yield` statement, which occurs during the next iteration of the `For...Next` loop.

```

Sub Main()
    For Each number In Power(2, 8)
        Console.WriteLine(number & " ")
    Next
    ' Output: 2 4 8 16 32 64 128 256
    Console.ReadKey()
End Sub

Private Iterator Function Power(
    ByVal base As Integer, ByVal highExponent As Integer) _
    As System.Collections.Generic.IEnumerable(Of Integer)

    Dim result = 1

    For counter = 1 To highExponent
        result = result * base
        Yield result
    Next
End Function

```

Example

The following example demonstrates a `Get` accessor that is an iterator. The `Iterator` modifier is in the property declaration.

```

Sub Main()
    Dim theGalaxies As New Galaxies
    For Each theGalaxy In theGalaxies.NextGalaxy
        With theGalaxy
            Console.WriteLine(.Name & " " & .MegaLightYears)
        End With
    Next
    Console.ReadKey()
End Sub

Public Class Galaxies
    Public ReadOnly Iterator Property NextGalaxy _
        As System.Collections.Generic.IEnumerable(Of Galaxy)
        Get
            Yield New Galaxy With {.Name = "Tadpole", .MegaLightYears = 400}
            Yield New Galaxy With {.Name = "Pinwheel", .MegaLightYears = 25}
            Yield New Galaxy With {.Name = "Milky Way", .MegaLightYears = 0}
            Yield New Galaxy With {.Name = "Andromeda", .MegaLightYears = 3}
        End Get
    End Property
End Class

Public Class Galaxy
    Public Property Name As String
    Public Property MegaLightYears As Integer
End Class

```

Key (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

The `Key` keyword enables you to specify behavior for properties of anonymous types. Only properties you designate as key properties participate in tests of equality between anonymous type instances, or calculation of hash code values. The values of key properties cannot be changed.

You designate a property of an anonymous type as a key property by placing the keyword `Key` in front of its declaration in the initialization list. In the following example, `Airline` and `FlightNo` are key properties, but `Gate` is not.

```
Dim flight1 = New With {Key .Airline = "Blue Yonder Airlines",
                      Key .FlightNo = 3554, .Gate = "C33"}
```

When a new anonymous type is created, it inherits directly from `Object`. The compiler overrides three inherited members: `Equals`, `GetHashCode`, and `ToString`. The override code that is produced for `Equals` and `GetHashCode` is based on key properties. If there are no key properties in the type, `GetHashCode` and `Equals` are not overridden.

Equality

Two anonymous type instances are equal if they are instances of the same type and if the values of their key properties are equal. In the following examples, `flight2` is equal to `flight1` from the previous example because they are instances of the same anonymous type and they have matching values for their key properties. However, `flight3` is not equal to `flight1` because it has a different value for a key property, `FlightNo`. Instance `flight4` is not the same type as `flight1` because they designate different properties as key properties.

```
Dim flight2 = New With {Key .Airline = "Blue Yonder Airlines",
                      Key .FlightNo = 3554, .Gate = "D14"}
' The following statement displays True. The values of the non-key
' property, Gate, do not have to be equal.
Console.WriteLine(flight1.Equals(flight2))

Dim flight3 = New With {Key .Airline = "Blue Yonder Airlines",
                      Key .FlightNo = 431, .Gate = "C33"}
' The following statement displays False, because flight3 has a
' different value for key property FlightNo.
Console.WriteLine(flight1.Equals(flight3))

Dim flight4 = New With {Key .Airline = "Blue Yonder Airlines",
                      .FlightNo = 3554, .Gate = "C33"}
' The following statement displays False. Instance flight4 is not the
' same type as flight1 because they have different key properties.
' FlightNo is a key property of flight1 but not of flight4.
Console.WriteLine(flight1.Equals(flight4))
```

If two instances are declared with only non-key properties, identical in name, type, order, and value, the two instances are not equal. An instance without key properties is equal only to itself.

For more information about the conditions under which two anonymous type instances are instances of the same anonymous type, see [Anonymous Types](#).

Hash Code Calculation

Like [Equals](#), the hash function that is defined in [GetHashCode](#) for an anonymous type is based on the key properties of the type. The following examples show the interaction between key properties and hash code values.

Instances of an anonymous type that have the same values for all key properties have the same hash code value, even if non-key properties do not have matching values. The following statement returns `True`.

```
Console.WriteLine(flight1.GetHashCode = flight2.GetHashCode)
```

Instances of an anonymous type that have different values for one or more key properties have different hash code values. The following statement returns `False`.

```
Console.WriteLine(flight1.GetHashCode = flight3.GetHashCode)
```

Instances of anonymous types that designate different properties as key properties are not instances of the same type. They have different hash code values even when the names and values of all properties are the same. The following statement returns `False`.

```
Console.WriteLine(flight1.GetHashCode = flight4.GetHashCode)
```

Read-Only Values

The values of key properties cannot be changed. For example, in `flight1` in the earlier examples, the `Airline` and `FlightNo` fields are read-only, but `Gate` can be changed.

```
' The following statement will not compile, because FlightNo is a key
' property and cannot be changed.
' flight1.FlightNo = 1234
'
' Gate is not a key property. Its value can be changed.
flight1.Gate = "C5"
```

Module <keyword> (Visual Basic)

1/30/2019 • 2 minutes to read • [Edit Online](#)

Specifies that an attribute at the beginning of a source file applies to the current assembly module.

Remarks

Many attributes pertain to an individual programming element, such as a class or property. You apply such an attribute by attaching the attribute block, within angle brackets (<>), directly to the declaration statement.

If an attribute pertains not only to the following element but to the current assembly module, you place the attribute block at the beginning of the source file and identify the attribute with the `Module` keyword. If it applies to the entire assembly, you use the `Assembly` keyword.

The `Module` modifier is not the same as the [Module Statement](#).

MustInherit (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a class can be used only as a base class and that you cannot create an object directly from it.

Remarks

The purpose of a *base class* (also known as an *abstract class*) is to define functionality that is common to all the classes derived from it. This saves the derived classes from having to redefine the common elements. In some cases, this common functionality is not complete enough to make a usable object, and each derived class defines the missing functionality. In such a case, you want the consuming code to create objects only from the derived classes. You use `MustInherit` on the base class to enforce this.

Another use of a `MustInherit` class is to restrict a variable to a set of related classes. You can define a base class and derive all these related classes from it. The base class does not need to provide any functionality common to all the derived classes, but it can serve as a filter for assigning values to variables. If your consuming code declares a variable as the base class, Visual Basic allows you to assign only an object from one of the derived classes to that variable.

The .NET Framework defines several `MustInherit` classes, among them `Array`, `Enum`, and `ValueType`. `ValueType` is an example of a base class that restricts a variable. All value types derive from `ValueType`. If you declare a variable as `ValueType`, you can assign only value types to that variable.

Rules

- **Declaration Context.** You can use `MustInherit` only in a `Class` statement.
- **Combined Modifiers.** You cannot specify `MustInherit` together with `NotInheritable` in the same declaration.

Example

The following example illustrates both forced inheritance and forced overriding. The base class `shape` defines a variable `acrossLine`. The classes `circle` and `square` derive from `shape`. They inherit the definition of `acrossLine`, but they must define the function `area` because that calculation is different for each kind of shape.

```

Public MustInherit Class shape
    Public acrossLine As Double
    Public MustOverride Function area() As Double
End Class
Public Class circle : Inherits shape
    Public Overrides Function area() As Double
        Return Math.PI * acrossLine
    End Function
End Class
Public Class square : Inherits shape
    Public Overrides Function area() As Double
        Return acrossLine * acrossLine
    End Function
End Class
Public Class consumeShapes
    Public Sub makeShapes()
        Dim shape1, shape2 As shape
        shape1 = New circle
        shape2 = New square
    End Sub
End Class

```

You can declare `shape1` and `shape2` to be of type `shape`. However, you cannot create an object from `shape` because it lacks the functionality of the function `area` and is marked `MustInherit`.

Because they are declared as `shape`, the variables `shape1` and `shape2` are restricted to objects from the derived classes `circle` and `square`. Visual Basic does not allow you to assign any other object to these variables, which gives you a high level of type safety.

Usage

The `MustInherit` modifier can be used in this context:

MustOverride (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a property or procedure is not implemented in this class and must be overridden in a derived class before it can be used.

Remarks

You can use `MustOverride` only in a property or procedure declaration statement. The property or procedure that specifies `MustOverride` must be a member of a class, and the class must be marked [MustInherit](#).

Rules

- **Incomplete Declaration.** When you specify `MustOverride`, you do not supply any additional lines of code for the property or procedure, not even the `End Function`, `End Property`, or `End Sub` statement.
- **Combined Modifiers.** You cannot specify `MustOverride` together with `NotOverridable`, `Overridable`, or `Shared` in the same declaration.
- **Shadowing and Overriding.** Both shadowing and overriding redefine an inherited element, but there are significant differences between the two approaches. For more information, see [Shadowing in Visual Basic](#).
- **Alternate Terms.** An element that cannot be used except in an override is sometimes called a *pure virtual* element.

The `MustOverride` modifier can be used in these contexts:

Narrowing (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Indicates that a conversion operator (`cType`) converts a class or structure to a type that might not be able to hold some of the possible values of the original class or structure.

Converting with the Narrowing Keyword

The conversion procedure must specify `Public Shared` in addition to `Narrowing`.

Narrowing conversions do not always succeed at run time, and can fail or incur data loss. Examples are `Long` to `Integer`, `String` to `Date`, and a base type to a derived type. This last conversion is narrowing because the base type might not contain all the members of the derived type and thus is not an instance of the derived type.

If `Option Strict` is `On`, the consuming code must use `cType` for all narrowing conversions.

The `Narrowing` keyword can be used in this context:

[Operator Statement](#)

NotInheritable (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a class cannot be used as a base class.

Remarks

Alternate Terms. A class that cannot be inherited is sometimes called a *sealed* class.

The `NotInheritable` modifier can be used in this context:

[Class Statement](#)

See also

- [Inherits Statement](#)
- [MustInherit](#)
- [Keywords](#)

NotOverridable (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a property or procedure cannot be overridden in a derived class.

Remarks

The `NotOverridable` modifier prevents a property or method from being overridden in a derived class. The `Overridable` modifier allows a property or method in a class to be overridden in a derived class. For more information, see [Inheritance Basics](#).

If the `Overridable` or `NotOverridable` modifier is not specified, the default setting depends on whether the property or method overrides a base class property or method. If the property or method overrides a base class property or method, the default setting is `Overridable`; otherwise, it is `NotOverridable`.

An element that cannot be overridden is sometimes called a *sealed* element.

You can use `NotOverridable` only in a property or procedure declaration statement. You can specify `NotOverridable` only on a property or procedure that overrides another property or procedure, that is, only in combination with `Overrides`.

Combined Modifiers

You cannot specify `Overridable` or `NotOverridable` for a `Private` method.

You cannot specify `NotOverridable` together with `MustOverride`, `Overridable`, or `Shared` in the same declaration.

Usage

The `NotOverridable` modifier can be used in these contexts:

[Function Statement](#)

[Property Statement](#)

[Sub Statement](#)

Optional (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a procedure argument can be omitted when the procedure is called.

Remarks

For each optional parameter, you must specify a constant expression as the default value of that parameter. If the expression evaluates to [Nothing](#), the default value of the value data type is used as the default value of the parameter.

If the parameter list contains an optional parameter, every parameter that follows it must also be optional.

The `Optional` modifier can be used in these contexts:

- [Declare Statement](#)
- [Function Statement](#)
- [Property Statement](#)
- [Sub Statement](#)

NOTE

When calling a procedure with or without optional parameters, you can pass arguments by position or by name. For more information, see [Passing Arguments by Position and by Name](#).

NOTE

You can also define a procedure with optional parameters by using overloading. If you have one optional parameter, you can define two overloaded versions of the procedure, one that accepts the parameter and one that doesn't. For more information, see [Procedure Overloading](#).

Example

The following example defines a procedure that has an optional parameter.

```

Public Function FindMatches(ByRef values As List(Of String),
                           ByVal searchString As String,
                           Optional ByVal matchCase As Boolean = False) As List(Of String)

    Dim results As IEnumerable(Of String)

    If matchCase Then
        results = From v In values
                  Where v.Contains(searchString)
    Else
        results = From v In values
                  Where UCase(v).Contains(UCase(searchString))
    End If

    Return results.ToList()
End Function

```

Example

The following example demonstrates how to call a procedure with arguments passed by position and with arguments passed by name. The procedure has two optional parameters.

```

Private Sub TestParameters()
    ' Call the procedure with its arguments passed by position,
    studentInfo("Mary", 19, #9/21/1981#)

    ' Omit one optional argument by holding its place with a comma.
    studentInfo("Mary", , #9/21/1981#)

    ' Call the procedure with its arguments passed by name.
    studentInfo(age:=19, birth:=#9/21/1981#, name:="Mary")

    ' Supply an argument by position and an argument by name.
    studentInfo("Mary", birth:=#9/21/1981#)
End Sub

Private Sub studentInfo(ByVal name As String,
                       Optional ByVal age As Short = 0,
                       Optional ByVal birth As Date = #1/1/2000#)

    Console.WriteLine("name: " & name)
    Console.WriteLine("age: " & age)
    Console.WriteLine("birth date: " & birth)
    Console.WriteLine()
End Sub

```

Out (Generic Modifier) (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

For generic type parameters, the `out` keyword specifies that the type is covariant.

Remarks

Covariance enables you to use a more derived type than that specified by the generic parameter. This allows for implicit conversion of classes that implement variant interfaces and implicit conversion of delegate types.

For more information, see [Covariance and Contravariance](#).

Rules

You can use the `out` keyword in generic interfaces and delegates.

In a generic interface, a type parameter can be declared covariant if it satisfies the following conditions:

- The type parameter is used only as a return type of interface methods and not used as a type of method arguments.

NOTE

There is one exception to this rule. If in a covariant interface you have a contravariant generic delegate as a method parameter, you can use the covariant type as a generic type parameter for this delegate. For more information about covariant and contravariant generic delegates, see [Variance in Delegates](#) and [Using Variance for Func and Action Generic Delegates](#).

- The type parameter is not used as a generic constraint for the interface methods.

In a generic delegate, a type parameter can be declared covariant if it is used only as a method return type and not used for method arguments.

Covariance and contravariance are supported for reference types, but they are not supported for value types.

In Visual Basic, you cannot declare events in covariant interfaces without specifying the delegate type. Also, covariant interfaces cannot have nested classes, enums, or structures, but they can have nested interfaces.

Behavior

An interface that has a covariant type parameter enables its methods to return more derived types than those specified by the type parameter. For example, because in .NET Framework 4, in `IEnumerable<T>`, type T is covariant, you can assign an object of the `IEnumerable(Of String)` type to an object of the `IEnumerable(Of Object)` type without using any special conversion methods.

A covariant delegate can be assigned another delegate of the same type, but with a more derived generic type parameter.

Example

The following example shows how to declare, extend, and implement a covariant generic interface. It also shows how to use implicit conversion for classes that implement a covariant interface.

```

' Covariant interface.
Interface ICovariant(Of Out R)
End Interface

' Extending covariant interface.
Interface IExtCovariant(Of Out R)
    Inherits ICovariant(Of R)
End Interface

' Implementing covariant interface.
Class Sample(Of R)
    Implements ICovariant(Of R)
End Class

Sub Main()
    Dim iobj As ICovariant(Of Object) = New Sample(Of Object)()
    Dim istr As ICovariant(Of String) = New Sample(Of String)()

    ' You can assign istr to iobj because
    ' the ICovariant interface is covariant.
    iobj = istr
End Sub

```

Example

The following example shows how to declare, instantiate, and invoke a covariant generic delegate. It also shows how you can use implicit conversion for delegate types.

```

' Covariant delegate.
Public Delegate Function DCovariant(Of Out R)() As R

' Methods that match the delegate signature.
Public Shared Function SampleControl() As Control
    Return New Control()
End Function

Public Shared Function SampleButton() As Button
    Return New Button()
End Function

Private Sub Test()

    ' Instantiating the delegates with the methods.
    Dim dControl As DCovariant(Of Control) =
        AddressOf SampleControl
    Dim dButton As DCovariant(Of Button) =
        AddressOf SampleButton

    ' You can assign dButton to dControl
    ' because the DCovariant delegate is covariant.
    dControl = dButton

    ' Invoke the delegate.
    dControl()
End Sub

```

Overloads (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a property or procedure redeclares one or more existing properties or procedures with the same name.

Remarks

Overloading is the practice of supplying more than one definition for a given property or procedure name in the same scope. Redeclaring a property or procedure with a different signature is sometimes called *hiding by signature*.

Rules

- **Declaration Context.** You can use `Overloads` only in a property or procedure declaration statement.
- **Combined Modifiers.** You cannot specify `Overloads` together with `Shadows` in the same procedure declaration.
- **Required Differences.** The *signature* in this declaration must be different from the signature of every property or procedure that it overloads. The signature comprises the property or procedure name together with the following:
 - the number of parameters
 - the order of the parameters
 - the data types of the parameters
 - the number of type parameters (for a generic procedure)
 - the return type (only for a conversion operator procedure)

All overloads must have the same name, but each must differ from all the others in one or more of the preceding respects. This allows the compiler to distinguish which version to use when code calls the property or procedure.

- **Disallowed Differences.** Changing one or more of the following is not valid for overloading a property or procedure, because they are not part of the signature:
 - whether or not it returns a value (for a procedure)
 - the data type of the return value (except for a conversion operator)
 - the names of the parameters or type parameters
 - the constraints on the type parameters (for a generic procedure)
 - parameter modifier keywords (such as `ByRef` or `Optional`)
 - property or procedure modifier keywords (such as `Public` or `Shared`)
- **Optional Modifier.** You do not have to use the `Overloads` modifier when you are defining multiple overloaded properties or procedures in the same class. However, if you use `Overloads` in one of the declarations, you must use it in all of them.

- **Shadowing and Overloading.** `Overloads` can also be used to shadow an existing member, or set of overloaded members, in a base class. When you use `Overloads` in this way, you declare the property or method with the same name and the same parameter list as the base class member, and you do not supply the `Shadows` keyword.

If you use `Overrides`, the compiler implicitly adds `overloads` so that your library APIs work with C# more easily.

The `Overloads` modifier can be used in these contexts:

Overridable (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a property or procedure can be overridden by an identically named property or procedure in a derived class.

Remarks

The `Overridable` modifier allows a property or method in a class to be overridden in a derived class. The `NotOverridable` modifier prevents a property or method from being overridden in a derived class. For more information, see [Inheritance Basics](#).

If the `Overridable` or `NotOverridable` modifier is not specified, the default setting depends on whether the property or method overrides a base class property or method. If the property or method overrides a base class property or method, the default setting is `Overridable`; otherwise, it is `NotOverridable`.

You can shadow or override to redefine an inherited element, but there are significant differences between the two approaches. For more information, see [Shadowing in Visual Basic](#).

An element that can be overridden is sometimes referred to as a *virtual* element. If it can be overridden, but does not have to be, it is sometimes also called a *concrete* element.

You can use `Overridable` only in a property or procedure declaration statement.

Combined Modifiers

You cannot specify `Overridable` or `NotOverridable` for a `Private` method.

You cannot specify `Overridable` together with `MustOverride`, `NotOverridable`, or `Shared` in the same declaration.

Because an overriding element is implicitly overridable, you cannot combine `Overridable` with `Overrides`.

Usage

The `Overridable` modifier can be used in these contexts:

Overrides (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a property or procedure overrides an identically named property or procedure inherited from a base class.

Remarks

Rules

- **Declaration Context.** You can use `Overrides` only in a property or procedure declaration statement.
- **Combined Modifiers.** You cannot specify `Overrides` together with `Shadows` or `Shared` in the same declaration. Because an overriding element is implicitly overridable, you cannot combine `Overridable` with `Overrides`.
- **Matching Signatures.** The signature of this declaration must exactly match the *signature* of the property or procedure that it overrides. This means the parameter lists must have the same number of parameters, in the same order, with the same data types.

In addition to the signature, the overriding declaration must also exactly match the following:

- The access level
 - The return type, if any
- **Generic Signatures.** For a generic procedure, the signature includes the number of type parameters. Therefore, the overriding declaration must match the base class version in that respect as well.
 - **Additional Matching.** In addition to matching the signature of the base class version, this declaration must also match it in the following respects:
 - Access-level modifier (such as `Public`)
 - Passing mechanism of each parameter (`ByVal` or `ByRef`)
 - Constraint lists on each type parameter of a generic procedure
 - **Shadowing and Overriding.** Both shadowing and overriding redefine an inherited element, but there are significant differences between the two approaches. For more information, see [Shadowing in Visual Basic](#).

If you use `Overrides`, the compiler implicitly adds `Overloads` so that your library APIs work with C# more easily.

The `Overrides` modifier can be used in these contexts:

ParamArray (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a procedure parameter takes an optional array of elements of the specified type. `ParamArray` can be used only on the last parameter of a parameter list.

Remarks

`ParamArray` allows you to pass an arbitrary number of arguments to the procedure. A `ParamArray` parameter is always declared using [ByVal](#).

You can supply one or more arguments to a `ParamArray` parameter by passing an array of the appropriate data type, a comma-separated list of values, or nothing at all. For details, see "Calling a ParamArray" in [Parameter Arrays](#).

IMPORTANT

Whenever you deal with an array which can be indefinitely large, there is a risk of overrunning some internal capacity of your application. If you accept a parameter array from the calling code, you should test its length and take appropriate steps if it is too large for your application.

The `ParamArray` modifier can be used in these contexts:

Partial (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Indicates that a type declaration is a partial definition of the type.

You can divide the definition of a type among several declarations by using the `Partial` keyword. You can use as many partial declarations as you want, in as many different source files as you want. However, all the declarations must be in the same assembly and the same namespace.

NOTE

Visual Basic supports *partial methods*, which are typically implemented in partial classes. For more information, see [Partial Methods](#) and [Sub Statement](#).

Syntax

```
[ <attrlist> ] [ accessmodifier ] [ Shadows ] [ MustInherit | NotInheritable ] _  
Partial { Class | Structure | Interface | Module } name [ (Of typelist) ]  
    [ Inherits classname ]  
    [ Implements interfacenames ]  
    [ variabledeclarations ]  
    [ proceduredeclarations ]  
{ End Class | End Structure }
```

Parts

TERM	DEFINITION
<code>attrlist</code>	Optional. List of attributes that apply to this type. You must enclose the Attribute List in angle brackets (<code><></code>).
<code>accessmodifier</code>	Optional. Specifies what code can access this type. See Access levels in Visual Basic .
<code>Shadows</code>	Optional. See Shadows .
<code>MustInherit</code>	Optional. See MustInherit .
<code>NotInheritable</code>	Optional. See NotInheritable .
<code>name</code>	Required. Name of this type. Must match the name defined in all other partial declarations of the same type.
<code>of</code>	Optional. Specifies that this is a generic type. See Generic Types in Visual Basic .
<code>typelist</code>	Required if you use <code>Of</code> . See Type List .
<code>Inherits</code>	Optional. See Inherits Statement .

TERM	DEFINITION
<code>classname</code>	Required if you use <code>Inherits</code> . The name of the class or interface from which this class derives.
<code>Implements</code>	Optional. See Implements Statement .
<code>interfacenames</code>	Required if you use <code>Implements</code> . The names of the interfaces this type implements.
<code>variabledeclarations</code>	Optional. Statements which declare additional variables and events for the type.
<code>proceduredeclarations</code>	Optional. Statements which declare and define additional procedures for the type.
<code>End Class</code> or <code>End Structure</code>	Ends this partial <code>Class</code> or <code>Structure</code> definition.

Remarks

Visual Basic uses partial-class definitions to separate generated code from user-authored code in separate source files. For example, the **Windows Form Designer** defines partial classes for controls such as `Form`. You should not modify the generated code in these controls.

All the rules for class, structure, interface, and module creation, such as those for modifier usage and inheritance, apply when creating a partial type.

Best Practices

- Under normal circumstances, you should not split the development of a single type across two or more declarations. Therefore, in most cases you do not need the `Partial` keyword.
- For readability, every partial declaration of a type should include the `Partial` keyword. The compiler allows at most one partial declaration to omit the keyword; if two or more omit it the compiler signals an error.

Behavior

- Union of Declarations.** The compiler treats the type as the union of all its partial declarations. Every modifier from every partial definition applies to the entire type, and every member from every partial definition is available to the entire type.
- Type Promotion Not Allowed For Partial Types in Modules.** If a partial definition is inside a module, type promotion of that type is automatically defeated. In such a case, a set of partial definitions can cause unexpected results and even compiler errors. For more information, see [Type Promotion](#).

The compiler merges partial definitions only when their fully qualified paths are identical.

The `Partial` keyword can be used in these contexts:

[Class Statement](#)

[Structure Statement](#)

Example

The following example splits the definition of class `sampleClass` into two declarations, each of which defines a different `Sub` procedure.

```
Partial Public Class sampleClass
    Public Sub sub1()
    End Sub
End Class
Partial Public Class sampleClass
    Public Sub sub2()
    End Sub
End Class
```

The two partial definitions in the preceding example could be in the same source file or in two different source files.

Private (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that one or more declared programming elements are accessible only from within their declaration context, including from within any contained types.

Remarks

If a programming element represents proprietary functionality, or contains confidential data, you usually want to limit access to it as strictly as possible. You achieve the maximum limitation by allowing only the module, class, or structure that defines it to access it. To limit access to an element in this way, you can declare it with `Private`.

NOTE

You can also use the [Private Protected](#) access modifier, which makes a member accessible from within that class and from derived classes located in its containing assembly.

Rules

- **Declaration Context.** You can use `Private` only at module level. This means the declaration context for a `Private` element must be a module, class, or structure, and cannot be a source file, namespace, interface, or procedure.

Behavior

- **Access Level.** All code within a declaration context can access its `Private` elements. This includes code within a contained type, such as a nested class or an assignment expression in an enumeration. No code outside of the declaration context can access its `Private` elements.
- **Access Modifiers.** The keywords that specify access level are called *access modifiers*. For a comparison of the access modifiers, see [Access levels in Visual Basic](#).

The `Private` modifier can be used in these contexts:

Private Protected (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

The `Private Protected` keyword combination is a member access modifier. A `Private Protected` member is accessible by all members in its containing class, as well as by types derived from the containing class, but only if they are found in its containing assembly.

You can specify `Private Protected` only on members of classes; you cannot apply `Private Protected` to members of a structure because structures cannot be inherited.

The `Private Protected` access modifier is supported by Visual Basic 15.5 and later. To use it, you can add the following element to your Visual Basic project (\*.vbproj) file. As long as Visual Basic 15.5 or later is installed on your system, it lets you take advantage of all the language features supported by the latest version of the Visual Basic compiler:

```
<PropertyGroup>
    <LangVersion>latest</LangVersion>
</PropertyGroup>
```

For more information see [setting the Visual Basic language version](#).

NOTE

In Visual Studio, selecting F1 help on `private protected` provides help for either `private` or `protected`. The IDE picks the single token under the cursor rather than the compound word.

Rules

- **Declaration Context.** You can use `Private Protected` only at the class level. This means the declaration context for a `Protected` element must be a class, and cannot be a source file, namespace, interface, module, structure, or procedure.

Behavior

- **Access Level.** All code in a class can access its elements. Code in any class that derives from a base class and is contained in the same assembly can access all the `Private Protected` elements of the base class. However, code in any class that derives from a base class and is contained in a different assembly can't access the base class `Private Protected` elements.
- **Access Modifiers.** The keywords that specify access level are called *access modifiers*. For a comparison of the access modifiers, see [Access levels in Visual Basic](#).

The `Private Protected` modifier can be used in these contexts:

- [Class Statement](#) of a nested class
- [Const Statement](#)
- [Declare Statement](#)
- [Delegate Statement](#) of a delegate nested in a class

- [Dim Statement](#)

Protected (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

A member access modifier that specifies that one or more declared programming elements are accessible only from within their own class or from a derived class.

Remarks

Sometimes a programming element declared in a class contains sensitive data or restricted code, and you want to limit access to the element. However, if the class is inheritable and you expect a hierarchy of derived classes, it might be necessary for these derived classes to access the data or code. In such a case, you want the element to be accessible both from the base class and from all derived classes. To limit access to an element in this manner, you can declare it with `Protected`.

NOTE

The `Protected` access modifier can be combined with two other modifiers:

- The `Protected Friend` modifier makes a class member accessible from within that class, from derived classes, and from the same assembly in which the class is defined.
- The `Private Protected` modifier makes a class member accessible by derived types, but only within its containing assembly.

Rules

- **Declaration Context.** You can use `Protected` only at the class level. This means the declaration context for a `Protected` element must be a class, and cannot be a source file, namespace, interface, module, structure, or procedure.

Behavior

- **Access Level.** All code in a class can access its elements. Code in any class that derives from a base class can access all the `Protected` elements of the base class. This is true for all generations of derivation. This means that a class can access `Protected` elements of the base class of the base class, and so on.

Protected access is not a superset or subset of friend access.

- **Access Modifiers.** The keywords that specify access level are called *access modifiers*. For a comparison of the access modifiers, see [Access levels in Visual Basic](#).

The `Protected` modifier can be used in these contexts:

Protected Friend (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The `Protected Friend` keyword combination is a member access modifier. It confers both [Friend](#) access and [Protected](#) access on the declared elements, so they are accessible from anywhere in the same assembly, from their own class, and from derived classes. You can specify `Protected Friend` only on members of classes; you cannot apply `Protected Friend` to members of a structure because structures cannot be inherited.

NOTE

In Visual Studio, selecting F1 help on `protected friend` provides help for either [protected](#) or [friend](#). The IDE picks the single token under the cursor rather than the compound word.

Rules

- **Declaration Context.** You can use `Protected Friend` only at the class level. This means the declaration context for a `Protected` element must be a class, and cannot be a source file, namespace, interface, module, structure, or procedure.

Public (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that one or more declared programming elements have no access restrictions.

Remarks

If you are publishing a component or set of components, such as a class library, you usually want the programming elements to be accessible by any code that interoperates with your assembly. To confer such unlimited access on an element, you can declare it with `Public`.

Public access is the normal level for a programming element when you do not need to limit access to it. Note that the access level of an element declared within an interface, module, class, or structure defaults to `Public` if you do not declare it otherwise.

Rules

- **Declaration Context.** You can use `Public` only at module, interface, or namespace level. This means the declaration context for a `Public` element must be a source file, namespace, interface, module, class, or structure, and cannot be a procedure.

Behavior

- **Access Level.** All code that can access a module, class, or structure can access its `Public` elements.
- **Default Access.** Local variables inside a procedure default to public access, and you cannot use any access modifiers on them.
- **Access Modifiers.** The keywords that specify access level are called *access modifiers*. For a comparison of the access modifiers, see [Access levels in Visual Basic](#).

The `Public` modifier can be used in these contexts:

ReadOnly (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a variable or property can be read but not written.

Remarks

Rules

- **Declaration Context.** You can use `ReadOnly` only at module level. This means the declaration context for a `ReadOnly` element must be a class, structure, or module, and cannot be a source file, namespace, or procedure.
- **Combined Modifiers.** You cannot specify `ReadOnly` together with `static` in the same declaration.
- **Assigning a Value.** Code consuming a `ReadOnly` property cannot set its value. But code that has access to the underlying storage can assign or change the value at any time.

You can assign a value to a `ReadOnly` variable only in its declaration or in the constructor of a class or structure in which it is defined.

When to Use a ReadOnly Variable

There are situations in which you cannot use a [Const Statement](#) to declare and assign a constant value. For example, the `Const` statement might not accept the data type you want to assign, or you might not be able to compute the value at compile time with a constant expression. You might not even know the value at compile time. In these cases, you can use a `ReadOnly` variable to hold a constant value.

IMPORTANT

If the data type of the variable is a reference type, such as an array or a class instance, its members can be changed even if the variable itself is `ReadOnly`. The following example illustrates this.

```
ReadOnly characterArray() As Char = {"x"c, "y"c, "z"c}

Sub changeArrayElement()

    characterArray(1) = "M"c

End Sub
```

When initialized, the array pointed to by `characterArray()` holds "x", "y", and "z". Because the variable `characterArray` is `ReadOnly`, you cannot change its value once it is initialized; that is, you cannot assign a new array to it. However, you can change the values of one or more of the array members. Following a call to the procedure `changeArrayElement`, the array pointed to by `characterArray()` holds "x", "M", and "z".

Note that this is similar to declaring a procedure parameter to be [ByVal](#), which prevents the procedure from changing the calling argument itself but allows it to change its members.

Example

The following example defines a `ReadOnly` property for the date on which an employee was hired. The class stores the property value internally as a `Private` variable, and only code inside the class can change that value. However, the property is `Public`, and any code that can access the class can read the property.

```
Class employee
    ' Only code inside class employee can change the value of hireDateValue.
    Private hireDateValue As Date
    ' Any code that can access class employee can read property dateHired.
    Public ReadOnly Property dateHired() As Date
        Get
            Return hireDateValue
        End Get
    End Property
End Class
```

The `ReadOnly` modifier can be used in these contexts:

Shadows (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a declared programming element redeclares and hides an identically named element, or set of overloaded elements, in a base class.

Remarks

The main purpose of shadowing (which is also known as *hiding by name*) is to preserve the definition of your class members. The base class might undergo a change that creates an element with the same name as one you have already defined. If this happens, the `Shadows` modifier forces references through your class to be resolved to the member you defined, instead of to the new base class element.

Both shadowing and overriding redefine an inherited element, but there are significant differences between the two approaches. For more information, see [Shadowing in Visual Basic](#).

Rules

- **Declaration Context.** You can use `Shadows` only at class level. This means the declaration context for a `Shadows` element must be a class, and cannot be a source file, namespace, interface, module, structure, or procedure.

You can declare only one shadowing element in a single declaration statement.

- **Combined Modifiers.** You cannot specify `Shadows` together with `Overloads`, `Overrides`, or `Static` in the same declaration.
- **Element Types.** You can shadow any kind of declared element with any other kind. If you shadow a property or procedure with another property or procedure, the parameters and the return type do not have to match those in the base class property or procedure.
- **Accessing.** The shadowed element in the base class is normally unavailable from within the derived class that shadows it. However, the following considerations apply.
 - If the shadowing element is not accessible from the code referring to it, the reference is resolved to the shadowed element. For example, if a `Private` element shadows a base class element, code that does not have permission to access the `Private` element accesses the base class element instead.
 - If you shadow an element, you can still access the shadowed element through an object declared with the type of the base class. You can also access it through `MyBase`.

The `Shadows` modifier can be used in these contexts:

Shared (Visual Basic)

1/23/2019 • 3 minutes to read • [Edit Online](#)

Specifies that one or more declared programming elements are associated with a class or structure at large, and not with a specific instance of the class or structure.

Remarks

When to Use Shared

Sharing a member of a class or structure makes it available to every instance, rather than *nonshared*, where each instance keeps its own copy. This is useful, for example, if the value of a variable applies to the entire application. If you declare that variable to be `Shared`, then all instances access the same storage location, and if one instance changes the variable's value, all instances access the updated value.

Sharing does not alter the access level of a member. For example, a class member can be shared and private (accessible only from within the class), or nonshared and public. For more information, see [Access levels in Visual Basic](#).

Rules

- **Declaration Context.** You can use `Shared` only at module level. This means the declaration context for a `Shared` element must be a class or structure, and cannot be a source file, namespace, or procedure.
- **Combined Modifiers.** You cannot specify `Shared` together with [Overrides](#), [Overridable](#), [NotOverridable](#), [MustOverride](#), or [Static](#) in the same declaration.
- **Accessing.** You access a shared element by qualifying it with its class or structure name, not with the variable name of a specific instance of its class or structure. You do not even have to create an instance of a class or structure to access its shared members.

The following example calls the shared procedure `IsNaN` exposed by the [Double](#) structure.

```
If Double.NaN(result) Then MsgBox("Result is mathematically undefined.")
```

- **Implicit Sharing.** You cannot use the `Shared` modifier in a [Const Statement](#), but constants are implicitly shared. Similarly, you cannot declare a member of a module or an interface to be `Shared`, but they are implicitly shared.

Behavior

- **Storage.** A shared variable or event is stored in memory only once, no matter how many or few instances you create of its class or structure. Similarly, a shared procedure or property holds only one set of local variables.
- **Accessing through an Instance Variable.** It is possible to access a shared element by qualifying it with the name of a variable that contains a specific instance of its class or structure. Although this usually works as expected, the compiler generates a warning message and makes the access through the class or structure name instead of the variable.
- **Accessing through an Instance Expression.** If you access a shared element through an expression that returns an instance of its class or structure, the compiler makes the access through the class or

structure name instead of evaluating the expression. This produces unexpected results if you intended the expression to perform other actions as well as returning the instance. The following example illustrates this.

```
Sub main()
    shareTotal.total = 10
    ' The preceding line is the preferred way to access total.
    Dim instanceVar As New shareTotal
    instanceVar.total += 100
    ' The preceding line generates a compiler warning message and
    ' accesses total through class shareTotal instead of through
    ' the variable instanceVar. This works as expected and adds
    ' 100 to total.
    returnClass().total += 1000
    ' The preceding line generates a compiler warning message and
    ' accesses total through class shareTotal instead of calling
    ' returnClass(). This adds 1000 to total but does not work as
    ' expected, because the MsgBox in returnClass() does not run.
    MsgBox("Value of total is " & CStr(shareTotal.total))
End Sub
Public Function returnClass() As shareTotal
    MsgBox("Function returnClass() called")
    Return New shareTotal
End Function
Public Class shareTotal
    Public Shared total As Integer
End Class
```

In the preceding example, the compiler generates a warning message both times the code accesses the shared variable `total` through an instance. In each case it makes the access directly through the class `shareTotal` and does not make use of any instance. In the case of the intended call to the procedure `returnClass`, this means it does not even generate a call to `returnClass`, so the additional action of displaying "Function returnClass() called" is not performed.

The `Shared` modifier can be used in these contexts:

Static (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies that one or more declared local variables are to continue to exist and retain their latest values after termination of the procedure in which they are declared.

Remarks

Normally, a local variable in a procedure ceases to exist as soon as the procedure stops. A static variable continues to exist and retains its most recent value. The next time your code calls the procedure, the variable is not reinitialized, and it still holds the latest value that you assigned to it. A static variable continues to exist for the lifetime of the class or module that it is defined in.

Rules

- **Declaration Context.** You can use `Static` only on local variables. This means the declaration context for a `Static` variable must be a procedure or a block in a procedure, and it cannot be a source file, namespace, class, structure, or module.

You cannot use `Static` inside a structure procedure.
- The data types of `Static` local variables cannot be inferred. For more information, see [Local Type Inference](#).
- **Combined Modifiers.** You cannot specify `Static` together with `ReadOnly`, `Shadows`, or `Shared` in the same declaration.

Behavior

When you declare a static variable in a `Shared` procedure, only one copy of the static variable is available for the whole application. You call a `Shared` procedure by using the class name, not a variable that points to an instance of the class.

When you declare a static variable in a procedure that isn't `Shared`, only one copy of the variable is available for each instance of the class. You call a non-shared procedure by using a variable that points to a specific instance of the class.

Example

The following example demonstrates the use of `Static`.

```
Function updateSales(ByVal thisSale As Decimal) As Decimal
    Static totalSales As Decimal = 0
    totalSales += thisSale
    Return totalSales
End Function
```

The `Static` variable `totalSales` is initialized to 0 only one time. Each time that you enter `updateSales`, `totalSales` still has the most recent value that you calculated for it.

The `Static` modifier can be used in this context:

Unicode (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that Visual Basic should marshal all strings to Unicode values regardless of the name of the external procedure being declared.

When you call a procedure defined outside your project, the Visual Basic compiler does not have access to the information it must have in order to call the procedure correctly. This information includes where the procedure is located, how it is identified, its calling sequence and return type, and the string character set it uses. The [Declare Statement](#) creates a reference to an external procedure and supplies this necessary information.

The `charsetmodifier` part in the `Declare` statement supplies the character set information to marshal strings during a call to the external procedure. It also affects how Visual Basic searches the external file for the external procedure name. The `Unicode` modifier specifies that Visual Basic should marshal all strings to Unicode values and should look up the procedure without modifying its name during the search.

If no character set modifier is specified, `Ansi` is the default.

Remarks

The `Unicode` modifier can be used in this context:

Widening (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Indicates that a conversion operator (`CType`) converts a class or structure to a type that can hold all possible values of the original class or structure.

Converting with the Widening Keyword

The conversion procedure must specify `Public Shared` in addition to `Widening`.

Widening conversions always succeed at run time and never incur data loss. Examples are `Single` to `Double`, `Char` to `String`, and a derived type to its base type. This last conversion is widening because the derived type contains all the members of the base type and thus is an instance of the base type.

The consuming code does not have to use `CType` for widening conversions, even if `Option Strict` is `On`.

The `Widening` keyword can be used in this context:

Operator Statement

WithEvents (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that one or more declared member variables refer to an instance of a class that can raise events.

Remarks

When a variable is defined using `WithEvents`, you can declaratively specify that a method handles the variable's events using the `Handles` keyword.

You can use `WithEvents` only at class or module level. This means the declaration context for a `WithEvents` variable must be a class or module and cannot be a source file, namespace, structure, or procedure.

You cannot use `WithEvents` on a structure member.

You can declare only individual variables—not arrays—with `WithEvents`.

Rules

- **Element Types.** You must declare `WithEvents` variables to be object variables so that they can accept class instances. However, you cannot declare them as `Object`. You must declare them as the specific class that can raise the events.

The `WithEvents` modifier can be used in this context: [Dim Statement](#)

WriteOnly (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that a property can be written but not read.

Remarks

Rules

Declaration Context. You can use `WriteOnly` only at module level. This means the declaration context for a `WriteOnly` property must be a class, structure, or module, and cannot be a source file, namespace, or procedure.

You can declare a property as `WriteOnly`, but not a variable.

When to Use WriteOnly

Sometimes you want the consuming code to be able to set a value but not discover what it is. For example, sensitive data, such as a social registration number or a password, needs to be protected from access by any component that did not set it. In these cases, you can use a `WriteOnly` property to set the value.

IMPORTANT

When you define and use a `WriteOnly` property, consider the following additional protective measures:

- **Overriding.** If the property is a member of a class, allow it to default to `NotOverridable`, and do not declare it `Overridable` or `MustOverride`. This prevents a derived class from making undesired access through an override.
- **Access Level.** If you hold the property's sensitive data in one or more variables, declare them `Private` so that no other code can access them.
- **Encryption.** Store all sensitive data in encrypted form rather than in plain text. If malicious code somehow gains access to that area of memory, it is more difficult to make use of the data. Encryption is also useful if it is necessary to serialize the sensitive data.
- **Resetting.** When the class, structure, or module defining the property is being terminated, reset the sensitive data to default values or to other meaningless values. This gives extra protection when that area of memory is freed for general access.
- **Persistence.** Do not persist any sensitive data, for example on disk, if you can avoid it. Also, do not write any sensitive data to the Clipboard.

The `WriteOnly` modifier can be used in this context:

Modules (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Visual Basic provides several modules that enable you to simplify common tasks in your code, including manipulating strings, performing mathematical calculations, getting system information, performing file and directory operations, and so on. The following table lists the modules provided by Visual Basic.

Constants	Contains miscellaneous constants. These constants can be used anywhere in your code.
ControlChars	Contains constant control characters for printing and displaying text.
Conversion	Contains members that convert decimal numbers to other bases, numbers to strings, strings to numbers, and one data type to another.
DateAndTime	Contains members that get the current date or time, perform date calculations, return a date or time, set the date or time, or time the duration of a process.
ErrObject	Contains information about run-time errors and methods to raise or clear an error.
FileSystem	Contains members that perform file, directory or folder, and system operations.
Financial	Contains procedures that are used to perform financial calculations.
Globals	Contains information about the current scripting engine version.
Information	Contains the members that return, test for, or verify information such as array size, type names, and so on.
Interaction	Contains members interact with objects, applications, and systems.
Strings	Contains members that perform string operations such as reformatting strings, searching a string, getting the length of a string, and so on.
VBMATH	Contains members perform mathematical operations.

Nothing (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Represents the default value of any data type. For reference types, the default value is the `null` reference. For value types, the default value depends on whether the value type is nullable.

NOTE

For non-nullable value types, `Nothing` in Visual Basic differs from `null` in C#. In Visual Basic, if you set a variable of a non-nullable value type to `Nothing`, the variable is set to the default value for its declared type. In C#, if you assign a variable of a non-nullable value type to `null`, a compile-time error occurs.

Remarks

`Nothing` represents the default value of a data type. The default value depends on whether the variable is of a value type or of a reference type.

A variable of a *value type* directly contains its value. Value types include all numeric data types, `Boolean`, `Char`, `Date`, all structures, and all enumerations. A variable of a *reference type* stores a reference to an instance of the object in memory. Reference types include classes, arrays, delegates, and strings. For more information, see [Value Types and Reference Types](#).

If a variable is of a value type, the behavior of `Nothing` depends on whether the variable is of a nullable data type. To represent a nullable value type, add a `?` modifier to the type name. Assigning `Nothing` to a nullable variable sets the value to `null`. For more information and examples, see [Nullable Value Types](#).

If a variable is of a value type that is not nullable, assigning `Nothing` to it sets it to the default value for its declared type. If that type contains variable members, they are all set to their default values. The following example illustrates this for scalar types.

```

Module Module1

Sub Main()
    Dim ts As TestStruct
    Dim i As Integer
    Dim b As Boolean

    ' The following statement sets ts.Name to Nothing and ts.Number to 0.
    ts = Nothing

    ' The following statements set i to 0 and b to False.
    i = Nothing
    b = Nothing

    Console.WriteLine("ts.Name: " & ts.Name)
    Console.WriteLine("ts.Number: " & ts.Number)
    Console.WriteLine("i: " & i)
    Console.WriteLine("b: " & b)

    Console.ReadKey()
End Sub

Public Structure TestStruct
    Public Name As String
    Public Number As Integer
End Structure
End Module

```

If a variable is of a reference type, assigning `Nothing` to the variable sets it to a `null` reference of the variable's type. A variable that is set to a `null` reference is not associated with any object. The following example demonstrates this.

```

Module Module1

Sub Main()

    Dim testObject As Object
    ' The following statement sets testObject so that it does not refer to
    ' any instance.
    testObject = Nothing

    Dim tc As New TestClass
    tc = Nothing
    ' The fields of tc cannot be accessed. The following statement causes
    ' a NullReferenceException at run time. (Compare to the assignment of
    ' Nothing to structure ts in the previous example.)
    'Console.WriteLine(tc.Field1)

End Sub

Class TestClass
    Public Field1 As Integer
    ' ...
End Class
End Module

```

When checking whether a reference (or nullable value type) variable is `null`, do not use `= Nothing` or `<> Nothing`. Always use `Is Nothing` or `IsNot Nothing`.

For strings in Visual Basic, the empty string equals `Nothing`. Therefore, `"" = Nothing` is true.

The following example shows comparisons that use the `Is` and `IsNot` operators.

```

Module Module1
    Sub Main()

        Dim testObject As Object
        testObject = Nothing
        Console.WriteLine(testObject Is Nothing)
        ' Output: True

        Dim tc As New TestClass
        tc = Nothing
        Console.WriteLine(tc IsNot Nothing)
        ' Output: False

        ' Declare a nullable value type.
        Dim n? As Integer
        Console.WriteLine(n Is Nothing)
        ' Output: True

        n = 4
        Console.WriteLine(n Is Nothing)
        ' Output: False

        n = Nothing
        Console.WriteLine(n IsNot Nothing)
        ' Output: False

        Console.ReadKey()
    End Sub

    Class TestClass
        Public Field1 As Integer
        Private field2 As Boolean
    End Class
End Module

```

If you declare a variable without using an `As` clause and set it to `Nothing`, the variable has a type of `Object`. An example of this is `Dim something = Nothing`. A compile-time error occurs in this case when `Option Strict` is on and `Option Infer` is off.

When you assign `Nothing` to an object variable, it no longer refers to any object instance. If the variable had previously referred to an instance, setting it to `Nothing` does not terminate the instance itself. The instance is terminated, and the memory and system resources associated with it are released, only after the garbage collector (GC) detects that there are no active references remaining.

`Nothing` differs from the `DBNull` object, which represents an uninitialized variant or a nonexistent database column.

Objects (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic provides links to other topics that document the Visual Basic run-time objects and contain tables of their member procedures, properties, and events.

Visual Basic Run-time Objects

Collection	Provides a convenient way to see a related group of items as a single object.
Err	Contains information about run-time errors.
<p>The <code>My.Application</code> object consists of the following classes:</p> <p>ApplicationBase provides members that are available in all projects.</p> <p>WindowsFormsApplicationBase provides members available in Windows Forms applications.</p> <p>ConsoleApplicationBase provides members available in console applications.</p>	<p>Provides data that is associated only with the current application or DLL. No system-level information can be altered with <code>My.Application</code>.</p> <p>Some members are available only for Windows Forms or console applications.</p>
My.Application.Info (Info)	Provides properties for getting the information about an application, such as the version number, description, loaded assemblies, and so on.
My.Application.Log (Log)	Provides a property and methods to write event and exception information to the application's log listeners.
My.Computer (Computer)	Provides properties for manipulating computer components such as audio, the clock, the keyboard, the file system, and so on.
My.Computer.Audio (Audio)	Provides methods for playing sounds.
My.Computer.Clipboard (Clipboard)	Provides methods for manipulating the Clipboard.
My.Computer.Clock (Clock)	Provides properties for accessing the current local time and Universal Coordinated Time (equivalent to Greenwich Mean Time) from the system clock.
My.Computer.FileSystem (FileSystem)	Provides properties and methods for working with drives, files, and directories.
My.Computer.FileSystem.SpecialDirectories (SpecialDirectories)	Provides properties for accessing commonly referenced directories.

<code>My.Computer.Info</code> (ComputerInfo)	Provides properties for getting information about the computer's memory, loaded assemblies, name, and operating system.
<code>My.Computer.Keyboard</code> (Keyboard)	Provides properties for accessing the current state of the keyboard, such as what keys are currently pressed, and provides a method to send keystrokes to the active window.
<code>My.Computer.Mouse</code> (Mouse)	Provides properties for getting information about the format and configuration of the mouse that is installed on the local computer.
<code>My.Computer.Network</code> (Network)	Provides a property, an event, and methods for interacting with the network to which the computer is connected.
<code>My.Computer.Ports</code> (Ports)	Provides a property and a method for accessing the computer's serial ports.
<code>My.Computer.Registry</code> (RegistryProxy)	Provides properties and methods for manipulating the registry.
My.Forms Object	Provides properties for accessing an instance of each Windows Form declared in the current project.
<code>My.Log</code> (AspLog)	Provides a property and methods for writing event and exception information to the application's log listeners for Web applications.
My.Request Object	<p>Gets the HttpRequest object for the requested page. The <code>My.Request</code> object contains information about the current HTTP request.</p> <p>The <code>My.Request</code> object is available only for ASP.NET applications.</p>
My.Resources Object	Provides properties and classes for accessing an application's resources.
My.Response Object	<p>Gets the HttpResponse object that is associated with the Page. This object allows you to send HTTP response data to a client and contains information about that response.</p> <p>The <code>My.Response</code> object is available only for ASP.NET applications.</p>
My.Settings Object	Provides properties and methods for accessing an application's settings.
<code>My.User</code> (User)	Provides access to information about the current user.
My.WebServices Object	Provides properties for creating and accessing a single instance of each Web service that is referenced by the current project.

My.Forms Object

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides properties for accessing an instance of each Windows form declared in the current project.

Remarks

The `My.Forms` object provides an instance of each form in the current project. The name of the property is the same as the name of the form that the property accesses.

You can access the forms provided by the `My.Forms` object by using the name of the form, without qualification. Because the property name is the same as the form's type name, this allows you to access a form as if it had a default instance. For example, `My.Forms.Form1.Show` is equivalent to `Form1.Show`.

The `My.Forms` object exposes only the forms associated with the current project. It does not provide access to forms declared in referenced DLLs. To access a form that a DLL provides, you must use the qualified name of the form, written as `DllName.FormName`.

You can use the [OpenForms](#) property to get a collection of all the application's open forms.

The object and its properties are available only for Windows applications.

Properties

Each property of the `My.Forms` object provides access to an instance of a form in the current project. The name of the property is the same as the name of the form that the property accesses, and the property type is the same as the form's type.

NOTE

If there is a name collision, the property name to access a form is `RootNamespace_Namespace_FormName`. For example, consider two forms named `Form1`. If one of these forms is in the root namespace `WindowsApplication1` and in the namespace `Namespace1`, you would access that form through `My.Forms.WindowsApplication1_Namespace1_Form1`.

The `My.Forms` object provides access to the instance of the application's main form that was created on startup. For all other forms, the `My.Forms` object creates a new instance of the form when it is accessed and stores it. Subsequent attempts to access that property return that instance of the form.

You can dispose of a form by assigning `Nothing` to the property for that form. The property setter calls the `Close` method of the form, and then assigns `Nothing` to the stored value. If you assign any value other than `Nothing` to the property, the setter throws an [ArgumentException](#) exception.

You can test whether a property of the `My.Forms` object stores an instance of the form by using the `Is` or `IsNot` operator. You can use those operators to check if the value of the property is `Nothing`.

NOTE

Typically, the `Is` or `IsNot` operator has to read the value of the property to perform the comparison. However, if the property currently stores `Nothing`, the property creates a new instance of the form and then returns that instance. However, the Visual Basic compiler treats the properties of the `My.Forms` object differently and allows the `Is` or `IsNot` operator to check the status of the property without altering its value.

Example

This example changes the title of the default `SidebarMenu` form.

```
Sub ShowSidebarMenu(ByVal newTitle As String)
    If My.Forms.SidebarMenu IsNot Nothing Then
        My.Forms.SidebarMenu.Text = newTitle
    End If
End Sub
```

For this example to work, your project must have a form named `SidebarMenu`.

This code will work only in a Windows Application project.

My.Log Object

7/13/2018 • 2 minutes to read • [Edit Online](#)

Provides a property and methods for writing event and exception information to the application's log listeners.

Remarks

For information about the methods and properties of the `My.Log` object, see [AspLog](#).

The `My.Log` object is available for ASP.NET applications only. For client applications, use [My.Application.Log Object](#).

Requirements

Namespace: [Microsoft.VisualBasic.Logging](#)

Class: [AspLog](#)

Assembly: Visual Basic Runtime Library (in Microsoft.VisualBasic.dll)

My.Request Object

3/1/2019 • 2 minutes to read • [Edit Online](#)

Gets the [HttpRequest](#) object for the requested page.

Remarks

The `My.Request` object contains information about the current HTTP request.

The `My.Request` object is available only for ASP.NET applications.

Example

The following example gets the header collection from the `My.Request` object and uses the `My.Response` object to write it to the ASP.NET page.

My.Response Object

3/1/2019 • 2 minutes to read • [Edit Online](#)

Gets the [HttpResponse](#) object associated with the [Page](#). This object allows you to send HTTP response data to a client and contains information about that response.

Remarks

The `My.Response` object contains the current [HttpResponse](#) object associated with the page.

The `My.Response` object is only available for ASP.NET applications.

Example

The following example gets the header collection from the `My.Request` object and uses the `My.Response` object to write it to the ASP.NET page.

My.Resources Object

2/28/2019 • 3 minutes to read • [Edit Online](#)

Provides properties and classes for accessing the application's resources.

Remarks

The `My.Resources` object provides access to the application's resources and lets you dynamically retrieve resources for your application. For more information, see [Managing Application Resources \(.NET\)](#).

The `My.Resources` object exposes only global resources. It does not provide access to resource files associated with forms. You must access the form resources from the form.

You can access the application's culture-specific resource files from the `My.Resources` object. By default, the `My.Resources` object looks up resources from the resource file that matches the culture in the `UICulture` property. However, you can override this behavior and specify a particular culture to use for the resources. For more information, see [Resources in Desktop Apps](#).

Properties

The properties of the `My.Resources` object provide read-only access to your application's resources. To add or remove resources, use the **Project Designer**. You can access resources added through the **Project Designer** by using `My.Resources.resourceName`.

You can also add or remove resource files by selecting your project in **Solution Explorer** and clicking **Add New Item** or **Add Existing Item** from the **Project** menu. You can access resources added in this manner by using `My.Resources.resourceFileName.resourceName`.

Each resource has a name, category, and value, and these resource settings determine how the property to access the resource appears in the `My.Resources` object. For resources added in the **Project Designer**:

- The name determines the name of the property,
- The resource data is the value of the property,
- The category determines the type of the property:

CATEGORY	PROPERTY DATA TYPE
Strings	String
Images	Bitmap
Icons	Icon
Audio	UnmanagedMemoryStream The <code>UnmanagedMemoryStream</code> class derives from the <code>Stream</code> class, so it can be used with methods that take streams, such as the <code>Play</code> method.

CATEGORY	PROPERTY DATA TYPE
Files	<ul style="list-style-type: none"> - String for text files. - Bitmap for image files. - Icon for icon files. - UnmanagedMemoryStream for sound files.
Other	Determined by the information in the designer's Type column.

Classes

The `My.Resources` object exposes each resource file as a class with shared properties. The class name is the same as the name of the resource file. As described in the previous section, the resources in a resource file are exposed as properties in the class.

Example

This example sets the title of a form to the string resource named `Form1Title` in the application resource file. For the example to work, the application must have a string named `Form1Title` in its resource file.

```
Sub SetFormTitle()
    Me.Text = My.Resources.Form1Title
End Sub
```

Example

This example sets the icon of the form to the icon named `Form1Icon` that is stored in the application's resource file. For the example to work, the application must have an icon named `Form1Icon` in its resource file.

```
Sub SetFormIcon()
    Me.Icon = My.Resources.Form1Icon
End Sub
```

Example

This example sets the background image of a form to the image resource named `Form1Background`, which is in the application resource file. For this example to work, the application must have an image resource named `Form1Background` in its resource file.

```
Sub SetFormBackgroundImage()
    Me.BackgroundImage = My.Resources.Form1Background
End Sub
```

Example

This example plays the sound that is stored as an audio resource named `Form1Greeting` in the application's resource file. For the example to work, the application must have an audio resource named `Form1Greeting` in its resource file. The `My.Computer.Audio.Play` method is available only for Windows Forms applications.

```
Sub PlayFormGreeting()
    My.Computer.Audio.Play(My.Resources.Form1Greeting,
        AudioPlayMode.Background)
End Sub
```

Example

This example retrieves the French-culture version of a string resource of the application. The resource is named `Message`. To change the culture that the `My.Resources` object uses, the example uses `ChangeUICulture`.

For this example to work, the application must have a string named `Message` in its resource file, and the application should have the French-culture version of that resource file, Resources.fr-FR.resx. If the application does not have the French-culture version of the resource file, the `My.Resource` object retrieves the resource from the default-culture resource file.

```
Sub ShowLocalizedMessage()
    Dim culture As String = My.Application.UICulture.Name
    My.Application.ChangeUICulture("fr-FR")
    MsgBox(My.Resources.Message)
    My.Application.ChangeUICulture(culture)
End Sub
```

My.Settings Object

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides properties and methods for accessing the application's settings.

Remarks

The `My.Settings` object provides access to the application's settings and allows you to dynamically store and retrieve property settings and other information for your application. For more information, see [Managing Application Settings \(.NET\)](#).

Properties

The properties of the `My.Settings` object provide access to your application's settings. To add or remove settings, use the **Settings Designer**.

Each setting has a **Name**, **Type**, **Scope**, and **Value**, and these settings determine how the property to access each setting appears in the `My.Settings` object:

- **Name** determines the name of the property.
- **Type** determines the type of the property.
- **Scope** indicates if the property is read-only. If the value is **Application**, the property is read-only; if the value is **User**, the property is read-write.
- **Value** is the default value of the property.

Methods

METHOD	DESCRIPTION
<code>Reload</code>	Reloads the user settings from the last saved values.
<code>Save</code>	Saves the current user settings.

The `My.Settings` object also provides advanced properties and methods, inherited from the [ApplicationSettingsBase](#) class.

Tasks

The following table lists examples of tasks involving the `My.Settings` object.

TO	SEE
Read an application setting	How to: Read Application Settings in Visual Basic
Change a user setting	How to: Change User Settings in Visual Basic
Persist user settings	How to: Persist User Settings in Visual Basic

TO	SEE

Example

This example displays the value of the `Nickname` setting.

```
Sub ShowNickname()
    MsgBox("Nickname is " & My.Settings.Nickname)
End Sub
```

For this example to work, your application must have a `Nickname` setting, of type `String`.

My.WebServices Object

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides properties for creating and accessing a single instance of each XML Web service referenced by the current project.

Remarks

The `My.WebServices` object provides an instance of each Web service referenced by the current project. Each instance is instantiated on demand. You can access these Web services through the properties of the `My.WebServices` object. The name of the property is the same as the name of the Web service that the property accesses. Any class that inherits from `SoapHttpClientProtocol` is a Web service. For information about adding Web services to a project, see [Accessing Application Web Services](#).

The `My.WebServices` object exposes only the Web services associated with the current project. It does not provide access to Web services declared in referenced DLLs. To access a Web service that a DLL provides, you must use the qualified name of the Web service, in the form `DllName.WebServiceName`. For more information, see [Accessing Application Web Services](#).

The object and its properties are not available for Web applications.

Properties

Each property of the `My.WebServices` object provides access to an instance of a Web service referenced by the current project. The name of the property is the same as the name of the Web service that the property accesses, and the property type is the same as the Web service's type.

NOTE

If there is a name collision, the property name for accessing a Web service is `RootNamespace_Namespace_ServiceName`. For example, consider two Web services named `Service1`. If one of these services is in the root namespace `WindowsApplication1` and in the namespace `Namespace1`, you would access that service by using `My.WebServices.WindowsApplication1_Namespace1_Service1`.

When you first access one of the `My.WebServices` object's properties, it creates a new instance of the Web service and stores it. Subsequent accesses of that property return that instance of the Web service.

You can dispose of a Web service by assigning `Nothing` to the property for that Web service. The property setter assigns `Nothing` to the stored value. If you assign any value other than `Nothing` to the property, the setter throws an [ArgumentException](#) exception.

You can test whether a property of the `My.WebServices` object stores an instance of the Web service by using the `Is` or `IsNot` operator. You can use those operators to check if the value of the property is `Nothing`.

NOTE

Typically, the `Is` or `IsNot` operator has to read the value of the property to perform the comparison. However, if the property currently stores `Nothing`, the property creates a new instance of the Web service and then returns that instance. However, the Visual Basic compiler treats the properties of the `My.WebServices` object specially, and allows the `Is` or `IsNot` operator to check the status of the property without altering its value.

Example

This example calls the `FahrenheitToCelsius` method of the `TemperatureConverter` XML Web service, and returns the result.

```
Function ConvertFromFahrenheitToCelsius(  
    ByVal dFahrenheit As Double) As Double  
  
    Return My.WebServices.TemperatureConverter.FahrenheitToCelsius(dFahrenheit)  
End Function
```

For this example to work, your project must reference a Web service named `Converter`, and that Web service must expose the `ConvertTemperature` method. For more information, see [Accessing Application Web Services](#).

This code does not work in a Web application project.

Operator Precedence in Visual Basic

1/23/2019 • 3 minutes to read • [Edit Online](#)

When several operations occur in an expression, each part is evaluated and resolved in a predetermined order called *operator precedence*.

Precedence Rules

When expressions contain operators from more than one category, they are evaluated according to the following rules:

- The arithmetic and concatenation operators have the order of precedence described in the following section, and all have greater precedence than the comparison, logical, and bitwise operators.
- All comparison operators have equal precedence, and all have greater precedence than the logical and bitwise operators, but lower precedence than the arithmetic and concatenation operators.
- The logical and bitwise operators have the order of precedence described in the following section, and all have lower precedence than the arithmetic, concatenation, and comparison operators.
- Operators with equal precedence are evaluated left to right in the order in which they appear in the expression.

Precedence Order

Operators are evaluated in the following order of precedence:

Await Operator

Await

Arithmetic and Concatenation Operators

Exponentiation (`^`)

Unary identity and negation (`+`, `-`)

Multiplication and floating-point division (`*`, `/`)

Integer division (`\`)

Modulus arithmetic (`Mod`)

Addition and subtraction (`+`, `-`)

String concatenation (`&`)

Arithmetic bit shift (`<<`, `>>`)

Comparison Operators

All comparison operators (`=`, `<>`, `<`, `<=`, `>`, `>=`, `Is`, `IsNot`, `Like`, `TypeOf` ... `Is`)

Logical and Bitwise Operators

Negation (`Not`)

Conjunction (`And`, `AndAlso`)

Inclusive disjunction (`Or`, `OrElse`)

Exclusive disjunction (`Xor`)

Comments

The `=` operator is only the equality comparison operator, not the assignment operator.

The string concatenation operator (`&`) is not an arithmetic operator, but in precedence it is grouped with the arithmetic operators.

The `Is` and `IsNot` operators are object reference comparison operators. They do not compare the values of two objects; they check only to determine whether two object variables refer to the same object instance.

Associativity

When operators of equal precedence appear together in an expression, for example multiplication and division, the compiler evaluates each operation as it encounters it from left to right. The following example illustrates this.

```
Dim n1 As Integer = 96 / 8 / 4
Dim n2 As Integer = (96 / 8) / 4
Dim n3 As Integer = 96 / (8 / 4)
```

The first expression evaluates the division $96 / 8$ (which results in 12) and then the division $12 / 4$, which results in three. Because the compiler evaluates the operations for `n1` from left to right, the evaluation is the same when that order is explicitly indicated for `n2`. Both `n1` and `n2` have a result of three. By contrast, `n3` has a result of 48, because the parentheses force the compiler to evaluate $8 / 4$ first.

Because of this behavior, operators are said to be *left associative* in Visual Basic.

Overriding Precedence and Associativity

You can use parentheses to force some parts of an expression to be evaluated before others. This can override both the order of precedence and the left associativity. Visual Basic always performs operations that are enclosed in parentheses before those outside. However, within parentheses, it maintains ordinary precedence and associativity, unless you use parentheses within the parentheses. The following example illustrates this.

```
Dim a, b, c, d, e, f, g As Double
a = 8.0
b = 3.0
c = 4.0
d = 2.0
e = 1.0
f = a - b + c / d * e
' The preceding line sets f to 7.0. Because of natural operator
' precedence and associativity, it is exactly equivalent to the
' following line.
f = (a - b) + ((c / d) * e)
' The following line overrides the natural operator precedence
' and left associativity.
g = (a - (b + c)) / (d * e)
' The preceding line sets g to 0.5.
```

Data Types of Operator Results (Visual Basic)

1/23/2019 • 7 minutes to read • [Edit Online](#)

Visual Basic determines the result data type of an operation based on the data types of the operands. In some cases this might be a data type with a greater range than that of either operand.

Data Type Ranges

The ranges of the relevant data types, in order from smallest to largest, are as follows:

- [Boolean](#) — two possible values
- [SByte](#), [Byte](#) — 256 possible integral values
- [Short](#), [UShort](#) — 65,536 (6.5...E+4) possible integral values
- [Integer](#), [UInteger](#) — 4,294,967,296 (4.2...E+9) possible integral values
- [Long](#), [ULong](#) — 18,446,744,073,709,551,615 (1.8...E+19) possible integral values
- [Decimal](#) — 1.5...E+29 possible integral values, maximum range 7.9...E+28 (absolute value)
- [Single](#) — maximum range 3.4...E+38 (absolute value)
- [Double](#) — maximum range 1.7...E+308 (absolute value)

For more information on Visual Basic data types, see [Data Types](#).

If an operand evaluates to [Nothing](#), the Visual Basic arithmetic operators treat it as zero.

Decimal Arithmetic

Note that the [Decimal](#) data type is neither floating-point nor integer.

If either operand of a [+](#), [-](#), [\\*](#), [/](#), or [Mod](#) operation is [Decimal](#) and the other is not [Single](#) or [Double](#), Visual Basic widens the other operand to [Decimal](#). It performs the operation in [Decimal](#), and the result data type is [Decimal](#).

Floating-Point Arithmetic

Visual Basic performs most floating-point arithmetic in [Double](#), which is the most efficient data type for such operations. However, if one operand is [Single](#) and the other is not [Double](#), Visual Basic performs the operation in [Single](#). It widens each operand as necessary to the appropriate data type before the operation, and the result has that data type.

/ and ^ Operators

The [/](#) operator is defined only for the [Decimal](#), [Single](#), and [Double](#) data types. Visual Basic widens each operand as necessary to the appropriate data type before the operation, and the result has that data type.

The following table shows the result data types for the [/](#) operator. Note that this table is symmetric; for a given combination of operand data types, the result data type is the same regardless of the order of the operands.

	Decimal	Single	Double	Any integer type
Decimal	Decimal	Single	Double	Decimal
Single	Single	Single	Double	Single
Double	Double	Double	Double	Double
Any integer type	Decimal	Single	Double	Double

The `^` operator is defined only for the `Double` data type. Visual Basic widens each operand as necessary to `Double` before the operation, and the result data type is always `Double`.

Integer Arithmetic

The result data type of an integer operation depends on the data types of the operands. In general, Visual Basic uses the following policies for determining the result data type:

- If both operands of a binary operator have the same data type, the result has that data type. An exception is `Boolean`, which is forced to `Short`.
 - If an unsigned operand participates with a signed operand, the result has a signed type with at least as large a range as either operand.
 - Otherwise, the result usually has the larger of the two operand data types.

Note that the result data type might not be the same as either operand data type.

NOTE

The result data type is not always large enough to hold all possible values resulting from the operation. An `OverflowException` exception can occur if the value is too large for the result data type.

Unary + and - Operators

The following table shows the result data types for the two unary operators, `+` and `-`.

	Boolean	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
Unary +	Short	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
Unary -	Short	SByte	Short	Short	Integer	Integer	Long	Long	Decimal

<< and >> Operators

The following table shows the result data types for the two bit-shift operators, `<<` and `>>`. Visual Basic treats each bit-shift operator as a unary operator on its left operand (the bit pattern to be shifted).

Boolean	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
---------	-------	------	-------	--------	---------	----------	------	-------

<code><<</code> , <code>>></code>	Short	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
--	-------	-------	------	-------	--------	---------	----------	------	-------

If the left operand is `Decimal`, `Single`, `Double`, or `String`, Visual Basic attempts to convert it to `Long` before the operation, and the result data type is `Long`. The right operand (the number of bit positions to shift) must be `Integer` or a type that widens to `Integer`.

Binary `+, -, *, and Mod Operators`

The following table shows the result data types for the binary `+` and `-` operators and the `*` and `Mod` operators. Note that this table is symmetric; for a given combination of operand data types, the result data type is the same regardless of the order of the operands.

	Boolean	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
Boolean	Short	SByte	Short	Short	Integer	Integer	Long	Long	Decimal
SByte	SByte	SByte	Short	Short	Integer	Integer	Long	Long	Decimal
Byte	Short	Short	Byte	Short	UShort	Integer	UInteger	Long	ULong
Short	Short	Short	Short	Short	Integer	Integer	Long	Long	Decimal
UShort	Integer	Integer	UShort	Integer	UShort	Integer	UInteger	Long	ULong
Integer	Integer	Integer	Integer	Integer	Integer	Integer	Long	Long	Decimal
UInteger	Long	Long	UInteger	Long	UInteger	Long	UInteger	Long	ULong
Long	Long	Long	Long	Long	Long	Long	Long	Long	Decimal
ULong	Decimal	Decimal	ULong	Decimal	ULong	Decimal	ULong	Decimal	ULong

\ Operator

The following table shows the result data types for the `\` operator. Note that this table is symmetric; for a given combination of operand data types, the result data type is the same regardless of the order of the operands.

	Boolean	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
Boolean	Short	SByte	Short	Short	Integer	Integer	Long	Long	Long
SByte	SByte	SByte	Short	Short	Integer	Integer	Long	Long	Long
Byte	Short	Short	Byte	Short	UShort	Integer	UInteger	Long	ULong
Short	Short	Short	Short	Short	Integer	Integer	Long	Long	Long

UShort	Integer	Integer	UShort	Integer	UShort	Integer	UInteger	Long	ULong
Integer	Integer	Integer	Integer	Integer	Integer	Integer	Long	Long	Long
UInteger	Long	Long	UInteger	Long	UInteger	Long	UInteger	Long	ULong
Long	Long	Long	Long	Long	Long	Long	Long	Long	Long
ULong	Long	Long	ULong	Long	ULong	Long	ULong	Long	ULong

If either operand of the `\` operator is [Decimal](#), [Single](#), or [Double](#), Visual Basic attempts to convert it to [Long](#) before the operation, and the result data type is `Long`.

Relational and Bitwise Comparisons

The result data type of a relational operation (`=`, `<>`, `<`, `>`, `<=`, `>=`) is always `Boolean` [Boolean Data Type](#). The same is true for logical operations (`And`, `AndAlso`, `Not`, `Or`, `OrElse`, `Xor`) on `Boolean` operands.

The result data type of a bitwise logical operation depends on the data types of the operands. Note that `AndAlso` and `OrElse` are defined only for `Boolean`, and Visual Basic converts each operand as necessary to `Boolean` before performing the operation.

=, <>, <, >, <=, and >= Operators

If both operands are `Boolean`, Visual Basic considers `True` to be less than `False`. If a numeric type is compared with a `String`, Visual Basic attempts to convert the `String` to `Double` before the operation. A `Char` or `Date` operand can be compared only with another operand of the same data type. The result data type is always `Boolean`.

Bitwise Not Operator

The following table shows the result data types for the bitwise `Not` operator.

	Boolean	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong
Not	Boolean	SByte	Byte	Short	UShort	Integer	UInteger	Long	ULong

If the operand is `Decimal`, `Single`, `Double`, or `String`, Visual Basic attempts to convert it to `Long` before the operation, and the result data type is `Long`.

Bitwise And, Or, and Xor Operators

The following table shows the result data types for the bitwise `And`, `or`, and `xor` operators. Note that this table is symmetric; for a given combination of operand data types, the result data type is the same regardless of the order of the operands.

	<code>Boolean</code>	<code>SByte</code>	<code>Byte</code>	<code>Short</code>	<code>UShort</code>	<code>Integer</code>	<code>UInteger</code>	<code>Long</code>	<code>ULong</code>
<code>Boolean</code>	<code>Boolean</code>	<code>SByte</code>	<code>Short</code>	<code>Short</code>	<code>Integer</code>	<code>Integer</code>	<code>Long</code>	<code>Long</code>	<code>Long</code>

SByte	SByte	SByte	Short	Short	Integer	Integer	Long	Long	Long
Byte	Short	Short	Byte	Short	UShort	Integer	UInteger	Long	ULong
Short	Short	Short	Short	Short	Integer	Integer	Long	Long	Long
UShort	Integer	Integer	UShort	Integer	UShort	Integer	UInteger	Long	ULong
Integer	Integer	Integer	Integer	Integer	Integer	Integer	Long	Long	Long
UInteger	Long	Long	UInteger	Long	UInteger	Long	UInteger	Long	ULong
Long	Long	Long	Long	Long	Long	Long	Long	Long	Long
ULong	Long	Long	ULong	Long	ULong	Long	ULong	Long	ULong

If an operand is `Decimal`, `Single`, `Double`, or `String`, Visual Basic attempts to convert it to `Long` before the operation, and the result data type is the same as if that operand had already been `Long`.

Miscellaneous Operators

The `&` operator is defined only for concatenation of `String` operands. Visual Basic converts each operand as necessary to `String` before the operation, and the result data type is always `String`. For the purposes of the `&` operator, all conversions to `String` are considered to be widening, even if `Option Strict` is `On`.

The `Is` and `IsNot` operators require both operands to be of a reference type. The `TypeOf ... Is` expression requires the first operand to be of a reference type and the second operand to be the name of a data type. In all these cases the result data type is `Boolean`.

The `Like` operator is defined only for pattern matching of `String` operands. Visual Basic attempts to convert each operand as necessary to `String` before the operation. The result data type is always `Boolean`.

Comparison Operators (Visual Basic)

3/5/2019 • 5 minutes to read • [Edit Online](#)

The following are the comparison operators defined in Visual Basic.

`<` operator

`<=` operator

`>` operator

`>=` operator

`=` operator

`<>` operator

[Is Operator](#)

[IsNot Operator](#)

[Like Operator](#)

These operators compare two expressions to determine whether or not they are equal, and if not, how they differ.

`Is`, `IsNot`, and `Like` are discussed in detail on separate Help pages. The relational comparison operators are discussed in detail on this page.

Syntax

```
result = expression1 comparisonoperator expression2
result = object1 [Is | IsNot] object2
result = string Like pattern
```

Parts

`result`

Required. A `Boolean` value representing the result of the comparison.

`expression`

Required. Any expression.

`comparisonoperator`

Required. Any relational comparison operator.

`object1`, `object2`

Required. Any reference object names.

`string`

Required. Any `String` expression.

`pattern`

Required. Any `String` expression or range of characters.

Remarks

The following table contains a list of the relational comparison operators and the conditions that determine whether `result` is `True` or `False`.

OPERATOR	TRUE IF	FALSE IF
<code><</code> (Less than)	<code>expression1 < expression2</code>	<code>expression1 >= expression2</code>
<code><=</code> (Less than or equal to)	<code>expression1 <= expression2</code>	<code>expression1 > expression2</code>
<code>></code> (Greater than)	<code>expression1 > expression2</code>	<code>expression1 <= expression2</code>
<code>>=</code> (Greater than or equal to)	<code>expression1 >= expression2</code>	<code>expression1 < expression2</code>
<code>=</code> (Equal to)	<code>expression1 = expression2</code>	<code>expression1 <> expression2</code>
<code><></code> (Not equal to)	<code>expression1 <> expression2</code>	<code>expression1 = expression2</code>

NOTE

The [= Operator](#) is also used as an assignment operator.

The `Is` operator, the `IsNot` operator, and the `Like` operator have specific comparison functionalities that differ from the operators in the preceding table.

Comparing Numbers

When you compare an expression of type `Single` to one of type `Double`, the `Single` expression is converted to `Double`. This behavior is opposite to the behavior found in Visual Basic 6.

Similarly, when you compare an expression of type `Decimal` to an expression of type `Single` or `Double`, the `Decimal` expression is converted to `Single` or `Double`. For `Decimal` expressions, any fractional value less than 1E-28 might be lost. Such fractional value loss may cause two values to compare as equal when they are not. For this reason, you should take care when using equality (`=`) to compare two floating-point variables. It is safer to test whether the absolute value of the difference between the two numbers is less than a small acceptable tolerance.

Floating-point Imprecision

When you work with floating-point numbers, keep in mind that they do not always have a precise representation in memory. This could lead to unexpected results from certain operations, such as value comparison and the [Mod Operator](#). For more information, see [Troubleshooting Data Types](#).

Comparing Strings

When you compare strings, the string expressions are evaluated based on their alphabetical sort order, which depends on the `Option Compare` setting.

`Option Compare Binary` bases string comparisons on a sort order derived from the internal binary representations of the characters. The sort order is determined by the code page. The following example shows a typical binary sort order.

```
A < B < E < Z < a < b < e < z < À < È < Ø < à < ê < ø
```

`Option Compare Text` bases string comparisons on a case-insensitive, textual sort order determined by your application's locale. When you set `Option Compare Text` and sort the characters in the preceding example, the following text sort order applies:

(A=a) < (À= à) < (B=b) < (E=e) < (È= ê) < (Ø = ø) < (Z=z)

Locale Dependence

When you set `Option Compare Text`, the result of a string comparison can depend on the locale in which the application is running. Two characters might compare as equal in one locale but not in another. If you are using a string comparison to make important decisions, such as whether to accept an attempt to log on, you should be alert to locale sensitivity. Consider either setting `Option Compare Binary` or calling the `StrComp`, which takes the locale into account.

Typeless Programming with Relational Comparison Operators

The use of relational comparison operators with `Object` expressions is not allowed under `Option Strict On`. When `Option Strict` is `off`, and either `expression1` or `expression2` is an `Object` expression, the run-time types determine how they are compared. The following table shows how the expressions are compared and the result from the comparison, depending on the runtime type of the operands.

IF OPERANDS ARE	COMPARISON IS
Both <code>String</code>	Sort comparison based on string sorting characteristics.
Both numeric	Objects converted to <code>Double</code> , numeric comparison.
One numeric and one <code>String</code>	The <code>String</code> is converted to a <code>Double</code> and numeric comparison is performed. If the <code>String</code> cannot be converted to <code>Double</code> , an <code>InvalidCastException</code> is thrown.
Either or both are reference types other than <code>String</code>	An <code>InvalidCastException</code> is thrown.

Numeric comparisons treat `Nothing` as 0. String comparisons treat `Nothing` as `""` (an empty string).

Overloading

The relational comparison operators (`<`, `<=`, `>`, `>=`, `=`, `<>`) can be *overloaded*, which means that a class or structure can redefine their behavior when an operand has the type of that class or structure. If your code uses any of these operators on such a class or structure, be sure you understand the redefined behavior. For more information, see [Operator Procedures](#).

Notice that the `= Operator` can be overloaded only as a relational comparison operator, not as an assignment operator.

Example

The following example shows various uses of relational comparison operators, which you use to compare expressions. Relational comparison operators return a `Boolean` result that represents whether or not the stated expression evaluates to `True`. When you apply the `>` and `<` operators to strings, the comparison is made using the normal alphabetical sorting order of the strings. This order can be dependent on your locale setting. Whether the sort is case-sensitive or not depends on the `Option Compare` setting.

```
Dim x As testClass
Dim y As New testClass()
x = y
If x Is y Then
    ' Insert code to run if x and y point to the same instance.
End If
```

In the preceding example, the first comparison returns `False` and the remaining comparisons return `True`.

& Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Generates a string concatenation of two expressions.

Syntax

```
result = expression1 & expression2
```

Parts

`result`

Required. Any `string` or `Object` variable.

`expression1`

Required. Any expression with a data type that widens to `String`.

`expression2`

Required. Any expression with a data type that widens to `String`.

Remarks

If the data type of `expression1` or `expression2` is not `String` but widens to `String`, it is converted to `String`. If either of the data types does not widen to `String`, the compiler generates an error.

The data type of `result` is `String`. If one or both expressions evaluate to `Nothing` or have a value of `DBNull.Value`, they are treated as a string with a value of "".

NOTE

The `&` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

NOTE

The ampersand (&) character can also be used to identify variables as type `Long`. For more information, see [Type Characters](#).

Example

This example uses the `&` operator to force string concatenation. The result is a string value representing the concatenation of the two string operands.

```
Dim sampleStr As String  
sampleStr = "Hello" & " World"  
' The preceding statement sets sampleStr to "Hello World".
```

&= Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Concatenates a `String` expression to a `String` variable or property and assigns the result to the variable or property.

Syntax

```
variableorproperty &= expression
```

Parts

`variableorproperty`

Required. Any `string` variable or property.

`expression`

Required. Any `string` expression.

Remarks

The element on the left side of the `&=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#). The `&=` operator concatenates the `String` expression on its right to the `String` variable or property on its left, and assigns the result to the variable or property on its left.

Overloading

The [& Operator](#) can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `&` operator affects the behavior of the `&=` operator. If your code uses `&=` on a class or structure that overloads `&`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `&=` operator to concatenate two `String` variables and assign the result to the first variable.

```
Dim var1 As String = "Hello "
Dim var2 As String = "World!"
var1 &= var2
' The value of var1 is now "Hello World!".

\* Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Multiplies two numbers.

Syntax

```
number1 * number2
```

Parts

TERM	DEFINITION
number1	Required. Any numeric expression.
number2	Required. Any numeric expression.

Result

The result is the product of `number1` and `number2`.

Supported Types

All numeric types, including the unsigned and floating-point types and `Decimal`.

Remarks

The data type of the result depends on the types of the operands. The following table shows how the data type of the result is determined.

OPERAND DATA TYPES	RESULT DATA TYPE
Both expressions are integral data types (SByte , Byte , Short , UShort , Integer , UInteger , Long , ULong)	A numeric data type appropriate for the data types of <code>number1</code> and <code>number2</code> . See the "Integer Arithmetic" tables in Data Types of Operator Results .
Both expressions are <code>Decimal</code>	<code>Decimal</code>
Both expressions are <code>Single</code>	<code>Single</code>
Either expression is a floating-point data type (<code>Single</code> or <code>Double</code>) but not both <code>Single</code> (note <code>Decimal</code> is not a floating-point data type)	<code>Double</code>

If an expression evaluates to [Nothing](#), it is treated as zero.

Overloading

The `*` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

This example uses the `*` operator to multiply two numbers. The result is the product of the two operands.

```
Dim testValue As Double
testValue = 2 * 2
' The preceding statement sets testValue to 4.
testValue = 459.35 * 334.9
' The preceding statement sets testValue to 153836.315.

\*= Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Multiples the value of a variable or property by the value of an expression and assigns the result to the variable or property.

Syntax

```
variableorproperty *= expression
```

Parts

`variableorproperty`

Required. Any numeric variable or property.

`expression`

Required. Any numeric expression.

Remarks

The element on the left side of the `=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `=` operator first multiplies the value of the expression (on the right-hand side of the operator) by the value of the variable or property (on the left-hand side of the operator). The operator then assigns the result of that operation to the variable or property.

Overloading

The [\\* Operator](#) can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `*` operator affects the behavior of the `=` operator. If your code uses `=` on a class or structure that overloads `*`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `=` operator to multiply one `Integer` variable by a second and assign the result to the first variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 *= var2
' The value of var1 is now 30.
```

+ Operator (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Adds two numbers or returns the positive value of a numeric expression. Can also be used to concatenate two string expressions.

Syntax

```
expression1 + expression2  
- or -  
+ expression1
```

Parts

TERM	DEFINITION
expression1	Required. Any numeric or string expression.
expression2	Required unless the + operator is calculating a negative value. Any numeric or string expression.

Result

If `expression1` and `expression2` are both numeric, the result is their arithmetic sum.

If `expression2` is absent, the + operator is the *unary* identity operator for the unchanged value of an expression. In this sense, the operation consists of retaining the sign of `expression1`, so the result is negative if `expression1` is negative.

If `expression1` and `expression2` are both strings, the result is the concatenation of their values.

If `expression1` and `expression2` are of mixed types, the action taken depends on their types, their contents, and the setting of the [Option Strict Statement](#). For more information, see the tables in "Remarks."

Supported Types

All numeric types, including the unsigned and floating-point types and `Decimal`, and `String`.

Remarks

In general, + performs arithmetic addition when possible, and concatenates only when both expressions are strings.

If neither expression is an `Object`, Visual Basic takes the following actions.

DATA TYPES OF EXPRESSIONS	ACTION BY COMPILER
Both expressions are numeric data types (<code>SByte</code> , <code>Byte</code> , <code>Short</code> , <code>UShort</code> , <code>Integer</code> , <code>UInteger</code> , <code>Long</code> , <code>ULong</code> , <code>Decimal</code> , <code>Single</code> , or <code>Double</code>)	Add. The result data type is a numeric type appropriate for the data types of <code>expression1</code> and <code>expression2</code> . See the "Integer Arithmetic" tables in Data Types of Operator Results .
Both expressions are of type <code>String</code>	Concatenate.
One expression is a numeric data type and the other is a string	<p>If <code>Option Strict</code> is <code>on</code>, then generate a compiler error.</p> <p>If <code>Option Strict</code> is <code>off</code>, then implicitly convert the <code>String</code> to <code>Double</code> and add.</p> <p>If the <code>String</code> cannot be converted to <code>Double</code>, then throw an InvalidCastException exception.</p>
One expression is a numeric data type, and the other is <code>Nothing</code>	Add, with <code>Nothing</code> valued as zero.
One expression is a string, and the other is <code>Nothing</code>	Concatenate, with <code>Nothing</code> valued as "".

If one expression is an `Object` expression, Visual Basic takes the following actions.

DATA TYPES OF EXPRESSIONS	ACTION BY COMPILER
<code>Object</code> expression holds a numeric value and the other is a numeric data type	<p>If <code>Option Strict</code> is <code>on</code>, then generate a compiler error.</p> <p>If <code>Option Strict</code> is <code>off</code>, then add.</p>
<code>Object</code> expression holds a numeric value and the other is of type <code>String</code>	<p>If <code>Option Strict</code> is <code>on</code>, then generate a compiler error.</p> <p>If <code>Option Strict</code> is <code>off</code>, then implicitly convert the <code>String</code> to <code>Double</code> and add.</p> <p>If the <code>String</code> cannot be converted to <code>Double</code>, then throw an InvalidCastException exception.</p>
<code>Object</code> expression holds a string and the other is a numeric data type	<p>If <code>Option Strict</code> is <code>on</code>, then generate a compiler error.</p> <p>If <code>Option Strict</code> is <code>off</code>, then implicitly convert the string <code>Object</code> to <code>Double</code> and add.</p> <p>If the string <code>Object</code> cannot be converted to <code>Double</code>, then throw an InvalidCastException exception.</p>
<code>Object</code> expression holds a string and the other is of type <code>String</code>	<p>If <code>Option Strict</code> is <code>on</code>, then generate a compiler error.</p> <p>If <code>Option Strict</code> is <code>off</code>, then implicitly convert <code>Object</code> to <code>String</code> and concatenate.</p>

If both expressions are `Object` expressions, Visual Basic takes the following actions (`Option Strict Off` only).

DATA TYPES OF EXPRESSIONS	ACTION BY COMPILER
Both <code>Object</code> expressions hold numeric values	Add.

DATA TYPES OF EXPRESSIONS	ACTION BY COMPILER
Both <code>Object</code> expressions are of type <code>String</code>	Concatenate.
One <code>Object</code> expression holds a numeric value and the other holds a string	<p>Implicitly convert the string <code>Object</code> to <code>Double</code> and add.</p> <p>If the string <code>Object</code> cannot be converted to a numeric value, then throw an <code>InvalidCastException</code> exception.</p>

If either `Object` expression evaluates to `Nothing` or `DBNull`, the `+` operator treats it as a `String` with a value of `""`.

NOTE

When you use the `+` operator, you might not be able to determine whether addition or string concatenation will occur. Use the `&` operator for concatenation to eliminate ambiguity and to provide self-documenting code.

Overloading

The `+` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `+` operator to add numbers. If the operands are both numeric, Visual Basic computes the arithmetic result. The arithmetic result represents the sum of the two operands.

```
Dim sumNumber As Integer
sumNumber = 2 + 2
sumNumber = 4257.04 + 98112
' The preceding statements set sumNumber to 4 and 102369.
```

You can also use the `+` operator to concatenate strings. If the operands are both strings, Visual Basic concatenates them. The concatenation result represents a single string consisting of the contents of the two operands one after the other.

If the operands are of mixed types, the result depends on the setting of the [Option Strict Statement](#). The following example illustrates the result when `Option Strict` is `On`.

```
Option Strict On
```

```
Dim var1 As String = "34"
Dim var2 As Integer = 6
Dim concatenatedNumber As Integer = var1 + var2
```

' The preceding statement generates a COMPILER ERROR.

The following example illustrates the result when `Option Strict` is `Off`.

```
Option Strict Off
```

```
Dim var1 As String = "34"  
Dim var2 As Integer = 6  
Dim concatenatedNumber As Integer = var1 + var2
```

' The preceding statement returns 40 after the string in var1 is
' converted to a numeric value. This might be an unexpected result.
' We do not recommend use of Option Strict Off for these operations.

To eliminate ambiguity, you should use the `&` operator instead of `+` for concatenation.

+= Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Adds the value of a numeric expression to the value of a numeric variable or property and assigns the result to the variable or property. Can also be used to concatenate a `String` expression to a `String` variable or property and assign the result to the variable or property.

Syntax

```
variableorproperty += expression
```

Parts

`variableorproperty`

Required. Any numeric or `String` variable or property.

`expression`

Required. Any numeric or `String` expression.

Remarks

The element on the left side of the `+=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `+=` operator adds the value on its right to the variable or property on its left, and assigns the result to the variable or property on its left. The `+=` operator can also be used to concatenate the `String` expression on its right to the `String` variable or property on its left, and assign the result to the variable or property on its left.

NOTE

When you use the `+=` operator, you might not be able to determine whether addition or string concatenation will occur. Use the `&=` operator for concatenation to eliminate ambiguity and to provide self-documenting code.

This assignment operator implicitly performs widening but not narrowing conversions if the compilation environment enforces strict semantics. For more information on these conversions, see [Widening and Narrowing Conversions](#). For more information on strict and permissive semantics, see [Option Strict Statement](#).

If permissive semantics are allowed, the `+=` operator implicitly performs a variety of string and numeric conversions identical to those performed by the `+` operator. For details on these conversions, see [+ Operator](#).

Overloading

The `+` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `+` operator affects the behavior of the `+=` operator. If your code uses `+=` on a class or structure that overloads `+`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `+=` operator to combine the value of one variable with another. The first part uses `+=` with numeric variables to add one value to another. The second part uses `+=` with `String` variables to concatenate one value with another. In both cases, the result is assigned to the first variable.

```
' This part uses numeric variables.  
Dim num1 As Integer = 10  
Dim num2 As Integer = 3  
num1 += num2
```

```
' This part uses string variables.  
Dim str1 As String = "10"  
Dim str2 As String = "3"  
str1 += str2
```

The value of `num1` is now 13, and the value of `str1` is now "103".

= Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Assigns a value to a variable or property.

Syntax

```
variableorproperty = value
```

Parts

`variableorproperty`

Any writable variable or any property.

`value`

Any literal, constant, or expression.

Remarks

The element on the left side of the equal sign (`=`) can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#). The `=` operator assigns the value on its right to the variable or property on its left.

NOTE

The `=` operator is also used as a comparison operator. For details, see [Comparison Operators](#).

Overloading

The `=` operator can be overloaded only as a relational comparison operator, not as an assignment operator. For more information, see [Operator Procedures](#).

Example

The following example demonstrates the assignment operator. The value on the right is assigned to the variable on the left.

```
Dim testInt As Integer
Dim testString As String
Dim testButton As System.Windows.Forms.Button
Dim testObject As Object
testInt = 42
testString = "This is an example of a string literal."
testButton = New System.Windows.Forms.Button()

- Operator (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Returns the difference between two numeric expressions or the negative value of a numeric expression.

Syntax

```
expression1 - expression2  
- or -  
- expression1
```

Parts

`expression1`

Required. Any numeric expression.

`expression2`

Required unless the `-` operator is calculating a negative value. Any numeric expression.

Result

The result is the difference between `expression1` and `expression2`, or the negated value of `expression1`.

The result data type is a numeric type appropriate for the data types of `expression1` and `expression2`. See the "Integer Arithmetic" tables in [Data Types of Operator Results](#).

Supported Types

All numeric types. This includes the unsigned and floating-point types and `Decimal`.

Remarks

In the first usage shown in the syntax shown previously, the `-` operator is the *binary* arithmetic subtraction operator for the difference between two numeric expressions.

In the second usage shown in the syntax shown previously, the `-` operator is the *unary* negation operator for the negative value of an expression. In this sense, the negation consists of reversing the sign of `expression1` so that the result is positive if `expression1` is negative.

If either expression evaluates to [Nothing](#), the `-` operator treats it as zero.

NOTE

The `-` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, make sure that you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `-` operator to calculate and return the difference between two numbers, and then

to negate a number.

```
Dim binaryResult As Double = 459.35 - 334.9  
Dim unaryResult As Double = -334.9
```

Following the execution of these statements, `binaryResult` contains 124.45 and `unaryResult` contains -334.90.

-= Operator (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Subtracts the value of an expression from the value of a variable or property and assigns the result to the variable or property.

Syntax

```
variableorproperty -= expression
```

Parts

`variableorproperty`

Required. Any numeric variable or property.

`expression`

Required. Any numeric expression.

Remarks

The element on the left side of the `-=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `-=` operator first subtracts the value of the expression (on the right-hand side of the operator) from the value of the variable or property (on the left-hand side of the operator). The operator then assigns the result of that operation to the variable or property.

Overloading

The [- Operator \(Visual Basic\)](#) can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `-` operator affects the behavior of the `-=` operator. If your code uses `-=` on a class or structure that overloads `-`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `-=` operator to subtract one `Integer` variable from another and assign the result to the latter variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 -= var2
' The value of var1 is now 7.
```

Comparison Operators (Visual Basic)

3/5/2019 • 5 minutes to read • [Edit Online](#)

The following are the comparison operators defined in Visual Basic.

`<` operator

`<=` operator

`>` operator

`>=` operator

`=` operator

`<>` operator

[Is Operator](#)

[IsNot Operator](#)

[Like Operator](#)

These operators compare two expressions to determine whether or not they are equal, and if not, how they differ.

`Is`, `IsNot`, and `Like` are discussed in detail on separate Help pages. The relational comparison operators are discussed in detail on this page.

Syntax

```
result = expression1 comparisonoperator expression2
result = object1 [Is | IsNot] object2
result = string Like pattern
```

Parts

`result`

Required. A `Boolean` value representing the result of the comparison.

`expression`

Required. Any expression.

`comparisonoperator`

Required. Any relational comparison operator.

`object1`, `object2`

Required. Any reference object names.

`string`

Required. Any `String` expression.

`pattern`

Required. Any `String` expression or range of characters.

Remarks

The following table contains a list of the relational comparison operators and the conditions that determine whether `result` is `True` or `False`.

OPERATOR	TRUE IF	FALSE IF
<code><</code> (Less than)	<code>expression1 < expression2</code>	<code>expression1 >= expression2</code>
<code><=</code> (Less than or equal to)	<code>expression1 <= expression2</code>	<code>expression1 > expression2</code>
<code>></code> (Greater than)	<code>expression1 > expression2</code>	<code>expression1 <= expression2</code>
<code>>=</code> (Greater than or equal to)	<code>expression1 >= expression2</code>	<code>expression1 < expression2</code>
<code>=</code> (Equal to)	<code>expression1 = expression2</code>	<code>expression1 <> expression2</code>
<code><></code> (Not equal to)	<code>expression1 <> expression2</code>	<code>expression1 = expression2</code>

NOTE

The [= Operator](#) is also used as an assignment operator.

The `Is` operator, the `IsNot` operator, and the `Like` operator have specific comparison functionalities that differ from the operators in the preceding table.

Comparing Numbers

When you compare an expression of type `Single` to one of type `Double`, the `Single` expression is converted to `Double`. This behavior is opposite to the behavior found in Visual Basic 6.

Similarly, when you compare an expression of type `Decimal` to an expression of type `Single` or `Double`, the `Decimal` expression is converted to `Single` or `Double`. For `Decimal` expressions, any fractional value less than 1E-28 might be lost. Such fractional value loss may cause two values to compare as equal when they are not. For this reason, you should take care when using equality (`=`) to compare two floating-point variables. It is safer to test whether the absolute value of the difference between the two numbers is less than a small acceptable tolerance.

Floating-point Imprecision

When you work with floating-point numbers, keep in mind that they do not always have a precise representation in memory. This could lead to unexpected results from certain operations, such as value comparison and the [Mod Operator](#). For more information, see [Troubleshooting Data Types](#).

Comparing Strings

When you compare strings, the string expressions are evaluated based on their alphabetical sort order, which depends on the `Option Compare` setting.

`Option Compare Binary` bases string comparisons on a sort order derived from the internal binary representations of the characters. The sort order is determined by the code page. The following example shows a typical binary sort order.

```
A < B < E < Z < a < b < e < z < À < È < Ø < à < ê < ø
```

`Option Compare Text` bases string comparisons on a case-insensitive, textual sort order determined by your application's locale. When you set `Option Compare Text` and sort the characters in the preceding example, the following text sort order applies:

(A=a) < (À= à) < (B=b) < (E=e) < (È= ê) < (Ø = ø) < (Z=z)

Locale Dependence

When you set `Option Compare Text`, the result of a string comparison can depend on the locale in which the application is running. Two characters might compare as equal in one locale but not in another. If you are using a string comparison to make important decisions, such as whether to accept an attempt to log on, you should be alert to locale sensitivity. Consider either setting `Option Compare Binary` or calling the `StrComp`, which takes the locale into account.

Typeless Programming with Relational Comparison Operators

The use of relational comparison operators with `Object` expressions is not allowed under `Option Strict On`. When `Option Strict` is `off`, and either `expression1` or `expression2` is an `Object` expression, the run-time types determine how they are compared. The following table shows how the expressions are compared and the result from the comparison, depending on the runtime type of the operands.

IF OPERANDS ARE	COMPARISON IS
Both <code>String</code>	Sort comparison based on string sorting characteristics.
Both numeric	Objects converted to <code>Double</code> , numeric comparison.
One numeric and one <code>String</code>	The <code>String</code> is converted to a <code>Double</code> and numeric comparison is performed. If the <code>String</code> cannot be converted to <code>Double</code> , an <code>InvalidCastException</code> is thrown.
Either or both are reference types other than <code>String</code>	An <code>InvalidCastException</code> is thrown.

Numeric comparisons treat `Nothing` as 0. String comparisons treat `Nothing` as `""` (an empty string).

Overloading

The relational comparison operators (`<`, `<=`, `>`, `>=`, `=`, `<>`) can be *overloaded*, which means that a class or structure can redefine their behavior when an operand has the type of that class or structure. If your code uses any of these operators on such a class or structure, be sure you understand the redefined behavior. For more information, see [Operator Procedures](#).

Notice that the `= Operator` can be overloaded only as a relational comparison operator, not as an assignment operator.

Example

The following example shows various uses of relational comparison operators, which you use to compare expressions. Relational comparison operators return a `Boolean` result that represents whether or not the stated expression evaluates to `True`. When you apply the `>` and `<` operators to strings, the comparison is made using the normal alphabetical sorting order of the strings. This order can be dependent on your locale setting. Whether the sort is case-sensitive or not depends on the `Option Compare` setting.

```
Dim x As testClass
Dim y As New testClass()
x = y
If x Is y Then
    ' Insert code to run if x and y point to the same instance.
End If
```

In the preceding example, the first comparison returns `False` and the remaining comparisons return `True`.

<< Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs an arithmetic left shift on a bit pattern.

Syntax

```
result = pattern << amount
```

Parts

`result`

Required. Integral numeric value. The result of shifting the bit pattern. The data type is the same as that of `pattern`.

`pattern`

Required. Integral numeric expression. The bit pattern to be shifted. The data type must be an integral type (`SByte`, `Byte`, `Short`, `UShort`, `Integer`, `UInteger`, `Long`, or `ULong`).

`amount`

Required. Numeric expression. The number of bits to shift the bit pattern. The data type must be `Integer` or widen to `Integer`.

Remarks

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic left shift, the bits shifted beyond the range of the result data type are discarded, and the bit positions vacated on the right are set to zero.

To prevent a shift by more bits than the result can hold, Visual Basic masks the value of `amount` with a size mask that corresponds to the data type of `pattern`. The binary AND of these values is used for the shift amount. The size masks are as follows:

DATA TYPE OF <code>PATTERN</code>	SIZE MASK (DECIMAL)	SIZE MASK (HEXADECIMAL)
<code>SByte</code> , <code>Byte</code>	7	&H00000007
<code>Short</code> , <code>UShort</code>	15	&H0000000F
<code>Integer</code> , <code>UInteger</code>	31	&H0000001F
<code>Long</code> , <code>ULong</code>	63	&H0000003F

If `amount` is zero, the value of `result` is identical to the value of `pattern`. If `amount` is negative, it is taken as an unsigned value and masked with the appropriate size mask.

Arithmetic shifts never generate overflow exceptions.

NOTE

The `<<` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure that you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `<<` operator to perform arithmetic left shifts on integral values. The result always has the same data type as that of the expression being shifted.

```
Dim pattern As Short = 192
' The bit pattern is 0000 0000 1100 0000.
Dim result1, result2, result3, result4, result5 As Short
result1 = pattern << 0
result2 = pattern << 4
result3 = pattern << 9
result4 = pattern << 17
result5 = pattern << -1
```

The results of the previous example are as follows:

- `result1` is 192 (0000 0000 1100 0000).
- `result2` is 3072 (0000 1100 0000 0000).
- `result3` is -32768 (1000 0000 0000 0000).
- `result4` is 384 (0000 0001 1000 0000).
- `result5` is 0 (shifted 15 places to the left).

The shift amount for `result4` is calculated as 17 AND 15, which equals 1.

Syntax

```
variableorproperty <<= amount
```

Parts

`variableorproperty`

Required. Variable or property of an integral type (`SByte`, `Byte`, `Short`, `UShort`, `Integer`, `UInteger`, `Long`, or `ULong`).

`amount`

Required. Numeric expression of a data type that widens to `Integer`.

Remarks

The element on the left side of the `<<=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `<<=` operator first performs an arithmetic left shift on the value of the variable or property. The operator then assigns the result of that operation back to that variable or property.

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic left shift, the bits shifted beyond the range of the result data type are discarded, and the bit positions vacated on the right are set to zero.

Overloading

The `<<` Operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `<<` operator affects the behavior of the `<<=` operator. If your code uses `<<=` on a class or structure that overloads `<<`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `<<=` operator to shift the bit pattern of an `Integer` variable left by the specified amount and assign the result to the variable.

```
Dim var As Integer = 10
Dim shift As Integer = 3
var <<= shift
' The value of var is now 80.

>> Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs an arithmetic right shift on a bit pattern.

Syntax

```
result = pattern >> amount
```

Parts

`result`

Required. Integral numeric value. The result of shifting the bit pattern. The data type is the same as that of `pattern`.

`pattern`

Required. Integral numeric expression. The bit pattern to be shifted. The data type must be an integral type (`SByte`, `Byte`, `Short`, `UShort`, `Integer`, `UInteger`, `Long`, or `ULong`).

`amount`

Required. Numeric expression. The number of bits to shift the bit pattern. The data type must be `Integer` or widen to `Integer`.

Remarks

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic right shift, the bits shifted beyond the rightmost bit position are discarded, and the leftmost (sign) bit is propagated into the bit positions vacated at the left. This means that if `pattern` has a negative value, the vacated positions are set to one; otherwise they are set to zero.

Note that the data types `Byte`, `UShort`, `UInteger`, and `ULong` are unsigned, so there is no sign bit to propagate. If `pattern` is of any unsigned type, the vacated positions are always set to zero.

To prevent shifting by more bits than the result can hold, Visual Basic masks the value of `amount` with a size mask corresponding to the data type of `pattern`. The binary AND of these values is used for the shift amount. The size masks are as follows:

DATA TYPE OF <code>PATTERN</code>	SIZE MASK (DECIMAL)	SIZE MASK (HEXADECIMAL)
<code>SByte</code> , <code>Byte</code>	7	&H00000007
<code>Short</code> , <code>UShort</code>	15	&H0000000F
<code>Integer</code> , <code>UInteger</code>	31	&H0000001F
<code>Long</code> , <code>ULong</code>	63	&H0000003F

If `amount` is zero, the value of `result` is identical to the value of `pattern`. If `amount` is negative, it is taken as an unsigned value and masked with the appropriate size mask.

Arithmetic shifts never generate overflow exceptions.

Overloading

The `>>` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `>>` operator to perform arithmetic right shifts on integral values. The result always has the same data type as that of the expression being shifted.

```
Dim pattern As Short = 2560
' The bit pattern is 0000 1010 0000 0000.
Dim result1, result2, result3, result4, result5 As Short
result1 = pattern >> 0
result2 = pattern >> 4
result3 = pattern >> 10
result4 = pattern >> 18
result5 = pattern >> -1
```

The results of the preceding example are as follows:

- `result1` is 2560 (0000 1010 0000 0000).
- `result2` is 160 (0000 0000 1010 0000).
- `result3` is 2 (0000 0000 0000 0010).
- `result4` is 640 (0000 0010 1000 0000).
- `result5` is 0 (shifted 15 places to the right).

The shift amount for `result4` is calculated as 18 AND 15, which equals 2.

The following example shows arithmetic shifts on a negative value.

```
Dim negPattern As Short = -8192
' The bit pattern is 1110 0000 0000 0000.
Dim negResult1, negResult2 As Short
negResult1 = negPattern >> 4
negResult2 = negPattern >> 13
```

The results of the preceding example are as follows:

- `negResult1` is -512 (1111 1110 0000 0000).
- `negResult2` is -1 (the sign bit is propagated).

>>= Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs an arithmetic right shift on the value of a variable or property and assigns the result back to the variable or property.

Syntax

```
variableorproperty >>= amount
```

Parts

`variableorproperty`

Required. Variable or property of an integral type (`sByte`, `Byte`, `Short`, `UShort`, `Integer`, `UInteger`, `Long`, or `ULong`).

`amount`

Required. Numeric expression of a data type that widens to `Integer`.

Remarks

The element on the left side of the `>>=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `>>=` operator first performs an arithmetic right shift on the value of the variable or property. The operator then assigns the result of that operation back to the variable or property.

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic right shift, the bits shifted beyond the rightmost bit position are discarded, and the leftmost bit is propagated into the bit positions vacated at the left. This means that if `variableorproperty` has a negative value, the vacated positions are set to one. If `variableorproperty` is positive, or if its data type is an unsigned type, the vacated positions are set to zero.

Overloading

The [>> Operator](#) can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `>>` operator affects the behavior of the `>>=` operator. If your code uses `>>=` on a class or structure that overloads `>>`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `>>=` operator to shift the bit pattern of an `Integer` variable right by the specified amount and assign the result to the variable.

```
Dim var As Integer = 10
Dim shift As Integer = 2
var >>= shift
' The value of var is now 2 (two bits were lost off the right end).

/ Operator (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Divides two numbers and returns a floating-point result.

Syntax

```
expression1 / expression2
```

Parts

`expression1`

Required. Any numeric expression.

`expression2`

Required. Any numeric expression.

Supported Types

All numeric types, including the unsigned and floating-point types and `Decimal`.

Result

The result is the full quotient of `expression1` divided by `expression2`, including any remainder.

The [\ Operator \(Visual Basic\)](#) returns the integer quotient, which drops the remainder.

Remarks

The data type of the result depends on the types of the operands. The following table shows how the data type of the result is determined.

OPERAND DATA TYPES	RESULT DATA TYPE
Both expressions are integral data types (<code>SByte</code> , <code>Byte</code> , <code>Short</code> , <code>UShort</code> , <code>Integer</code> , <code>UInteger</code> , <code>Long</code> , <code>ULong</code>)	<code>Double</code>
One expression is a <code>Single</code> data type and the other is not a <code>Double</code>	<code>Single</code>
One expression is a <code>Decimal</code> data type and the other is not a <code>Single</code> or a <code>Double</code>	<code>Decimal</code>
Either expression is a <code>Double</code> data type	<code>Double</code>

Before division is performed, any integral numeric expressions are widened to `Double`. If you assign the result to an integral data type, Visual Basic attempts to convert the result from `Double` to that type. This can throw an exception if the result does not fit in that type. In particular, see "Attempted Division by Zero" on this Help page.

If `expression1` or `expression2` evaluates to `Nothing`, it is treated as zero.

Attempted Division by Zero

If `expression2` evaluates to zero, the `/` operator behaves differently for different operand data types. The following table shows the possible behaviors.

OPERAND DATA TYPES	BEHAVIOR IF <code>expression2</code> IS ZERO
Floating-point (<code>Single</code> or <code>Double</code>)	Returns infinity (<code>PositiveInfinity</code> or <code>NegativeInfinity</code>), or <code>NaN</code> (not a number) if <code>expression1</code> is also zero
<code>Decimal</code>	Throws <code>DivideByZeroException</code>
Integral (signed or unsigned)	Attempted conversion back to integral type throws <code>OverflowException</code> because integral types cannot accept <code>PositiveInfinity</code> , <code>NegativeInfinity</code> , or <code>NaN</code>

NOTE

The `/` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

This example uses the `/` operator to perform floating-point division. The result is the quotient of the two operands.

```
Dim resultValue As Double  
resultValue = 10 / 4  
resultValue = 10 / 3
```

The expressions in the preceding example return values of 2.5 and 3.333333. Note that the result is always floating-point (`Double`), even though both operands are integer constants.

/= Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Divides the value of a variable or property by the value of an expression and assigns the floating-point result to the variable or property.

Syntax

```
variableorproperty /= expression
```

Parts

`variableorproperty`

Required. Any numeric variable or property.

`expression`

Required. Any numeric expression.

Remarks

The element on the left side of the `/=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `/=` operator first divides the value of the variable or property (on the left-hand side of the operator) by the value of the expression (on the right-hand side of the operator). The operator then assigns the floating-point result of that operation to the variable or property.

This statement assigns a `Double` value to the variable or property on the left. If `Option Strict` is `On`, `variableorproperty` must be a `Double`. If `Option Strict` is `Off`, Visual Basic performs an implicit conversion and assigns the resulting value to `variableorproperty`, with a possible error at run time. For more information, see [Widening and Narrowing Conversions](#) and [Option Strict Statement](#).

Overloading

The [/ Operator \(Visual Basic\)](#) can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `/` operator affects the behavior of the `/=` operator. If your code uses `/=` on a class or structure that overloads `/`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `/=` operator to divide one `Integer` variable by a second and assign the quotient to the first variable.

```
Dim var1 As Integer = 12
Dim var2 As Integer = 3
var1 /= var2
' The value of var1 is now 4.
```

\ Operator (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Divides two numbers and returns an integer result.

Syntax

```
expression1 \ expression2
```

Parts

`expression1`

Required. Any numeric expression.

`expression2`

Required. Any numeric expression.

Supported Types

All numeric types, including the unsigned and floating-point types and `Decimal`.

Result

The result is the integer quotient of `expression1` divided by `expression2`, which discards any remainder and retains only the integer portion. This is known as *truncation*.

The result data type is a numeric type appropriate for the data types of `expression1` and `expression2`. See the "Integer Arithmetic" tables in [Data Types of Operator Results](#).

The [/ Operator \(Visual Basic\)](#) returns the full quotient, which retains the remainder in the fractional portion.

Remarks

Before performing the division, Visual Basic attempts to convert any floating-point numeric expression to `Long`. If `Option Strict` is `On`, a compiler error occurs. If `Option Strict` is `Off`, an [OverflowException](#) is possible if the value is outside the range of the [Long Data Type](#). The conversion to `Long` is also subject to *banker's rounding*. For more information, see "Fractional Parts" in [Type Conversion Functions](#).

If `expression1` or `expression2` evaluates to [Nothing](#), it is treated as zero.

Attempted Division by Zero

If `expression2` evaluates to zero, the `\` operator throws a [DivideByZeroException](#) exception. This is true for all numeric data types of the operands.

NOTE

The `\` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `\` operator to perform integer division. The result is an integer that represents the integer quotient of the two operands, with the remainder discarded.

```
Dim resultValue As Integer  
resultValue = 11 \ 4  
resultValue = 9 \ 3  
resultValue = 100 \ 3  
resultValue = 67 \ -3
```

The expressions in the preceding example return values of 2, 3, 33, and -22, respectively.

```

Parts

`variableorproperty`

Required. Any numeric variable or property.

`expression`

Required. Any numeric expression.

Remarks

The element on the left side of the `\=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `\=` operator divides the value of a variable or property on its left by the value on its right, and assigns the integer result to the variable or property on its left.

For further information on integer division, see [\ Operator \(Visual Basic\)](#).

Overloading

The `\` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. `^` Operator (Visual Basic)

3/8/2019 • 2 minutes to read • [Edit Online](#)

Raises a number to the power of another number.

Syntax

```
number ^ exponent
```

Parts

`number`

Required. Any numeric expression.

`exponent`

Required. Any numeric expression.

Result

The result is `number` raised to the power of `exponent`, always as a `Double` value.

Supported Types

`Double`. Operands of any different type are converted to `Double`.

Remarks

Visual Basic always performs exponentiation in the [Double Data Type](#).

The value of `exponent` can be fractional, negative, or both.

When more than one exponentiation is performed in a single expression, the `^` operator is evaluated as it is encountered from left to right.

NOTE

The `^` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `^` operator to raise a number to the power of an exponent. The result is the first operand raised to the power of the second.

```
Dim exp1, exp2, exp3, exp4, exp5, exp6 As Double  
exp1 = 2 ^ 2  
exp2 = 3 ^ 3 ^ 3  
exp3 = (-5) ^ 3  
exp4 = (-5) ^ 4  
exp5 = 8 ^ (1.0 / 3.0)  
exp6 = 8 ^ (-1.0 / 3.0)
```

The preceding example produces the following results:

`exp1` is set to 4 (2 squared).

`exp2` is set to 19683 (3 cubed, then that value cubed).

`exp3` is set to -125 (-5 cubed).

`exp4` is set to 625 (-5 to the fourth power).

`exp5` is set to 2 (cube root of 8).

`exp6` is set to 0.5 (1.0 divided by the cube root of 8).

Note the importance of the parentheses in the expressions in the preceding example. Because of *operator precedence*, Visual Basic normally performs the `^` operator before any others, even the unary `-` operator. If `exp4` and `exp6` had been calculated without parentheses, they would have produced the following results:

`exp4 = -5 ^ 4` would be calculated as $-(5 \text{ to the fourth power})$, which would result in -625 .

`^=` Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Raises the value of a variable or property to the power of an expression and assigns the result back to the variable or property.

Syntax

```
variableorproperty ^= expression
```

Parts

`variableorproperty`

Required. Any numeric variable or property.

`expression`

Required. Any numeric expression.

Remarks

The element on the left side of the `^=` operator can be a simple scalar variable, a property, or an element of an array. The variable or property cannot be [ReadOnly](#).

The `^=` operator first raises the value of the variable or property (on the left-hand side of the operator) to the power of the value of the expression (on the right-hand side of the operator). The operator then assigns the result of that operation back to the variable or property.

Visual Basic always performs exponentiation in the [Double Data Type](#). Operands of any different type are converted to `Double`, and the result is always `Double`.

The value of `expression` can be fractional, negative, or both.

Overloading

The [^ Operator](#) can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. Overloading the `^` operator affects the behavior of the `^=` operator. If your code uses `^=` on a class or structure that overloads `^`, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `^=` operator to raise the value of one `Integer` variable to the power of a second variable and assign the result to the first variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 ^= var2
' The value of var1 is now 1000.

? . and ?() null-conditional operators (Visual Basic)

3/22/2019 • 2 minutes to read • [Edit Online](#)

Tests the value of the left-hand operand for null (`Nothing`) before performing a member access (`?.`) or index (`?()`) operation; returns `Nothing` if the left-hand operand evaluates to `Nothing`. Note that in expressions that ordinarily return value types, the null-conditional operator returns a `Nullable<T>`.

These operators help you write less code to handle null checks, especially when descending into data structures. For example:

```
' Nothing if customers is Nothing
Dim length As Integer? = customers?.Length

' Nothing if customers is Nothing
Dim first As Customer = customers?(0)

' Nothing if customers, the first customer, or Orders is Nothing
Dim count As Integer? = customers?(0)?.Orders?.Count()
```

For comparison, the alternative code for the first of these expressions without a null-conditional operator is:

```
Dim length As Integer
If customers IsNot Nothing Then
    length = customers.Length
End If
```

The null-conditional operators are short-circuiting. If one operation in a chain of conditional member access and index operations returns `Nothing`, the rest of the chain's execution stops. In the following example, `C(E)` isn't evaluated if `A`, `B`, or `C` evaluates to `Nothing`.

```
A?.B?.C?(E);
```

Another use for null-conditional member access is to invoke delegates in a thread-safe way with much less code. The following example defines two types, a `NewsBroadcaster` and a `NewsReceiver`. News items are sent to the receiver by the `NewsBroadcaster.SendNews` delegate.

```

Public Module NewsBroadcaster
    Dim SendNews As Action(Of String)

    Public Sub Main()
        Dim rec As New NewsReceiver()
        Dim rec2 As New NewsReceiver()
        SendNews?.Invoke("Just in: A newsworthy item...")
    End Sub

    Public Sub Register(client As Action(Of String))
        SendNews = SendNews.Combine({SendNews, client})
    End Sub
End Module

Public Class NewsReceiver
    Public Sub New()
        NewsBroadcaster.Register(AddressOf Me.DisplayNews)
    End Sub

    Public Sub DisplayNews(newsItem As String)
        Console.WriteLine(newsItem)
    End Sub
End Class

```

If there are no elements in the `SendNews` invocation list, the `SendNews` delegate throws a [NullReferenceException](#). Before null conditional operators, code like the following ensured that the delegate invocation list was not `Nothing`:

```

SendNews = SendNews.Combine({SendNews, client})
If SendNews IsNot Nothing Then
    SendNews("Just in...")
End If

```

The new way is much simpler:

```

SendNews = SendNews.Combine({SendNews, client})
SendNews?.Invoke("Just in...")

```

The new way is thread-safe because the compiler generates code to evaluate `SendNews` one time only, keeping the result in a temporary variable. You need to explicitly call the `Invoke` method because there is no null-conditional delegate invocation syntax `SendNews?(String)`.

AddressOf Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Creates a procedure delegate instance that references the specific procedure.

Syntax

```
AddressOf procedurename
```

Parts

`procedurename`

Required. Specifies the procedure to be referenced by the newly created procedure delegate.

Remarks

The `AddressOf` operator creates a function delegate that points to the function specified by `procedurename`. When the specified procedure is an instance method then the function delegate refers to both the instance and the method. Then, when the function delegate is invoked the specified method of the specified instance is called.

The `AddressOf` operator can be used as the operand of a delegate constructor or it can be used in a context in which the type of the delegate can be determined by the compiler.

Example

This example uses the `AddressOf` operator to designate a delegate to handle the `Click` event of a button.

```
' Add the following line to Sub Form1_Load().
AddHandler Button1.Click, AddressOf Button1_Click
```

Example

The following example uses the `AddressOf` operator to designate the startup function for a thread.

```
Public Sub CountSheep()
    Dim i As Integer = 1 ' Sheep do not count from 0.
    Do While (True) ' Endless loop.
        Console.WriteLine("Sheep " & i & " Baah")
        i = i + 1

And Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs a logical conjunction on two `Boolean` expressions, or a bitwise conjunction on two numeric expressions.

Syntax

```
result = expression1 And expression2
```

Parts

`result`

Required. Any `Boolean` or numeric expression. For Boolean comparison, `result` is the logical conjunction of two `Boolean` values. For bitwise operations, `result` is a numeric value representing the bitwise conjunction of two numeric bit patterns.

`expression1`

Required. Any `Boolean` or numeric expression.

`expression2`

Required. Any `Boolean` or numeric expression.

Remarks

For Boolean comparison, `result` is `True` if and only if both `expression1` and `expression2` evaluate to `True`. The following table illustrates how `result` is determined.

IF <code>EXPRESSION1</code> IS	AND <code>EXPRESSION2</code> IS	THE VALUE OF <code>RESULT</code> IS
<code>True</code>	<code>True</code>	<code>True</code>
<code>True</code>	<code>False</code>	<code>False</code>
<code>False</code>	<code>True</code>	<code>False</code>
<code>False</code>	<code>False</code>	<code>False</code>

NOTE

In a Boolean comparison, the `And` operator always evaluates both expressions, which could include making procedure calls. The [AndAlso Operator](#) performs *short-circuiting*, which means that if `expression1` is `False`, then `expression2` is not evaluated.

When applied to numeric values, the `And` operator performs a bitwise comparison of identically positioned bits in two numeric expressions and sets the corresponding bit in `result` according to the following table.

IF BIT IN <code>EXPRESSION1</code> IS	AND BIT IN <code>EXPRESSION2</code> IS	THE BIT IN <code>RESULT</code> IS
1	1	1
1	0	0
0	1	0
0	0	0

NOTE

Since the logical and bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate results.

Data Types

If the operands consist of one `Boolean` expression and one numeric expression, Visual Basic converts the `Boolean` expression to a numeric value (–1 for `True` and 0 for `False`) and performs a bitwise operation.

For a Boolean comparison, the data type of the result is `Boolean`. For a bitwise comparison, the result data type is a numeric type appropriate for the data types of `expression1` and `expression2`. See the "Relational and Bitwise Comparisons" table in [Data Types of Operator Results](#).

NOTE

The `And` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `And` operator to perform a logical conjunction on two expressions. The result is a `Boolean` value that represents whether both of the expressions are `True`.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstCheck, secondCheck As Boolean
firstCheck = a > b And b > c
secondCheck = b > a And b > c
```

The preceding example produces results of `True` and `False`, respectively.

Example

The following example uses the `And` operator to perform logical conjunction on the individual bits of two numeric expressions. The bit in the result pattern is set if the corresponding bits in the operands are both set to 1.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstPattern, secondPattern, thirdPattern As Integer
firstPattern = (a And b)
secondPattern = (a And c)
thirdPattern = (b And c)
```

The preceding example produces results of 8, 2, and 0, respectively.

AndAlso Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs short-circuiting logical conjunction on two expressions.

Syntax

```
result = expression1 AndAlso expression2
```

Parts

TERM	DEFINITION
result	Required. Any <code>Boolean</code> expression. The result is the <code>Boolean</code> result of comparison of the two expressions.
expression1	Required. Any <code>Boolean</code> expression.
expression2	Required. Any <code>Boolean</code> expression.

Remarks

A logical operation is said to be *short-circuiting* if the compiled code can bypass the evaluation of one expression depending on the result of another expression. If the result of the first expression evaluated determines the final result of the operation, there is no need to evaluate the second expression, because it cannot change the final result. Short-circuiting can improve performance if the bypassed expression is complex, or if it involves procedure calls.

If both expressions evaluate to `True`, `result` is `True`. The following table illustrates how `result` is determined.

IF <code>EXPRESSION1</code> IS	AND <code>EXPRESSION2</code> IS	THE VALUE OF <code>RESULT</code> IS
<code>True</code>	<code>True</code>	<code>True</code>
<code>True</code>	<code>False</code>	<code>False</code>
<code>False</code>	(not evaluated)	<code>False</code>

Data Types

The `AndAlso` operator is defined only for the [Boolean Data Type](#). Visual Basic converts each operand as necessary to `Boolean` and performs the operation entirely in `Boolean`. If you assign the result to a numeric type, Visual Basic converts it from `Boolean` to that type. This could produce unexpected behavior. For example, `5 AndAlso 12` results in `-1` when converted to `Integer`.

Overloading

The [And Operator](#) and the [IsFalse Operator](#) can be *overloaded*, which means that a class or structure can redefine their behavior when an operand has the type of that class or structure. Overloading the `And` and `IsFalse` operators affects the behavior of the `AndAlso` operator. If your code uses `AndAlso` on a class or structure that overloads `And` and `IsFalse`, be sure you understand their redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `AndAlso` operator to perform a logical conjunction on two expressions. The result is a `Boolean` value that represents whether the entire conjoined expression is true. If the first expression is `False`, the second is not evaluated.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstCheck, secondCheck, thirdCheck As Boolean
firstCheck = a > b AndAlso b > c
secondCheck = b > a AndAlso b > c
thirdCheck = a > b AndAlso c > b
```

The preceding example produces results of `True`, `False`, and `False`, respectively. In the calculation of `secondCheck`, the second expression is not evaluated because the first is already `False`. However, the second expression is evaluated in the calculation of `thirdCheck`.

Example

The following example shows a `Function` procedure that searches for a given value among the elements of an array. If the array is empty, or if the array length has been exceeded, the `While` statement does not test the array element against the search value.

```
Public Function findValue(ByVal arr() As Double,
    ByVal searchValue As Double) As Double
    Dim i As Integer = 0
    While i <= UBound(arr) AndAlso arr(i) <> searchValue
        ' If i is greater than UBound(arr), searchValue is not checked.
        i += 1
    End While
    If i > UBound(arr) Then i = -1
    Return i
End Function
```

Await Operator (Visual Basic)

1/23/2019 • 4 minutes to read • [Edit Online](#)

You apply the `Await` operator to an operand in an asynchronous method or lambda expression to suspend execution of the method until the awaited task completes. The task represents ongoing work.

The method in which `Await` is used must have an `Async` modifier. Such a method, defined by using the `Async` modifier, and usually containing one or more `Await` expressions, is referred to as an *async method*.

NOTE

The `Async` and `Await` keywords were introduced in Visual Studio 2012. For an introduction to async programming, see [Asynchronous Programming with Async and Await](#).

Typically, the task to which you apply the `Await` operator is the return value from a call to a method that implements the [Task-Based Asynchronous Pattern](#), that is, a `Task` or a `Task<TResult>`.

In the following code, the `HttpClient` method `GetByteArrayAsync` returns `getContentsTask`, a `Task(Of Byte())`. The task is a promise to produce the actual byte array when the operation is complete. The `Await` operator is applied to `getContentsTask` to suspend execution in `SumPageSizesAsync` until `getContentsTask` is complete. In the meantime, control is returned to the caller of `SumPageSizesAsync`. When `getContentsTask` is finished, the `Await` expression evaluates to a byte array.

```
Private Async Function SumPageSizesAsync() As Task

    ' To use the HttpClient type in desktop apps, you must include a using directive and add a
    ' reference for the System.Net.Http namespace.
    Dim client As HttpClient = New HttpClient()
    ' ...
    Dim getContentsTask As Task(Of Byte()) = client.GetByteArrayAsync(url)
    Dim urlContents As Byte() = Await getContentsTask

    ' Equivalently, now that you see how it works, you can write the same thing in a single line.
    'Dim urlContents As Byte() = Await client.GetByteArrayAsync(url)
    ' ...
End Function
```

IMPORTANT

For the complete example, see [Walkthrough: Accessing the Web by Using Async and Await](#). You can download the sample from [Developer Code Samples](#) on the Microsoft website. The example is in the `AsyncWalkthrough_HttpClient` project.

If `Await` is applied to the result of a method call that returns a `Task(Of TResult)`, the type of the `Await` expression is `TResult`. If `Await` is applied to the result of a method call that returns a `Task`, the `Await` expression doesn't return a value. The following example illustrates the difference.

```
' Await used with a method that returns a Task(Of TResult).  
Dim result As TResult = Await AsyncMethodThatReturnsTaskTResult()  
  
' Await used with a method that returns a Task.  
Await AsyncMethodThatReturnsTask()
```

An `Await` expression or statement does not block the thread on which it is executing. Instead, it causes the compiler to sign up the rest of the async method, after the `Await` expression, as a continuation on the awaited task. Control then returns to the caller of the async method. When the task completes, it invokes its continuation, and execution of the async method resumes where it left off.

An `Await` expression can occur only in the body of an immediately enclosing method or lambda expression that is marked by an `Async` modifier. The term *Await* serves as a keyword only in that context. Elsewhere, it is interpreted as an identifier. Within the async method or lambda expression, an `Await` expression cannot occur in a query expression, in the `catch` or `finally` block of a [Try...Catch...Finally](#) statement, in the loop control variable expression of a `For` or `For Each` loop, or in the body of a [SyncLock](#) statement.

Exceptions

Most async methods return a `Task` or `Task<TResult>`. The properties of the returned task carry information about its status and history, such as whether the task is complete, whether the async method caused an exception or was canceled, and what the final result is. The `Await` operator accesses those properties.

If you await a task-returning async method that causes an exception, the `Await` operator rethrows the exception.

If you await a task-returning async method that is canceled, the `Await` operator rethrows an [OperationCanceledException](#).

A single task that is in a faulted state can reflect multiple exceptions. For example, the task might be the result of a call to [Task.WhenAll](#). When you await such a task, the await operation rethrows only one of the exceptions. However, you can't predict which of the exceptions is rethrown.

For examples of error handling in async methods, see [Try...Catch...Finally Statement](#).

Example

The following Windows Forms example illustrates the use of `Await` in an async method, `WaitAsynchronouslyAsync`. Contrast the behavior of that method with the behavior of `WaitSynchronously`. Without an `Await` operator, `WaitSynchronously` runs synchronously despite the use of the `Async` modifier in its definition and a call to [Thread.Sleep](#) in its body.

```

Private Async Sub Button1_Click(sender As Object, e As EventArgs) Handles Button1.Click
    ' Call the method that runs asynchronously.
    Dim result As String = Await WaitAsynchronouslyAsync()

    ' Call the method that runs synchronously.
    'Dim result As String = Await WaitSynchronously()

    ' Display the result.
    TextBox1.Text &= result
End Sub

' The following method runs asynchronously. The UI thread is not
' blocked during the delay. You can move or resize the Form1 window
' while Task.Delay is running.
Public Async Function WaitAsynchronouslyAsync() As Task(Of String)
    Await Task.Delay(10000)
    Return "Finished"
End Function

' The following method runs synchronously, despite the use of Async.
' You cannot move or resize the Form1 window while Thread.Sleep
' is running because the UI thread is blocked.
Public Async Function WaitSynchronously() As Task(Of String)
    ' Import System.Threading for the Sleep method.
    Thread.Sleep(10000)
    Return "Finished"
End Function

```

DirectCast Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Introduces a type conversion operation based on inheritance or implementation.

Remarks

`DirectCast` does not use the Visual Basic run-time helper routines for conversion, so it can provide somewhat better performance than `CType` when converting to and from data type `Object`.

You use the `DirectCast` keyword similar to the way you use the [CType Function](#) and the [TryCast Operator](#) keyword. You supply an expression as the first argument and a type to convert it to as the second argument.

`DirectCast` requires an inheritance or implementation relationship between the data types of the two arguments. This means that one type must inherit from or implement the other.

Errors and Failures

`DirectCast` generates a compiler error if it detects that no inheritance or implementation relationship exists. But the lack of a compiler error does not guarantee a successful conversion. If the desired conversion is narrowing, it could fail at run time. If this happens, the runtime throws an [InvalidOperationException](#) error.

Conversion Keywords

A comparison of the type conversion keywords is as follows.

KEYWORD	DATA TYPES	ARGUMENT RELATIONSHIP	RUN-TIME FAILURE
CType Function	Any data types	Widening or narrowing conversion must be defined between the two data types	Throws InvalidOperationException
<code>DirectCast</code>	Any data types	One type must inherit from or implement the other type	Throws InvalidOperationException
TryCast Operator	Reference types only	One type must inherit from or implement the other type	Returns Nothing

Example

The following example demonstrates two uses of `DirectCast`, one that fails at run time and one that succeeds.

```
Dim q As Object = 2.37
Dim i As Integer = CType(q, Integer)
' The following conversion fails at run time
Dim j As Integer = DirectCast(q, Integer)
Dim f As New System.Windows.Forms.Form
Dim c As System.Windows.Forms.Control
' The following conversion succeeds.
c = DirectCast(f, System.Windows.Forms.Control)
```

In the preceding example, the run-time type of `q` is `Double`. `CType` succeeds because `Double` can be converted

to `Integer`. However, the first `DirectCast` fails at run time because the run-time type of `Double` has no inheritance relationship with `Integer`, even though a conversion exists. The second `DirectCast` succeeds because it converts from type `Form` to type `Control`, from which `Form` inherits.

Function Expression (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Declares the parameters and code that define a function lambda expression.

Syntax

```
Function ( [ parameterlist ] ) expression
- or -
Function ( [ parameterlist ] )
[ statements ]
End Function
```

Parts

TERM	DEFINITION
parameterlist	Optional. A list of local variable names that represent the parameters of this procedure. The parentheses must be present even when the list is empty. See Parameter List .
expression	Required. A single expression. The type of the expression is the return type of the function.
statements	Required. A list of statements that returns a value by using the <code>Return</code> statement. (See Return Statement .) The type of the value returned is the return type of the function.

Remarks

A *lambda expression* is a function without a name that calculates and returns a value. You can use a lambda expression anywhere you can use a delegate type, except as an argument to `RemoveHandler`. For more information about delegates, and the use of lambda expressions with delegates, see [Delegate Statement](#) and [Relaxed Delegate Conversion](#).

Lambda Expression Syntax

The syntax of a lambda expression resembles that of a standard function. The differences are as follows:

- A lambda expression does not have a name.
- Lambda expressions cannot have modifiers, such as `overloads` or `Overrides`.
- Lambda expressions do not use an `As` clause to designate the return type of the function. Instead, the type is inferred from the value that the body of a single-line lambda expression evaluates to, or the return value of a multiline lambda expression. For example, if the body of a single-line lambda expression is
`Where cust.City = "London"`, its return type is `Boolean`.
- The body of a single-line lambda expression must be an expression, not a statement. The body can consist of a call to a function procedure, but not a call to a sub procedure.

- Either all parameters must have specified data types or all must be inferred.
- Optional and Paramarray parameters are not permitted.
- Generic parameters are not permitted.

Example

The following examples show two ways to create simple lambda expressions. The first uses a `Dim` to provide a name for the function. To call the function, you send in a value for the parameter.

```
Dim add1 = Function(num As Integer) num + 1
```

```
' The following line prints 6.
Console.WriteLine(add1(5))
```

Example

Alternatively, you can declare and run the function at the same time.

```
Console.WriteLine((Function(num As Integer) num + 1)(5))
```

Example

Following is an example of a lambda expression that increments its argument and returns the value. The example shows both the single-line and multiline lambda expression syntax for a function. For more examples, see [Lambda Expressions](#).

```
Dim increment1 = Function(x) x + 1
Dim increment2 = Function(x)
    Return x + 2
End Function

' Write the value 2.
Console.WriteLine(increment1(1))

' Write the value 4.
Console.WriteLine(increment2(2))
```

Example

Lambda expressions underlie many of the query operators in Language-Integrated Query (LINQ), and can be used explicitly in method-based queries. The following example shows a typical LINQ query, followed by the translation of the query into method format.

```
Dim londonCusts = From cust In db.Customers
    Where cust.City = "London"
    Select cust

' This query is compiled to the following code:
Dim londonCusts = db.Customers.
    Where(Function(cust) cust.City = "London").
    Select(Function(cust) cust)
```

For more information about query methods, see [Queries](#). For more information about standard query operators, see [Standard Query Operators Overview](#).

GetType Operator (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Returns a [Type](#) object for the specified type. The [Type](#) object provides information about the type such as its properties, methods, and events.

Syntax

```
GetType(typename)
```

Parameters

PARAMETER	DESCRIPTION
<code>typename</code>	The name of the type for which you desire information.

Remarks

The `GetType` operator returns the [Type](#) object for the specified `typename`. You can pass the name of any defined type in `typename`. This includes the following:

- Any Visual Basic data type, such as `Boolean` or `Date`.
- Any .NET Framework class, structure, module, or interface, such as [System.ArgumentException](#) or [System.Double](#).
- Any class, structure, module, or interface defined by your application.
- Any array defined by your application.
- Any delegate defined by your application.
- Any enumeration defined by Visual Basic, the .NET Framework, or your application.

If you want to get the type object of an object variable, use the [Type.GetType](#) method.

The `GetType` operator can be useful in the following circumstances:

- You must access the metadata for a type at run time. The [Type](#) object supplies metadata such as type members and deployment information. You need this, for example, to reflect over an assembly. For more information, see [System.Reflection](#).
- You want to compare two object references to see if they refer to instances of the same type. If they do, `GetType` returns references to the same [Type](#) object.

Example

The following examples show the `GetType` operator in use.

```
' The following statement returns the Type object for Integer.  
MsgBox(GetType(Integer).ToString())  
' The following statement returns the Type object for one-dimensional string arrays.  
MsgBox(GetType(String()).ToString())
```

GetXmlNamespace Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Gets the [XNamespace](#) object that corresponds to the specified XML namespace prefix.

Syntax

```
GetXmlNamespace(xmlNamespacePrefix)
```

Parts

`xmlNamespacePrefix`

Optional. The string that identifies the XML namespace prefix. If supplied, this string must be a valid XML identifier. For more information, see [Names of Declared XML Elements and Attributes](#). If no prefix is specified, the default namespace is returned. If no default namespace is specified, the empty namespace is returned.

Return Value

The [XNamespace](#) object that corresponds to the XML namespace prefix.

Remarks

The `GetXmlNamespace` operator gets the [XNamespace](#) object that corresponds to the XML namespace prefix `xmlNamespacePrefix`.

You can use XML namespace prefixes directly in XML literals and XML axis properties. However, you must use the `GetXmlNamespace` operator to convert a namespace prefix to an [XNamespace](#) object before you can use it in your code. You can append an unqualified element name to an [XNamespace](#) object to get a fully qualified [XName](#) object, which many LINQ to XML methods require.

Example

The following example imports `ns` as an XML namespace prefix. It then uses the prefix of the namespace to create an XML literal and access the first child node that has the qualified name `ns:phone`. It then passes that child node to the `ShowName` subroutine, which constructs a qualified name by using the `GetXmlNamespace` operator. The `ShowName` subroutine then passes the qualified name to the `Ancestors` method to get the parent `ns:contact` node.

```
' Place Imports statements at the top of your program.  
Imports <xmlns:ns="http://SomeNamespace">  
  
Module GetXmlNamespaceSample  
  
Sub RunSample()  
  
    ' Create test by using a global XML namespace prefix.  
  
    Dim contact =  
        <ns:contact>  
            <ns:name>Patrick Hines</ns:name>  
            <ns:phone ns:type="home">206-555-0144</ns:phone>  
            <ns:phone ns:type="work">425-555-0145</ns:phone>  
        </ns:contact>  
  
    ShowName(contact.<ns:phone>(0))  
End Sub  
  
Sub ShowName(ByVal phone As XElement)  
    Dim qualifiedName = GetXmlNamespace(ns) + "contact"  
    Dim contact = phone.Ancestors(qualifiedName)(0)  
    Console.WriteLine("Name: " & contact.<ns:name>.Value)  
End Sub  
  
End Module
```

When you call `TestGetXmlNamespace.RunSample()`, it displays a message box that contains the following text:

Name: Patrick Hines

If Operator (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Uses short-circuit evaluation to conditionally return one of two values. The `If` operator can be called with three arguments or with two arguments.

Syntax

```
If( [argument1,] argument2, argument3 )
```

If Operator Called with Three Arguments

When `If` is called by using three arguments, the first argument must evaluate to a value that can be cast as a `Boolean`. That `Boolean` value will determine which of the other two arguments is evaluated and returned. The following list applies only when the `If` operator is called by using three arguments.

Parts

TERM	DEFINITION
<code>argument1</code>	Required. <code>Boolean</code> . Determines which of the other arguments to evaluate and return.
<code>argument2</code>	Required. <code>Object</code> . Evaluated and returned if <code>argument1</code> evaluates to <code>True</code> .
<code>argument3</code>	Required. <code>Object</code> . Evaluated and returned if <code>argument1</code> evaluates to <code>False</code> or if <code>argument1</code> is a <code>Nullable Boolean</code> variable that evaluates to <code>Nothing</code> .

An `If` operator that is called with three arguments works like an `IIf` function except that it uses short-circuit evaluation. An `IIf` function always evaluates all three of its arguments, whereas an `If` operator that has three arguments evaluates only two of them. The first `If` argument is evaluated and the result is cast as a `Boolean` value, `True` or `False`. If the value is `True`, `argument2` is evaluated and its value is returned, but `argument3` is not evaluated. If the value of the `Boolean` expression is `False`, `argument3` is evaluated and its value is returned, but `argument2` is not evaluated. The following examples illustrate the use of `If` when three arguments are used:

```

' This statement prints TruePart, because the first argument is true.
Console.WriteLine(If(True, "TruePart", "FalsePart"))

' This statement prints FalsePart, because the first argument is false.
Console.WriteLine(If(False, "TruePart", "FalsePart"))

Dim number = 3
' With number set to 3, this statement prints Positive.
Console.WriteLine(If(number >= 0, "Positive", "Negative"))

number = -1
' With number set to -1, this statement prints Negative.
Console.WriteLine(If(number >= 0, "Positive", "Negative"))

```

The following example illustrates the value of short-circuit evaluation. The example shows two attempts to divide variable `number` by variable `divisor` except when `divisor` is zero. In that case, a 0 should be returned, and no attempt should be made to perform the division because a run-time error would result. Because the `If` expression uses short-circuit evaluation, it evaluates either the second or the third argument, depending on the value of the first argument. If the first argument is true, the divisor is not zero and it is safe to evaluate the second argument and perform the division. If the first argument is false, only the third argument is evaluated and a 0 is returned. Therefore, when the divisor is 0, no attempt is made to perform the division and no error results. However, because `IIf` does not use short-circuit evaluation, the second argument is evaluated even when the first argument is false. This causes a run-time divide-by-zero error.

```

number = 12

' When the divisor is not 0, both If and IIf return 4.
Dim divisor = 3
Console.WriteLine(If(divisor <> 0, number \ divisor, 0))
Console.WriteLine(IIf(divisor <> 0, number \ divisor, 0))

' When the divisor is 0, IIf causes a run-time error, but If does not.
divisor = 0
Console.WriteLine(If(divisor <> 0, number \ divisor, 0))
' Console.WriteLine(IIf(divisor <> 0, number \ divisor, 0))

```

If Operator Called with Two Arguments

The first argument to `If` can be omitted. This enables the operator to be called by using only two arguments. The following list applies only when the `If` operator is called with two arguments.

Parts

TERM	DEFINITION
<code>argument2</code>	Required. <code>Object</code> . Must be a reference or nullable type. Evaluated and returned when it evaluates to anything other than <code>Nothing</code> .
<code>argument3</code>	Required. <code>Object</code> . Evaluated and returned if <code>argument2</code> evaluates to <code>Nothing</code> .

When the `Boolean` argument is omitted, the first argument must be a reference or nullable type. If the first argument evaluates to `Nothing`, the value of the second argument is returned. In all other cases, the value of the first argument is returned. The following example illustrates how this evaluation works.

```
' Variable first is a nullable type.  
Dim first? As Integer = 3  
Dim second As Integer = 6  
  
' Variable first <> Nothing, so its value, 3, is returned.  
Console.WriteLine(If(first, second))  
  
second = Nothing  
' Variable first <> Nothing, so the value of first is returned again.  
Console.WriteLine(If(first, second))  
  
first = Nothing  
second = 6  
' Variable first = Nothing, so 6 is returned.  
Console.WriteLine(If(first, second))
```

Is Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Compares two object reference variables.

Syntax

```
result = object1 Is object2
```

Parts

`result`

Required. Any `Boolean` value.

`object1`

Required. Any `Object` name.

`object2`

Required. Any `Object` name.

Remarks

The `Is` operator determines if two object references refer to the same object. However, it does not perform value comparisons. If `object1` and `object2` both refer to the exact same object instance, `result` is `True`; if they do not, `result` is `False`.

`Is` can also be used with the `TypeOf` keyword to make a `TypeOf ... Is` expression, which tests whether an object variable is compatible with a data type.

NOTE

The `Is` keyword is also used in the `Select...Case Statement`.

Example

The following example uses the `Is` operator to compare pairs of object references. The results are assigned to a `Boolean` value representing whether the two objects are identical.

```
Dim myObject As New Object
Dim otherObject As New Object
Dim yourObject, thisObject, thatObject As Object
Dim myCheck As Boolean
yourObject = myObject
thisObject = myObject
thatObject = otherObject
' The following statement sets myCheck to True.
myCheck = yourObject Is thisObject
' The following statement sets myCheck to False.
myCheck = thatObject Is thisObject
' The following statement sets myCheck to False.
myCheck = myObject Is thatObject
thatObject = myObject
' The following statement sets myCheck to True.
myCheck = thisObject Is thatObject
```

As the preceding example demonstrates, you can use the `Is` operator to test both early bound and late bound objects.

IsFalse Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Determines whether an expression is `False`.

You cannot call `IsFalse` explicitly in your code, but the Visual Basic compiler can use it to generate code from `AndAlso` clauses. If you define a class or structure and then use a variable of that type in an `AndAlso` clause, you must define `IsFalse` on that class or structure.

The compiler considers the `IsFalse` and `IsTrue` operators as a *matched pair*. This means that if you define one of them, you must also define the other one.

NOTE

The `IsFalse` operator can be *overloaded*, which means that a class or structure can redefine its behavior when its operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following code example defines the outline of a structure that includes definitions for the `IsFalse` and `IsTrue` operators.

```
Public Structure p
    Dim a As Double
    Public Shared Operator IsFalse(ByVal w As p) As Boolean
        Dim b As Boolean
        ' Insert code to calculate IsFalse of w.
        Return b
    End Operator
    Public Shared Operator IsTrue(ByVal w As p) As Boolean
        Dim b As Boolean
        ' Insert code to calculate IsTrue of w.
        Return b
    End Operator
End Structure
```

IsNot Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Compares two object reference variables.

Syntax

```
result = object1 IsNot object2
```

Parts

`result`

Required. A `Boolean` value.

`object1`

Required. Any `Object` variable or expression.

`object2`

Required. Any `Object` variable or expression.

Remarks

The `IsNot` operator determines if two object references refer to different objects. However, it does not perform value comparisons. If `object1` and `object2` both refer to the exact same object instance, `result` is `False`; if they do not, `result` is `True`.

`IsNot` is the opposite of the `Is` operator. The advantage of `IsNot` is that you can avoid awkward syntax with `Not` and `Is`, which can be difficult to read.

You can use the `Is` and `IsNot` operators to test both early-bound and late-bound objects.

NOTE

The `IsNot` operator cannot be used to compare expressions returned from the `TypeOf` operator. Instead, you must use the `Not` and `Is` operators.

Example

The following code example uses both the `Is` operator and the `IsNot` operator to accomplish the same comparison.

```
Dim o1, o2 As New Object
If Not o1 Is o2 Then MsgBox("o1 and o2 do not refer to the same instance.")
If o1 IsNot o2 Then MsgBox("o1 and o2 do not refer to the same instance.")
```

IsTrue Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Determines whether an expression is `True`.

You cannot call `IsTrue` explicitly in your code, but the Visual Basic compiler can use it to generate code from `OrElse` clauses. If you define a class or structure and then use a variable of that type in an `OrElse` clause, you must define `IsTrue` on that class or structure.

The compiler considers the `IsTrue` and `IsFalse` operators as a *matched pair*. This means that if you define one of them, you must also define the other one.

Compiler Use of IsTrue

When you have defined a class or structure, you can use a variable of that type in a `For`, `If`, `Else If`, or `While` statement, or in a `When` clause. If you do this, the compiler requires an operator that converts your type into a `Boolean` value so it can test a condition. It searches for a suitable operator in the following order:

1. A widening conversion operator from your class or structure to `Boolean`.
2. A widening conversion operator from your class or structure to `Boolean?`.
3. The `IsTrue` operator on your class or structure.
4. A narrowing conversion to `Boolean?` that does not involve a conversion from `Boolean` to `Boolean?`.
5. A narrowing conversion operator from your class or structure to `Boolean`.

If you have not defined any conversion to `Boolean` or an `IsTrue` operator, the compiler signals an error.

NOTE

The `IsTrue` operator can be *overloaded*, which means that a class or structure can redefine its behavior when its operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following code example defines the outline of a structure that includes definitions for the `IsFalse` and `IsTrue` operators.

```
Public Structure p
    Dim a As Double
    Public Shared Operator IsFalse(ByVal w As p) As Boolean
        Dim b As Boolean
        ' Insert code to calculate IsFalse of w.
        Return b
    End Operator
    Public Shared Operator IsTrue(ByVal w As p) As Boolean
        Dim b As Boolean
        ' Insert code to calculate IsTrue of w.
        Return b
    End Operator
End Structure
```

Like Operator (Visual Basic)

2/28/2019 • 5 minutes to read • [Edit Online](#)

Compares a string against a pattern.

IMPORTANT

The `Like` operator is currently not supported in .NET Core and .NET Standard projects.

Syntax

```
result = string Like pattern
```

Parts

`result`

Required. Any `Boolean` variable. The result is a `Boolean` value indicating whether or not the `string` satisfies the `pattern`.

`string`

Required. Any `String` expression.

`pattern`

Required. Any `String` expression conforming to the pattern-matching conventions described in "Remarks."

Remarks

If the value in `string` satisfies the pattern contained in `pattern`, `result` is `True`. If the string does not satisfy the pattern, `result` is `False`. If both `string` and `pattern` are empty strings, the result is `True`.

Comparison Method

The behavior of the `Like` operator depends on the [Option Compare Statement](#). The default string comparison method for each source file is `Option Compare Binary`.

Pattern Options

Built-in pattern matching provides a versatile tool for string comparisons. The pattern-matching features allow you to match each character in `string` against a specific character, a wildcard character, a character list, or a character range. The following table shows the characters allowed in `pattern` and what they match.

CHARACTERS IN PATTERN	MATCHES IN STRING
?	Any single character
*	Zero or more characters

CHARACTERS IN PATTERN	MATCHES IN STRING
#	Any single digit (0–9)
[charlist]	Any single character in charlist
[!charlist]	Any single character not in charlist

Character Lists

A group of one or more characters (charlist) enclosed in brackets ([]) can be used to match any single character in string and can include almost any character code, including digits.

An exclamation point (!) at the beginning of charlist means that a match is made if any character except the characters in charlist is found in string. When used outside brackets, the exclamation point matches itself.

Special Characters

To match the special characters left bracket ([), question mark (?), number sign (#), and asterisk (\*), enclose them in brackets. The right bracket (]) cannot be used within a group to match itself, but it can be used outside a group as an individual character.

The character sequence [] is considered a zero-length string (""). However, it cannot be part of a character list enclosed in brackets. If you want to check whether a position in string contains one of a group of characters or no character at all, you can use Like twice. For an example, see [How to: Match a String against a Pattern](#).

Character Ranges

By using a hyphen (-) to separate the lower and upper bounds of the range, charlist can specify a range of characters. For example, [A-Z] results in a match if the corresponding character position in string contains any character within the range A – Z, and [!H-L] results in a match if the corresponding character position contains any character outside the range H – L.

When you specify a range of characters, they must appear in ascending sort order, that is, from lowest to highest. Thus, [A-Z] is a valid pattern, but [Z-A] is not.

Multiple Character Ranges

To specify multiple ranges for the same character position, put them within the same brackets without delimiters. For example, [A-CX-Z] results in a match if the corresponding character position in string contains any character within either the range A – C or the range X – Z.

Usage of the Hyphen

A hyphen (-) can appear either at the beginning (after an exclamation point, if any) or at the end of charlist to match itself. In any other location, the hyphen identifies a range of characters delimited by the characters on either side of the hyphen.

Collating Sequence

The meaning of a specified range depends on the character ordering at run time, as determined by

Option Compare and the locale setting of the system the code is running on. With Option Compare Binary, the range [A-E] matches A, B, C, D, and E. With Option Compare Text, [A-E] matches A, a, À, à, B, b, C, c, D, d, E, and e. The range does not match È or ê because accented characters collate after unaccented characters in the sort order.

Digraph Characters

In some languages, there are alphabetic characters that represent two separate characters. For example, several languages use the character `æ` to represent the characters `a` and `e` when they appear together. The `Like` operator recognizes that the single digraph character and the two individual characters are equivalent.

When a language that uses a digraph character is specified in the system locale settings, an occurrence of the single digraph character in either `pattern` or `string` matches the equivalent two-character sequence in the other string. Similarly, a digraph character in `pattern` enclosed in brackets (by itself, in a list, or in a range) matches the equivalent two-character sequence in `string`.

Overloading

The `Like` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

This example uses the `Like` operator to compare strings to various patterns. The results go into a `Boolean` variable indicating whether each string satisfies the pattern.

```
Dim testCheck As Boolean
' The following statement returns True (does "F" satisfy "F"?)  
testCheck = "F" Like "F"  
' The following statement returns False for Option Compare Binary  
' and True for Option Compare Text (does "F" satisfy "f"?)  
testCheck = "F" Like "f"  
' The following statement returns False (does "F" satisfy "FFF"?)  
testCheck = "F" Like "FFF"  
' The following statement returns True (does "aBBBBa" have an "a" at the  
' beginning, an "a" at the end, and any number of characters in  
' between?)  
testCheck = "aBBBBa" Like "a*a"  
' The following statement returns True (does "F" occur in the set of  
' characters from "A" through "Z"?)  
testCheck = "F" Like "[A-Z]"  
' The following statement returns False (does "F" NOT occur in the  
' set of characters from "A" through "Z"?)  
testCheck = "F" Like "[!A-Z]"  
' The following statement returns True (does "a2a" begin and end with  
' an "a" and have any single-digit number in between?)  
testCheck = "a2a" Like "a#a"  
' The following statement returns True (does "aM5b" begin with an "a",  
' followed by any character from the set "L" through "P", followed  
' by any single-digit number, and end with any character NOT in  
' the character set "c" through "e"?)  
testCheck = "aM5b" Like "a[L-P]#[!c-e]"  
' The following statement returns True (does "BAT123khg" begin with a  
' "B", followed by any single character, followed by a "T", and end  
' with zero or more characters of any type?)  
testCheck = "BAT123khg" Like "B?T*"  
' The following statement returns False (does "CAT123khg"?) begin with  
' a "B", followed by any single character, followed by a "T", and  
' end with zero or more characters of any type?)  
testCheck = "CAT123khg" Like "B?T*"
```

Mod operator (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Divides two numbers and returns only the remainder.

Syntax

```
number1 Mod number2
```

Parts

`number1`

Required. Any numeric expression.

`number2`

Required. Any numeric expression.

Supported types

All numeric types. This includes the unsigned and floating-point types and `Decimal`.

Result

The result is the remainder after `number1` is divided by `number2`. For example, the expression `14 Mod 4` evaluates to 2.

NOTE

There is a difference between *remainder* and *modulus* in mathematics, with different results for negative numbers. The `Mod` operator in Visual Basic, the .NET Framework `op_Modulus` operator, and the underlying `rem` IL instruction all perform a remainder operation.

The result of a `Mod` operation retains the sign of the dividend, `number1`, and so it may be positive or negative.

The result is always in the range $(-\text{number2}, \text{number2})$, exclusive. For example:

```
Public Module Example
    Public Sub Main()
        Console.WriteLine($" 8 Mod 3 = {8 Mod 3}")
        Console.WriteLine($"-8 Mod 3 = {-8 Mod 3}")
        Console.WriteLine($" 8 Mod -3 = {8 Mod -3}")
        Console.WriteLine($"-8 Mod -3 = {-8 Mod -3}")
    End Sub
End Module
' The example displays the following output:
'      8 Mod 3 = 2
'     -8 Mod 3 = -2
'      8 Mod -3 = 2
'     -8 Mod -3 = -2
```

Remarks

If either `number1` or `number2` is a floating-point value, the floating-point remainder of the division is returned.

The data type of the result is the smallest data type that can hold all possible values that result from division with the data types of `number1` and `number2`.

If `number1` or `number2` evaluates to [Nothing](#), it is treated as zero.

Related operators include the following:

- The [\ Operator \(Visual Basic\)](#) returns the integer quotient of a division. For example, the expression `14 \ 4` evaluates to 3.
- The [/ Operator \(Visual Basic\)](#) returns the full quotient, including the remainder, as a floating-point number. For example, the expression `14 / 4` evaluates to 3.5.

Attempted division by zero

If `number2` evaluates to zero, the behavior of the `Mod` operator depends on the data type of the operands. An integral division throws a [DivideByZeroException](#) exception. A floating-point division returns [NaN](#).

Equivalent formula

The expression `a Mod b` is equivalent to either of the following formulas:

`a - (b * (a \ b))`

`a - (b * Fix(a / b))`

Floating-point imprecision

When you work with floating-point numbers, remember that they do not always have a precise decimal representation in memory. This can lead to unexpected results from certain operations, such as value comparison and the `Mod` operator. For more information, see [Troubleshooting Data Types](#).

Overloading

The `Mod` operator can be *overloaded*, which means that a class or structure can redefine its behavior. If your code applies `Mod` to an instance of a class or structure that includes such an overload, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `Mod` operator to divide two numbers and return only the remainder. If either number is a floating-point number, the result is a floating-point number that represents the remainder.

```
Debug.WriteLine(10 Mod 5)
' Output: 0
Debug.WriteLine(10 Mod 3)
' Output: 1
Debug.WriteLine(-10 Mod 3)
' Output: -1
Debug.WriteLine(12 Mod 4.3)
' Output: 3.4
Debug.WriteLine(12.6 Mod 5)
' Output: 2.6
Debug.WriteLine(47.9 Mod 9.35)
' Output: 1.15
```

Example

The following example demonstrates the potential imprecision of floating-point operands. In the first statement, the operands are `Double`, and 0.2 is an infinitely repeating binary fraction with a stored value of 0.20000000000000001. In the second statement, the literal type character `D` forces both operands to `Decimal`, and 0.2 has a precise representation.

```
firstResult = 2.0 Mod 0.2
' Double operation returns 0.2, not 0.
secondResult = 2D Mod 0.2D
' Decimal operation returns 0.
```

New Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Introduces a `New` clause to create a new object instance, specifies a constructor constraint on a type parameter, or identifies a `Sub` procedure as a class constructor.

Remarks

In a declaration or assignment statement, a `New` clause must specify a defined class from which the instance can be created. This means that the class must expose one or more constructors that the calling code can access.

You can use a `New` clause in a declaration statement or an assignment statement. When the statement runs, it calls the appropriate constructor of the specified class, passing any arguments you have supplied. The following example demonstrates this by creating instances of a `Customer` class that has two constructors, one that takes no parameters and one that takes a string parameter.

```
' For customer1, call the constructor that takes no arguments.  
Dim customer1 As New Customer()  
  
' For customer2, call the constructor that takes the name of the  
' customer as an argument.  
Dim customer2 As New Customer("Blue Yonder Airlines")  
  
' For customer3, declare an instance of Customer in the first line  
' and instantiate it in the second.  
Dim customer3 As Customer  
customer3 = New Customer()  
  
' With Option Infer set to On, the following declaration declares  
' and instantiates a new instance of Customer.  
Dim customer4 = New Customer("Coho Winery")
```

Since arrays are classes, `New` can create a new array instance, as shown in the following examples.

```
Dim intArray1() As Integer  
intArray1 = New Integer() {1, 2, 3, 4}  
  
Dim intArray2() As Integer = {5, 6}  
  
' The following example requires that Option Infer be set to On.  
Dim intArray3() = New Integer() {6, 7, 8}
```

The common language runtime (CLR) throws an [OutOfMemoryException](#) error if there is insufficient memory to create the new instance.

NOTE

The `New` keyword is also used in type parameter lists to specify that the supplied type must expose an accessible parameterless constructor. For more information about type parameters and constraints, see [Type List](#).

To create a constructor procedure for a class, set the name of a `Sub` procedure to the `New` keyword. For more information, see [Object Lifetime: How Objects Are Created and Destroyed](#).

The `New` keyword can be used in these contexts:

Not Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs logical negation on a `Boolean` expression, or bitwise negation on a numeric expression.

Syntax

```
result = Not expression
```

Parts

`result`

Required. Any `Boolean` or numeric expression.

`expression`

Required. Any `Boolean` or numeric expression.

Remarks

For `Boolean` expressions, the following table illustrates how `result` is determined.

IF <code>EXPRESSION</code> IS	THE VALUE OF <code>RESULT</code> IS
<code>True</code>	<code>False</code>
<code>False</code>	<code>True</code>

For numeric expressions, the `Not` operator inverts the bit values of any numeric expression and sets the corresponding bit in `result` according to the following table.

IF BIT IN <code>EXPRESSION</code> IS	THE BIT IN <code>RESULT</code> IS
1	0
0	1

NOTE

Since the logical and bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

Data Types

For a Boolean negation, the data type of the result is `Boolean`. For a bitwise negation, the result data type is the same as that of `expression`. However, if `expression` is `Decimal`, the result is `Long`.

Overloading

The `Not` operator can be *overloaded*, which means that a class or structure can redefine its behavior when its operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `Not` operator to perform logical negation on a `Boolean` expression. The result is a `Boolean` value that represents the reverse of the value of the expression.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstCheck, secondCheck As Boolean
firstCheck = Not (a > b)
secondCheck = Not (b > a)
```

The preceding example produces results of `False` and `True`, respectively.

Example

The following example uses the `Not` operator to perform logical negation of the individual bits of a numeric expression. The bit in the result pattern is set to the reverse of the corresponding bit in the operand pattern, including the sign bit.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstPattern, secondPattern, thirdPattern As Integer
firstPattern = (Not a)
secondPattern = (Not b)
thirdPattern = (Not c)
```

The preceding example produces results of `-11`, `-9`, and `-7`, respectively.

Or Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs a logical disjunction on two `Boolean` expressions, or a bitwise disjunction on two numeric expressions.

Syntax

```
result = expression1 Or expression2
```

Parts

`result`

Required. Any `Boolean` or numeric expression. For `Boolean` comparison, `result` is the inclusive logical disjunction of two `Boolean` values. For bitwise operations, `result` is a numeric value representing the inclusive bitwise disjunction of two numeric bit patterns.

`expression1`

Required. Any `Boolean` or numeric expression.

`expression2`

Required. Any `Boolean` or numeric expression.

Remarks

For `Boolean` comparison, `result` is `False` if and only if both `expression1` and `expression2` evaluate to `False`. The following table illustrates how `result` is determined.

IF <code>EXPRESSION1</code> IS	AND <code>EXPRESSION2</code> IS	THE VALUE OF <code>RESULT</code> IS
<code>True</code>	<code>True</code>	<code>True</code>
<code>True</code>	<code>False</code>	<code>True</code>
<code>False</code>	<code>True</code>	<code>True</code>
<code>False</code>	<code>False</code>	<code>False</code>

NOTE

In a `Boolean` comparison, the `or` operator always evaluates both expressions, which could include making procedure calls. The [OrElse Operator](#) performs *short-circuiting*, which means that if `expression1` is `True`, then `expression2` is not evaluated.

For bitwise operations, the `or` operator performs a bitwise comparison of identically positioned bits in two numeric expressions and sets the corresponding bit in `result` according to the following table.

IF BIT IN <code>EXPRESSION1</code> IS	AND BIT IN <code>EXPRESSION2</code> IS	THE BIT IN <code>RESULT</code> IS
1	1	1
1	0	1
0	1	1
0	0	0

NOTE

Since the logical and bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

Data Types

If the operands consist of one `Boolean` expression and one numeric expression, Visual Basic converts the `Boolean` expression to a numeric value (–1 for `True` and 0 for `False`) and performs a bitwise operation.

For a `Boolean` comparison, the data type of the result is `Boolean`. For a bitwise comparison, the result data type is a numeric type appropriate for the data types of `expression1` and `expression2`. See the "Relational and Bitwise Comparisons" table in [Data Types of Operator Results](#).

Overloading

The `or` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, be sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `or` operator to perform an inclusive logical disjunction on two expressions. The result is a `Boolean` value that represents whether either of the two expressions is `True`.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstCheck, secondCheck, thirdCheck As Boolean
firstCheck = a > b Or b > c
secondCheck = b > a Or b > c
thirdCheck = b > a Or c > b
```

The preceding example produces results of `True`, `True`, and `False`, respectively.

Example

The following example uses the `or` operator to perform inclusive logical disjunction on the individual bits of two numeric expressions. The bit in the result pattern is set if either of the corresponding bits in the operands is set to 1.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstPattern, secondPattern, thirdPattern As Integer
firstPattern = (a Or b)
secondPattern = (a Or c)
thirdPattern = (b Or c)
```

The preceding example produces results of 10, 14, and 14, respectively.

OrElse Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Performs short-circuiting inclusive logical disjunction on two expressions.

Syntax

```
result = expression1 OrElse expression2
```

Parts

`result`

Required. Any `Boolean` expression.

`expression1`

Required. Any `Boolean` expression.

`expression2`

Required. Any `Boolean` expression.

Remarks

A logical operation is said to be *short-circuiting* if the compiled code can bypass the evaluation of one expression depending on the result of another expression. If the result of the first expression evaluated determines the final result of the operation, there is no need to evaluate the second expression, because it cannot change the final result. Short-circuiting can improve performance if the bypassed expression is complex, or if it involves procedure calls.

If either or both expressions evaluate to `True`, `result` is `True`. The following table illustrates how `result` is determined.

IF <code>EXPRESSION1</code> IS	AND <code>EXPRESSION2</code> IS	THE VALUE OF <code>RESULT</code> IS
<code>True</code>	(not evaluated)	<code>True</code>
<code>False</code>	<code>True</code>	<code>True</code>
<code>False</code>	<code>False</code>	<code>False</code>

Data Types

The `OrElse` operator is defined only for the [Boolean Data Type](#). Visual Basic converts each operand as necessary to `Boolean` and performs the operation entirely in `Boolean`. If you assign the result to a numeric type, Visual Basic converts it from `Boolean` to that type. This could produce unexpected behavior. For example, `5 OrElse 12` results in `-1` when converted to `Integer`.

Overloading

The [Or Operator](#) and the [IsTrue Operator](#) can be *overloaded*, which means that a class or structure can redefine their behavior when an operand has the type of that class or structure. Overloading the `Or` and `.IsTrue` operators affects the behavior of the `OrElse` operator. If your code uses `OrElse` on a class or structure that overloads `Or` and `.IsTrue`, be sure you understand their redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `OrElse` operator to perform logical disjunction on two expressions. The result is a `Boolean` value that represents whether either of the two expressions is true. If the first expression is `True`, the second is not evaluated.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstCheck, secondCheck, thirdCheck As Boolean
firstCheck = a > b OrElse b > c
secondCheck = b > a OrElse b > c
thirdCheck = b > a OrElse c > b
```

The preceding example produces results of `True`, `True`, and `False` respectively. In the calculation of `firstCheck`, the second expression is not evaluated because the first is already `True`. However, the second expression is evaluated in the calculation of `secondCheck`.

Example

The following example shows an `If ... Then` statement containing two procedure calls. If the first call returns `True`, the second procedure is not called. This could produce unexpected results if the second procedure performs important tasks that should always be performed when this section of the code runs.

```
If testFunction(5) = True OrElse otherFunction(4) = True Then
    ' If testFunction(5) is True, otherFunction(4) is not called.
    ' Insert code to be executed.
End If
```

Sub Expression (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Declares the parameters and code that define a subroutine lambda expression.

Syntax

```
Sub ( [ parameterlist ] ) statement
- or -
Sub ( [ parameterlist ] )
    [ statements ]
End Sub
```

Parts

TERM	DEFINITION
parameterlist	Optional. A list of local variable names that represent the parameters of the procedure. The parentheses must be present even when the list is empty. For more information, see Parameter List .
statement	Required. A single statement.
statements	Required. A list of statements.

Remarks

A *lambda expression* is a subroutine that does not have a name and that executes one or more statements. You can use a lambda expression anywhere that you can use a delegate type, except as an argument to `RemoveHandler`. For more information about delegates, and the use of lambda expressions with delegates, see [Delegate Statement](#) and [Relaxed Delegate Conversion](#).

Lambda Expression Syntax

The syntax of a lambda expression resembles that of a standard subroutine. The differences are as follows:

- A lambda expression does not have a name.
- A lambda expression cannot have a modifier, such as `overloads` or `Overrides`.
- The body of a single-line lambda expression must be a statement, not an expression. The body can consist of a call to a sub procedure, but not a call to a function procedure.
- In a lambda expression, either all parameters must have specified data types or all parameters must be inferred.
- Optional and `ParamArray` parameters are not permitted in lambda expressions.
- Generic parameters are not permitted in lambda expressions.

Example

Following is an example of a lambda expression that writes a value to the console. The example shows both the single-line and multiline lambda expression syntax for a subroutine. For more examples, see [Lambda Expressions](#).

```
Dim writeline1 = Sub(x) Console.WriteLine(x)
Dim writeline2 = Sub(x)
    Console.WriteLine(x)
End Sub

' Write "Hello".
writeline1("Hello")

' Write "World"
writeline2("World")
```

TryCast Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Introduces a type conversion operation that does not throw an exception.

Remarks

If an attempted conversion fails, `ctype` and `DirectCast` both throw an `InvalidCastException` error. This can adversely affect the performance of your application. `TryCast` returns `Nothing`, so that instead of having to handle a possible exception, you need only test the returned result against `Nothing`.

You use the `TryCast` keyword the same way you use the [CType Function](#) and the [DirectCast Operator](#) keyword. You supply an expression as the first argument and a type to convert it to as the second argument. `TryCast` operates only on reference types, such as classes and interfaces. It requires an inheritance or implementation relationship between the two types. This means that one type must inherit from or implement the other.

Errors and Failures

`TryCast` generates a compiler error if it detects that no inheritance or implementation relationship exists. But the lack of a compiler error does not guarantee a successful conversion. If the desired conversion is narrowing, it could fail at run time. If this happens, `TryCast` returns `Nothing`.

Conversion Keywords

A comparison of the type conversion keywords is as follows.

KEYWORD	DATA TYPES	ARGUMENT RELATIONSHIP	RUN-TIME FAILURE
CType Function	Any data types	Widening or narrowing conversion must be defined between the two data types	Throws <code>InvalidCastException</code>
DirectCast Operator	Any data types	One type must inherit from or implement the other type	Throws <code>InvalidCastException</code>
<code>TryCast</code>	Reference types only	One type must inherit from or implement the other type	Returns <code>Nothing</code>

Example

The following example shows how to use `TryCast`.

```
Function PrintTypeCode(ByVal obj As Object) As String
    Dim objAsConvertible As IConvertible = TryCast(obj, IConvertible)
    If objAsConvertible Is Nothing Then
        Return obj.ToString() & " does not implement IConvertible"
    Else
        Return "Type code is " & objAsConvertible.GetTypeCode()
    End If
End Function
```

TypeOf Operator (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Compares an object reference variable to a data type.

Syntax

```
result = TypeOf objectexpression Is typename
```

```
result = TypeOf objectexpression IsNot typename
```

Parts

`result`

Returned. A `Boolean` value.

`objectexpression`

Required. Any expression that evaluates to a reference type.

`typename`

Required. Any data type name.

Remarks

The `TypeOf` operator determines whether the run-time type of `objectexpression` is compatible with `typename`.

The compatibility depends on the type category of `typename`. The following table shows how compatibility is determined.

TYPE CATEGORY OF <code>TYPENAME</code>	COMPATIBILITY CRITERION
Class	<code>objectexpression</code> is of type <code>typename</code> or inherits from <code>typename</code>
Structure	<code>objectexpression</code> is of type <code>typename</code>
Interface	<code>objectexpression</code> implements <code>typename</code> or inherits from a class that implements <code>typename</code>

If the run-time type of `objectexpression` satisfies the compatibility criterion, `result` is `True`. Otherwise, `result` is `False`. If `objectexpression` is null, then `TypeOf ... Is` returns `False`, and `... IsNot` returns `True`.

`TypeOf` is always used with the `Is` keyword to construct a `TypeOf ... Is` expression, or with the `IsNot` keyword to construct a `TypeOf ... IsNot` expression.

Example

The following example uses `TypeOf ... Is` expressions to test the type compatibility of two object reference variables with various data types.

```
Dim refInteger As Object = 2
MsgBox("TypeOf Object[Integer] Is Integer? " & TypeOf refInteger Is Integer)
MsgBox("TypeOf Object[Integer] Is Double? " & TypeOf refInteger Is Double)
Dim refForm As Object = New System.Windows.Forms.Form
MsgBox("TypeOf Object[Form] Is Form? " & TypeOf refForm Is System.Windows.Forms.Form)
MsgBox("TypeOf Object[Form] Is Label? " & TypeOf refForm Is System.Windows.Forms.Label)
MsgBox("TypeOf Object[Form] Is Control? " & TypeOf refForm Is System.Windows.Forms.Control)
MsgBox("TypeOf Object[Form] Is IComponent? " & TypeOf refForm Is System.ComponentModel.IComponent)
```

The variable `refInteger` has a run-time type of `Integer`. It is compatible with `Integer` but not with `Double`. The variable `refForm` has a run-time type of `Form`. It is compatible with `Form` because that is its type, with `Control` because `Form` inherits from `Control`, and with `IComponent` because `Form` inherits from `Component`, which implements `IComponent`. However, `refForm` is not compatible with `Label`.

Xor Operator (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Performs a logical exclusion on two `Boolean` expressions, or a bitwise exclusion on two numeric expressions.

Syntax

```
result = expression1 Xor expression2
```

Parts

`result`

Required. Any `Boolean` or numeric variable. For Boolean comparison, `result` is the logical exclusion (exclusive logical disjunction) of two `Boolean` values. For bitwise operations, `result` is a numeric value that represents the bitwise exclusion (exclusive bitwise disjunction) of two numeric bit patterns.

`expression1`

Required. Any `Boolean` or numeric expression.

`expression2`

Required. Any `Boolean` or numeric expression.

Remarks

For Boolean comparison, `result` is `True` if and only if exactly one of `expression1` and `expression2` evaluates to `True`. That is, if and only if `expression1` and `expression2` evaluate to opposite `Boolean` values. The following table illustrates how `result` is determined.

IF <code>EXPRESSION1</code> IS	AND <code>EXPRESSION2</code> IS	THE VALUE OF <code>RESULT</code> IS
<code>True</code>	<code>True</code>	<code>False</code>
<code>True</code>	<code>False</code>	<code>True</code>
<code>False</code>	<code>True</code>	<code>True</code>
<code>False</code>	<code>False</code>	<code>False</code>

NOTE

In a Boolean comparison, the `Xor` operator always evaluates both expressions, which could include making procedure calls. There is no short-circuiting counterpart to `Xor`, because the result always depends on both operands. For *short-circuiting* logical operators, see [AndAlso Operator](#) and [OrElse Operator](#).

For bitwise operations, the `Xor` operator performs a bitwise comparison of identically positioned bits in two numeric expressions and sets the corresponding bit in `result` according to the following table.

IF BIT IN <code>EXPRESSION1</code> IS	AND BIT IN <code>EXPRESSION2</code> IS	THE BIT IN <code>RESULT</code> IS
1	1	0
1	0	1
0	1	1
0	0	0

NOTE

Since the logical and bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

For example, `5 xor 3` is 6. To see why this is so, convert 5 and 3 to their binary representations, 101 and 011. Then use the previous table to determine that 101 Xor 011 is 110, which is the binary representation of the decimal number 6.

Data Types

If the operands consist of one `Boolean` expression and one numeric expression, Visual Basic converts the `Boolean` expression to a numeric value (-1 for `True` and 0 for `False`) and performs a bitwise operation.

For a `Boolean` comparison, the data type of the result is `Boolean`. For a bitwise comparison, the result data type is a numeric type appropriate for the data types of `expression1` and `expression2`. See the "Relational and Bitwise Comparisons" table in [Data Types of Operator Results](#).

Overloading

The `xor` operator can be *overloaded*, which means that a class or structure can redefine its behavior when an operand has the type of that class or structure. If your code uses this operator on such a class or structure, make sure you understand its redefined behavior. For more information, see [Operator Procedures](#).

Example

The following example uses the `xor` operator to perform logical exclusion (exclusive logical disjunction) on two expressions. The result is a `Boolean` value that represents whether exactly one of the expressions is `True`.

```
Dim a As Integer = 10
Dim b As Integer = 8
Dim c As Integer = 6
Dim firstCheck, secondCheck, thirdCheck As Boolean
firstCheck = a > b Xor b > c
secondCheck = b > a Xor b > c
thirdCheck = b > a Xor c > b
```

The previous example produces results of `False`, `True`, and `False`, respectively.

Example

The following example uses the `xor` operator to perform logical exclusion (exclusive logical disjunction) on the individual bits of two numeric expressions. The bit in the result pattern is set if exactly one of the corresponding

bits in the operands is set to 1.

```
Dim a As Integer = 10 ' 1010 in binary
Dim b As Integer = 8  ' 1000 in binary
Dim c As Integer = 6  ' 0110 in binary
Dim firstPattern, secondPattern, thirdPattern As Integer
firstPattern = (a Xor b) ' 2, 0010 in binary
secondPattern = (a Xor c) ' 12, 1100 in binary
thirdPattern = (b Xor c) ' 14, 1110 in binary
```

The previous example produces results of 2, 12, and 14, respectively.

Queries (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Visual Basic enables you to create Language-Integrated Query (LINQ) expressions in your code.

In This Section

[Aggregate Clause](#)

Describes the `Aggregate` clause, which applies one or more aggregate functions to a collection.

[Distinct Clause](#)

Describes the `Distinct` clause, which restricts the values of the current range variable to eliminate duplicate values in query results.

[From Clause](#)

Describes the `From` clause, which specifies a collection and a range variable for a query.

[Group By Clause](#)

Describes the `Group By` clause, which groups the elements of a query result and can be used to apply aggregate functions to each group.

[Group Join Clause](#)

Describes the `Group Join` clause, which combines two collections into a single hierarchical collection.

[Join Clause](#)

Describes the `Join` clause, which combines two collections into a single collection.

[Let Clause](#)

Describes the `Let` clause, which computes a value and assigns it to a new variable in the query.

[Order By Clause](#)

Describes the `Order By` clause, which specifies the sort order for columns in a query.

[Select Clause](#)

Describes the `Select` clause, which declares a set of range variables for a query.

[Skip Clause](#)

Describes the `Skip` clause, which bypasses a specified number of elements in a collection and then returns the remaining elements.

[Skip While Clause](#)

Describes the `Skip While` clause, which bypasses elements in a collection as long as a specified condition is `true` and then returns the remaining elements.

[Take Clause](#)

Describes the `Take` clause, which returns a specified number of contiguous elements from the start of a collection.

[Take While Clause](#)

Describes the `Take While` clause, which includes elements in a collection as long as a specified condition is `true` and bypasses the remaining elements.

[Where Clause](#)

Describes the `Where` clause, which specifies a filtering condition for a query.

Aggregate Clause (Visual Basic)

2/28/2019 • 6 minutes to read • [Edit Online](#)

Applies one or more aggregate functions to a collection.

Syntax

```
Aggregate element [As type] In collection _  
[, element2 [As type2] In collection2, [...]]  
[ clause ]  
Into expressionList
```

Parts

TERM	DEFINITION
<code>element</code>	Required. Variable used to iterate through the elements of the collection.
<code>type</code>	Optional. The type of <code>element</code> . If no type is specified, the type of <code>element</code> is inferred from <code>collection</code> .
<code>collection</code>	Required. Refers to the collection to operate on.
<code>clause</code>	Optional. One or more query clauses, such as a <code>Where</code> clause, to refine the query result to apply the aggregate clause or clauses to.
<code>expressionList</code>	Required. One or more comma-delimited expressions that identify an aggregate function to apply to the collection. You can apply an alias to an aggregate function to specify a member name for the query result. If no alias is supplied, the name of the aggregate function is used. For examples, see the section about aggregate functions later in this topic.

Remarks

The `Aggregate` clause can be used to include aggregate functions in your queries. Aggregate functions perform checks and computations over a set of values and return a single value. You can access the computed value by using a member of the query result type. The standard aggregate functions that you can use are the `All`, `Any`, `Average`, `Count`, `LongCount`, `Max`, `Min`, and `Sum` functions. These functions are familiar to developers who are familiar with aggregates in SQL. They are described in the following section of this topic.

The result of an aggregate function is included in the query result as a field of the query result type. You can supply an alias for the aggregate function result to specify the name of the member of the query result type that will hold the aggregate value. If no alias is supplied, the name of the aggregate function is used.

The `Aggregate` clause can begin a query, or it can be included as an additional clause in a query. If the `Aggregate` clause begins a query, the result is a single value that is the result of the aggregate function specified in the `Into` clause. If more than one aggregate function is specified in the `Into` clause, the query returns a single type with a

separate property to reference the result of each aggregate function in the `Into` clause. If the `Aggregate` clause is included as an additional clause in a query, the type returned in the query collection will have a separate property to reference the result of each aggregate function in the `Into` clause.

Aggregate Functions

The following are the standard aggregate functions that can be used with the `Aggregate` clause.

All

Returns `true` if all elements in the collection satisfy a specified condition; otherwise returns `false`. The following is an example:

```
Dim customerList1 = Aggregate order In orders
    Into AllOrdersOver100 = All(order.Total >= 100)
```

Any

Returns `true` if any element in the collection satisfies a specified condition; otherwise returns `false`. The following is an example:

```
Dim customerList2 = From cust In customers
    Aggregate order In cust.Orders
    Into AnyOrderOver500 = Any(order.Total >= 500)
```

Average

Computes the average of all elements in the collection, or computes a supplied expression for all elements in the collection. The following is an example:

```
Dim customerOrderAverage = Aggregate order In orders
    Into Average(order.Total)
```

Count

Counts the number of elements in the collection. You can supply an optional `Boolean` expression to count only the number of elements in the collection that satisfy a condition. The following is an example:

```
Dim customerOrderAfter1996 = From cust In customers
    Aggregate order In cust.Orders
    Into Count(order.OrderDate > #12/31/1996#)
```

Group

Refers to query results that are grouped as a result of a `Group By` or `Group Join` clause. The `Group` function is valid only in the `Into` clause of a `Group By` or `Group Join` clause. For more information and examples, see [Group By Clause](#) and [Group Join Clause](#).

LongCount

Counts the number of elements in the collection. You can supply an optional `Boolean` expression to count only the number of elements in the collection that satisfy a condition. Returns the result as a `Long`. For an example, see the `Count` aggregate function.

Max

Computes the maximum value from the collection, or computes a supplied expression for all elements in the collection. The following is an example:

```
Dim customerMaxOrder = Aggregate order In orders
    Into MaxOrder = Max(order.Total)
```

Min

Computes the minimum value from the collection, or computes a supplied expression for all elements in the collection. The following is an example:

```
Dim customerMinOrder = From cust In customers
    Aggregate order In cust.Orders
    Into MinOrder = Min(order.Total)
```

Sum

Computes the sum of all elements in the collection, or computes a supplied expression for all elements in the collection. The following is an example:

```
Dim customerTotals = From cust In customers
    Aggregate order In cust.Orders
    Into Sum(order.Total)
```

Example

The following example shows how to use the `Aggregate` clause to apply aggregate functions to a query result.

```
Public Sub AggregateSample()
    Dim customers = GetCustomerList()

    Dim customerOrderTotal =
        From cust In customers
        Aggregate order In cust.Orders
        Into Sum(order.Total), MaxOrder = Max(order.Total),
        MinOrder = Min(order.Total), Avg = Average(order.Total)

    For Each customer In customerOrderTotal
        Console.WriteLine(customer.cust.CompanyName & vbCrLf &
            vbTab & "Sum = " & customer.Sum & vbCrLf &
            vbTab & "Min = " & customer.MinOrder & vbCrLf &
            vbTab & "Max = " & customer.MaxOrder & vbCrLf &
            vbTab & "Avg = " & customer.Avg.ToString("#.##"))

    Next
End Sub
```

Creating User-Defined Aggregate Functions

You can include your own custom aggregate functions in a query expression by adding extension methods to the `IEnumerable<T>` type. Your custom method can then perform a calculation or operation on the enumerable collection that has referenced your aggregate function. For more information about extension methods, see [Extension Methods](#).

For example, the following example shows a custom aggregate function that calculates the median value of a collection of numbers. There are two overloads of the `Median` extension method. The first overload accepts, as input, a collection of type `IEnumerable(Of Double)`. If the `Median` aggregate function is called for a query field of type `Double`, this method will be called. The second overload of the `Median` method can be passed any generic type. The generic overload of the `Median` method takes a second parameter that references the `Func(Of T, Double)` lambda expression to project a value for a type (from a collection) as the corresponding

value of type `Double`. It then delegates the calculation of the median value to the other overload of the `Median` method. For more information about lambda expressions, see [Lambda Expressions](#).

```
Imports System.Runtime.CompilerServices

Module UserDefinedAggregates

    ' Calculate the median value for a collection of type Double.
    <Extension()
    Function Median(ByVal values As IEnumerable(Of Double)) As Double
        If values.Count = 0 Then
            Throw New InvalidOperationException("Cannot compute median for an empty set.")
        End If

        Dim sortedList = From number In values
                        Order By number

        Dim medianValue As Double

        Dim itemIndex = CInt(Int(sortedList.Count / 2))

        If sortedList.Count Mod 2 = 0 Then
            ' Even number of items in list.
            medianValue = ((sortedList(itemIndex) + sortedList(itemIndex - 1)) / 2)
        Else
            ' Odd number of items in list.
            medianValue = sortedList(itemIndex)
        End If

        Return medianValue
    End Function

    ' "Cast" the collection of generic items as type Double and call the
    ' Median() method to calculate the median value.
    <Extension()
    Function Median(Of T)(ByVal values As IEnumerable(Of T),
                           ByVal selector As Func(Of T, Double)) As Double
        Return (From element In values Select selector(element)).Median()
    End Function

End Module
```

The following example shows sample queries that call the `Median` aggregate function on a collection of type `Integer`, and a collection of type `Double`. The query that calls the `Median` aggregate function on the collection of type `Double` calls the overload of the `Median` method that accepts, as input, a collection of type `Double`. The query that calls the `Median` aggregate function on the collection of type `Integer` calls the generic overload of the `Median` method.

```
Module Module1

Sub Main()
    Dim numbers1 = {1, 2, 3, 4, 5}

    Dim query1 = Aggregate num In numbers1 Into Median(num)

    Console.WriteLine("Median = " & query1)

    Dim numbers2 = {1.9, 2, 8, 4, 5.7, 6, 7.2, 0}

    Dim query2 = Aggregate num In numbers2 Into Median()

    Console.WriteLine("Median = " & query2)
End Sub

End Module
```

Distinct Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Restricts the values of the current range variable to eliminate duplicate values in subsequent query clauses.

Syntax

```
Distinct
```

Remarks

You can use the `Distinct` clause to return a list of unique items. The `Distinct` clause causes the query to ignore duplicate query results. The `Distinct` clause applies to duplicate values for all return fields specified by the `Select` clause. If no `Select` clause is specified, the `Distinct` clause is applied to the range variable for the query identified in the `From` clause. If the range variable is not an immutable type, the query will only ignore a query result if all members of the type match an existing query result.

Example

The following query expression joins a list of customers and a list of customer orders. The `Distinct` clause is included to return a list of unique customer names and order dates.

```
Dim customerOrders = From cust In customers, ord In orders  
    Where cust.CustomerID = ord.CustomerID  
    Select cust.CompanyName, ord.OrderDate  
    Distinct
```

From Clause (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Specifies one or more range variables and a collection to query.

Syntax

```
From element [ As type ] In collection [ _ ]
[, element2 [ As type2 ] In collection2 [, ... ] ]
```

Parts

TERM	DEFINITION
element	Required. A <i>range variable</i> used to iterate through the elements of the collection. A range variable is used to refer to each member of the <code>collection</code> as the query iterates through the <code>collection</code> . Must be an enumerable type.
type	Optional. The type of <code>element</code> . If no <code>type</code> is specified, the type of <code>element</code> is inferred from <code>collection</code> .
collection	Required. Refers to the collection to be queried. Must be an enumerable type.

Remarks

The `From` clause is used to identify the source data for a query and the variables that are used to refer to an element from the source collection. These variables are called *range variables*. The `From` clause is required for a query, except when the `Aggregate` clause is used to identify a query that returns only aggregated results. For more information, see [Aggregate Clause](#).

You can specify multiple `From` clauses in a query to identify multiple collections to be joined. When multiple collections are specified, they are iterated over independently, or you can join them if they are related. You can join collections implicitly by using the `Select` clause, or explicitly by using the `Join` or `Group Join` clauses. As an alternative, you can specify multiple range variables and collections in a single `From` clause, with each related range variable and collection separated from the others by a comma. The following code example shows both syntax options for the `From` clause.

```
' Multiple From clauses in a query.
Dim result = From var1 In collection1, var2 In collection2

' Equivalent syntax with a single From clause.
Dim result2 = From var1 In collection1
              From var2 In collection2
```

The `From` clause defines the scope of a query, which is similar to the scope of a `For` loop. Therefore, each `element` range variable in the scope of a query must have a unique name. Because you can specify multiple `From` clauses for a query, subsequent `From` clauses can refer to range variables in the `From` clause, or they can

refer to range variables in a previous `From` clause. For example, the following example shows a nested `From` clause where the collection in the second clause is based on a property of the range variable in the first clause.

```
Dim allOrders = From cust In GetCustomerList()
    From ord In cust.Orders
    Select ord
```

Each `From` clause can be followed by any combination of additional query clauses to refine the query. You can refine the query in the following ways:

- Combine multiple collections implicitly by using the `From` and `Select` clauses, or explicitly by using the `Join` or `Group Join` clauses.
- Use the `Where` clause to filter the query result.
- Sort the result by using the `Order By` clause.
- Group similar results together by using the `Group By` clause.
- Use the `Aggregate` clause to identify aggregate functions to evaluate for the whole query result.
- Use the `Let` clause to introduce an iteration variable whose value is determined by an expression instead of a collection.
- Use the `Distinct` clause to ignore duplicate query results.
- Identify parts of the result to return by using the `Skip`, `Take`, `Skip While`, and `Take While` clauses.

Example

The following query expression uses a `From` clause to declare a range variable `cust` for each `Customer` object in the `customers` collection. The `Where` clause uses the range variable to restrict the output to customers from the specified region. The `For Each` loop displays the company name for each customer in the query result.

```
Sub DisplayCustomersForRegion(ByVal customers As List(Of Customer),
    ByVal region As String)

    Dim customersForRegion = From cust In customers
        Where cust.Region = region

    For Each cust In customersForRegion
        Console.WriteLine(cust.CompanyName)
    Next
End Sub
```

Group By Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Groups the elements of a query result. Can also be used to apply aggregate functions to each group. The grouping operation is based on one or more keys.

Syntax

```
Group [ listField1 [, listField2 [...] ] By keyExp1 [, keyExp2 [...] ]  
    Into aggregateList
```

Parts

- `listField1`, `listField2`

Optional. One or more fields of the query variable or variables that explicitly identify the fields to be included in the grouped result. If no fields are specified, all fields of the query variable or variables are included in the grouped result.

- `keyExp1`

Required. An expression that identifies the key to use to determine the groups of elements. You can specify more than one key to specify a composite key.

- `keyExp2`

Optional. One or more additional keys that are combined with `keyExp1` to create a composite key.

- `aggregateList`

Required. One or more expressions that identify how the groups are aggregated. To identify a member name for the grouped results, use the `Group` keyword, which can be in either of the following forms:

```
    Into Group
```

-or-

```
    Into <alias> = Group
```

You can also include aggregate functions to apply to the group.

Remarks

You can use the `Group By` clause to break the results of a query into groups. The grouping is based on a key or a composite key consisting of multiple keys. Elements that are associated with matching key values are included in the same group.

You use the `aggregateList` parameter of the `Into` clause and the `Group` keyword to identify the member name that is used to reference the group. You can also include aggregate functions in the `Into` clause to compute values for the grouped elements. For a list of standard aggregate functions, see [Aggregate Clause](#).

Example

The following code example groups a list of customers based on their location (country) and provides a count of the customers in each group. The results are ordered by country name. The grouped results are ordered by city name.

```
Public Sub GroupBySample()
    Dim customers = GetCustomerList()

    Dim customersByCountry = From cust In customers
        Order By cust.City
        Group By CountryName = cust.Country
        Into RegionalCustomers = Group, Count()
        Order By CountryName

    For Each country In customersByCountry
        Console.WriteLine(country.CountryName &
            " (" & country.Count & ")" & vbCrLf)

        For Each customer In country.RegionalCustomers
            Console.WriteLine(vbTab & customer.CompanyName &
                " (" & customer.City & ")")
        Next
    Next
End Sub
```

Group Join Clause (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Combines two collections into a single hierarchical collection. The join operation is based on matching keys.

Syntax

```
Group Join element [As type] In collection _  
    On key1 Equals key2 [ And key3 Equals key4 [ ... ] ] _  
    Into expressionList
```

Parts

TERM	DEFINITION
<code>element</code>	Required. The control variable for the collection being joined.
<code>type</code>	Optional. The type of <code>element</code> . If no <code>type</code> is specified, the type of <code>element</code> is inferred from <code>collection</code> .
<code>collection</code>	Required. The collection to combine with the collection that is on the left side of the <code>Group Join</code> operator. A <code>Group Join</code> clause can be nested in a <code>Join</code> clause or in another <code>Group Join</code> clause.
<code>key1 Equals key2</code>	Required. Identifies keys for the collections being joined. You must use the <code>Equals</code> operator to compare keys from the collections being joined. You can combine join conditions by using the <code>And</code> operator to identify multiple keys. The <code>key1</code> parameter must be from the collection on the left side of the <code>Join</code> operator. The <code>key2</code> parameter must be from the collection on the right side of the <code>Join</code> operator. The keys used in the join condition can be expressions that include more than one item from the collection. However, each key expression can contain only items from its respective collection.
<code>expressionList</code>	Required. One or more expressions that identify how the groups of elements from the collection are aggregated. To identify a member name for the grouped results, use the <code>Group</code> keyword (<code><alias> = Group</code>). You can also include aggregate functions to apply to the group.

Remarks

The `Group Join` clause combines two collections based on matching key values from the collections being joined. The resulting collection can contain a member that references a collection of elements from the second collection that match the key value from the first collection. You can also specify aggregate functions to apply to the grouped elements from the second collection. For information about aggregate functions, see [Aggregate](#)

Clause.

Consider, for example, a collection of managers and a collection of employees. Elements from both collections have a ManagerID property that identifies the employees that report to a particular manager. The results from a join operation would contain a result for each manager and employee with a matching ManagerID value. The results from a `Group Join` operation would contain the complete list of managers. Each manager result would have a member that referenced the list of employees that were a match for the specific manager.

The collection resulting from a `Group Join` operation can contain any combination of values from the collection identified in the `From` clause and the expressions identified in the `Into` clause of the `Group Join` clause. For more information about valid expressions for the `Into` clause, see [Aggregate Clause](#).

A `Group Join` operation will return all results from the collection identified on the left side of the `Group Join` operator. This is true even if there are no matches in the collection being joined. This is like a `LEFT OUTER JOIN` in SQL.

You can use the `Join` clause to combine collections into a single collection. This is equivalent to an `INNER JOIN` in SQL.

Example

The following code example joins two collections by using the `Group Join` clause.

```
Dim customerList = From cust In customers
    Group Join ord In orders On
        cust.CustomerID Equals ord.CustomerID
    Into CustomerOrders = Group,
        OrderTotal = Sum(ord.Total)
    Select cust.CompanyName, cust.CustomerID,
        CustomerOrders, OrderTotal

For Each customer In customerList
    Console.WriteLine(customer.CompanyName &
        " (" & customer.OrderTotal & ")")

    For Each order In customer.CustomerOrders
        Console.WriteLine(vbTab & order.OrderID & ": " & order.Total)
    Next
Next
```

Join Clause (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Combines two collections into a single collection. The join operation is based on matching keys and uses the `Equals` operator.

Syntax

```
Join element In collection _  
[ joinClause _ ]  
[ groupJoinClause ... _ ]  
On key1 Equals key2 [ And key3 Equals key4 [ ... ] ]
```

Parts

element

Required. The control variable for the collection being joined.

collection

Required. The collection to combine with the collection identified on the left side of the `Join` operator. A `Join` clause can be nested in another `Join` clause, or in a `Group Join` clause.

joinClause

Optional. One or more additional `Join` clauses to further refine the query.

groupJoinClause

Optional. One or more additional `Group Join` clauses to further refine the query.

key1 Equals key2

Required. Identifies keys for the collections being joined. You must use the `Equals` operator to compare keys from the collections being joined. You can combine join conditions by using the `And` operator to identify multiple keys. `key1` must be from the collection on the left side of the `Join` operator. `key2` must be from the collection on the right side of the `Join` operator.

The keys used in the join condition can be expressions that include more than one item from the collection. However, each key expression can contain only items from its respective collection.

Remarks

The `Join` clause combines two collections based on matching key values from the collections being joined. The resulting collection can contain any combination of values from the collection identified on the left side of the `Join` operator and the collection identified in the `Join` clause. The query will return only results for which the condition specified by the `Equals` operator is met. This is equivalent to an `INNER JOIN` in SQL.

You can use multiple `Join` clauses in a query to join two or more collections into a single collection.

You can perform an implicit join to combine collections without the `Join` clause. To do this, include multiple `In` clauses in your `From` clause and specify a `Where` clause that identifies the keys that you want to use for the join.

You can use the `Group Join` clause to combine collections into a single hierarchical collection. This is like a `LEFT OUTER JOIN` in SQL.

Example

The following code example performs an implicit join to combine a list of customers with their orders.

```
Dim customerIDs() = {"ALFKI", "VICTE", "BLAUS", "TRAIH"}  
  
Dim customerList = From cust In customers, custID In customerIDs  
    Where cust.CustomerID = custID  
    Select cust.CompanyName  
  
For Each companyName In customerList  
    Console.WriteLine(companyName)  
Next
```

Example

The following code example joins two collections by using the `Join` clause.

```
Imports System.Diagnostics  
Imports System.Security.Permissions  
  
Public Class JoinSample  
  
<SecurityPermission(SecurityAction.Demand)>  
Public Sub ListProcesses()  
    Dim processDescriptions As New List(Of ProcessDescription)  
    processDescriptions.Add(New ProcessDescription With {  
        .ProcessName = "explorer",  
        .Description = "Windows Explorer"})  
    processDescriptions.Add(New ProcessDescription With {  
        .ProcessName = "winlogon",  
        .Description = "Windows Logon"})  
    processDescriptions.Add(New ProcessDescription With {  
        .ProcessName = "cmd",  
        .Description = "Command Window"})  
    processDescriptions.Add(New ProcessDescription With {  
        .ProcessName = "iexplore",  
        .Description = "Internet Explorer"})  
  
    Dim processes = From proc In Process.GetProcesses  
        Join desc In processDescriptions  
        On proc.ProcessName Equals desc.ProcessName  
        Select proc.ProcessName, proc.Id, desc.Description  
  
    For Each proc In processes  
        Console.WriteLine("{0} ({1}), {2}",  
            proc.ProcessName, proc.Id, proc.Description)  
    Next  
End Sub  
  
End Class  
  
Public Class ProcessDescription  
    Public ProcessName As String  
    Public Description As String  
End Class
```

This example will produce output similar to the following:

```
winlogon (968), Windows Logon
```

```
explorer (2424), File Explorer
```

Example

The following code example joins two collections by using the `Join` clause with two key columns.

```

Imports System.Diagnostics
Imports System.Security.Permissions

Public Class JoinSample2

    <SecurityPermission(SecurityAction.Demand)>
    Public Sub ListProcesses()
        Dim processDescriptions As New List(Of ProcessDescription2)

        ' 8 = Normal priority, 13 = High priority
        processDescriptions.Add(New ProcessDescription2 With {
            .ProcessName = "explorer",
            .Description = "Windows Explorer",
            .Priority = 8})
        processDescriptions.Add(New ProcessDescription2 With {
            .ProcessName = "winlogon",
            .Description = "Windows Logon",
            .Priority = 13})
        processDescriptions.Add(New ProcessDescription2 With {
            .ProcessName = "cmd",
            .Description = "Command Window",
            .Priority = 8})
        processDescriptions.Add(New ProcessDescription2 With {
            .ProcessName = "iexplore",
            .Description = "Internet Explorer",
            .Priority = 8})

        Dim processes = From proc In Process.GetProcesses
                        Join desc In processDescriptions
                        On proc.ProcessName Equals desc.ProcessName And
                            proc.BasePriority Equals desc.Priority
                        Select proc.ProcessName, proc.Id, desc.Description,
                            desc.Priority

        For Each proc In processes
            Console.WriteLine("{0} ({1}), {2}, Priority = {3}",
                proc.ProcessName,
                proc.Id,
                proc.Description,
                proc.Priority)
        Next
    End Sub

End Class

Public Class ProcessDescription2
    Public ProcessName As String
    Public Description As String
    Public Priority As Integer
End Class

```

The example will produce output similar to the following:

```
winlogon (968), Windows Logon, Priority = 13
```

```
cmd (700), Command Window, Priority = 8
```

```
explorer (2424), File Explorer, Priority = 8
```

Let Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Computes a value and assigns it to a new variable within the query.

Syntax

```
Let variable = expression [, ...]
```

Parts

TERM	DEFINITION
variable	Required. An alias that can be used to reference the results of the supplied expression.
expression	Required. An expression that will be evaluated and assigned to the specified variable.

Remarks

The `Let` clause enables you to compute values for each query result and reference them by using an alias. The alias can be used in other clauses, such as the `Where` clause. The `Let` clause enables you to create a query statement that is easier to read because you can specify an alias for an expression clause included in the query and substitute the alias each time the expression clause is used.

You can include any number of `variable` and `expression` assignments in the `Let` clause. Separate each assignment with a comma (,).

Example

The following code example uses the `Let` clause to compute a 10 percent discount on products.

```
Dim discountedProducts = From prod In products
    Let Discount = prod.UnitPrice * 0.1
    Where Discount >= 50
    Select prod.ProductName, prod.UnitPrice, Discount

For Each prod In discountedProducts
    Console.WriteLine("Product: {0}, Price: {1}, Discounted Price: {2}",
        prod.ProductName, prod.UnitPrice.ToString("#.00"),
        (prod.UnitPrice - prod.Discount).ToString("#.00"))
Next
```

Order By Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies the sort order for a query result.

Syntax

```
Order By orderExp1 [ Ascending | Descending ] [, orderExp2 [...] ]
```

Parts

`orderExp1`

Required. One or more fields from the current query result that identify how to order the returned values. The field names must be separated by commas (,). You can identify each field as sorted in ascending or descending order by using the `Ascending` or `Descending` keywords. If no `Ascending` or `Descending` keyword is specified, the default sort order is ascending. The sort order fields are given precedence from left to right.

Remarks

You can use the `Order By` clause to sort the results of a query. The `Order By` clause can only sort a result based on the range variable for the current scope. For example, the `Select` clause introduces a new scope in a query expression with new iteration variables for that scope. Range variables defined before a `Select` clause in a query are not available after the `Select` clause. Therefore, if you want to order your results by a field that is not available in the `Select` clause, you must put the `Order By` clause before the `Select` clause. One example of when you would have to do this is when you want to sort your query by fields that are not returned as part of the result.

Ascending and descending order for a field is determined by the implementation of the [IComparable](#) interface for the data type of the field. If the data type does not implement the [IComparable](#) interface, the sort order is ignored.

Example

The following query expression uses a `From` clause to declare a range variable `book` for the `books` collection. The `Order By` clause sorts the query result by price in ascending order (the default). Books with the same price are sorted by title in ascending order. The `Select` clause selects the `Title` and `Price` properties as the values returned by the query.

```
Dim titlesAscendingPrice = From book In books
                           Order By book.Price, book.Title
                           Select book.Title, book.Price
```

Example

The following query expression uses the `Order By` clause to sort the query result by price in descending order. Books with the same price are sorted by title in ascending order.

```
Dim titlesDescendingPrice = From book In books
                            Order By book.Price Descending, book.Title
                            Select book.Title, book.Price
```

Example

The following query expression uses a `Select` clause to select the book title, price, publish date, and author. It then populates the `Title`, `Price`, `PublishDate`, and `Author` fields of the range variable for the new scope. The `Order By` clause orders the new range variable by author name, book title, and then price. Each column is sorted in the default order (ascending).

```
Dim bookOrders =
    From book In books
    Select book.Title, book.Price, book.PublishDate, book.Author
    Order By Author, Title, Price
```

Select Clause (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Defines the result of a query.

Syntax

```
Select [ var1 = ] fieldName1 [, [ var2 = ] fieldName2 [...] ]
```

Parts

`var1`

Optional. An alias that can be used to reference the results of the column expression.

`fieldName1`

Required. The name of the field to return in the query result.

Remarks

You can use the `Select` clause to define the results to return from a query. This enables you to either define the members of a new anonymous type that is created by a query, or to target the members of a named type that is returned by a query. The `Select` clause is not required for a query. If no `Select` clause is specified, the query will return a type based on all members of the range variables identified for the current scope. For more information, see [Anonymous Types](#). When a query creates a named type, it will return a result of type `IEnumerable<T>` where `T` is the created type.

The `Select` clause can reference any variables in the current scope. This includes range variables identified in the `From` clause (or `From` clauses). It also includes any new variables created with an alias by the `Aggregate`, `Let`, `Group By`, or `Group Join` clauses, or variables from a previous `Select` clause in the query expression.

The `Select` clause can also include static values. For example, the following code example shows a query expression in which the `Select` clause defines the query result as a new anonymous type with four members: `ProductName`, `Price`, `Discount`, and `DiscountedPrice`. The `ProductName` and `Price` member values are taken from the product range variable that is defined in the `From` clause. The `DiscountedPrice` member value is calculated in the `Let` clause. The `Discount` member is a static value.

```
' 10% discount
Dim discount_10 = 0.1
Dim priceList =
    From product In products
    Let DiscountedPrice = product.UnitPrice * (1 - discount_10)
    Select product.ProductName, Price = product.UnitPrice,
        Discount = discount_10, DiscountedPrice
```

The `Select` clause introduces a new set of range variables for subsequent query clauses, and previous range variables are no longer in scope. The last `Select` clause in a query expression determines the return value of the query. For example, the following query returns the company name and order ID for every customer order for which the total exceeds 500. The first `Select` clause identifies the range variables for the `Where` clause and the second `Select` clause. The second `Select` clause identifies the values returned by the query as a new anonymous type.

```
Dim customerList = From cust In customers, ord In cust.Orders  
    Select Name = cust.CompanyName,  
          Total = ord.Total, ord.OrderID  
    Where Total > 500  
    Select Name, OrderID
```

If the `Select` clause identifies a single item to return, the query expression returns a collection of the type of that single item. If the `Select` clause identifies multiple items to return, the query expression returns a collection of a new anonymous type, based on the selected items. For example, the following two queries return collections of two different types based on the `Select` clause. The first query returns a collection of company names as strings. The second query returns a collection of `Customer` objects populated with the company names and address information.

```
Dim customerNames = From cust In customers  
    Select cust.CompanyName  
  
Dim customerInfo As IEnumerable(Of Customer) =  
    From cust In customers  
    Select New Customer With {.CompanyName = cust.CompanyName,  
                           .Address = cust.Address,  
                           .City = cust.City,  
                           .Region = cust.Region,  
                           .Country = cust.Country}
```

Example

The following query expression uses a `From` clause to declare a range variable `cust` for the `customers` collection. The `Select` clause selects the customer name and ID value and populates the `CompanyName` and `CustomerID` columns of the new range variable. The `For Each` statement loops over each returned object and displays the `CompanyName` and `CustomerID` columns for each record.

```
Sub SelectCustomerNameAndId(ByVal customers() As Customer)  
    Dim nameIds = From cust In customers  
        Select cust.CompanyName, cust.CustomerID  
    For Each nameId In nameIds  
        Console.WriteLine(nameId.CompanyName & ":" & nameId.CustomerID)  
    Next  
End Sub
```

Skip Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Bypasses a specified number of elements in a collection and then returns the remaining elements.

Syntax

```
Skip count
```

Parts

count

Required. A value or an expression that evaluates to the number of elements of the sequence to skip.

Remarks

The `skip` clause causes a query to bypass elements at the beginning of a results list and return the remaining elements. The number of elements to skip is identified by the `count` parameter.

You can use the `skip` clause with the `Take` clause to return a range of data from any segment of a query. To do this, pass the index of the first element of the range to the `skip` clause and the size of the range to the `Take` clause.

When you use the `skip` clause in a query, you may also need to ensure that the results are returned in an order that will enable the `skip` clause to bypass the intended results. For more information about ordering query results, see [Order By Clause](#).

You can use the `SkipWhile` clause to specify that only certain elements are ignored, depending on a supplied condition.

Example

The following code example uses the `skip` clause together with the `Take` clause to return data from a query in pages. The `GetCustomers` function uses the `skip` clause to bypass the customers in the list until the supplied starting index value, and uses the `Take` clause to return a page of customers starting from that index value.

```

Public Sub PagingSample()
    Dim pageNumber As Integer = 0
    Dim pageSize As Integer = 10

    Dim customersPage = GetCustomers(pageNumber * pageSize, pageSize)

    Do While customersPage IsNot Nothing
        Console.WriteLine(vbCrLf & "Page: " & pageNumber + 1 & vbCrLf)

        For Each cust In customersPage
            Console.WriteLine(cust.CustomerID & ", " & cust.CompanyName)
        Next

        Console.WriteLine(vbCrLf)

        pageNumber += 1
        customersPage = GetCustomers(pageNumber * pageSize, pageSize)
    Loop
End Sub

Public Function GetCustomers(ByVal startIndex As Integer,
                            ByVal pageSize As Integer) As List(Of Customer)

    Dim customers = GetCustomerList()

    Dim returnCustomers = From cust In customers
                           Skip startIndex Take pageSize

    If returnCustomers.Count = 0 Then Return Nothing

    Return returnCustomers
End Function

Skip While Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Bypasses elements in a collection as long as a specified condition is `true` and then returns the remaining elements.

Syntax

```
Skip While expression
```

Parts

TERM	DEFINITION
<code>expression</code>	Required. An expression that represents a condition to test elements for. The expression must return a <code>Boolean</code> value or a functional equivalent, such as an <code>Integer</code> to be evaluated as a <code>Boolean</code> .

Remarks

The `skip While` clause bypasses elements from the beginning of a query result until the supplied `expression` returns `false`. After `expression` returns `false`, the query returns all the remaining elements. The `expression` is ignored for the remaining results.

The `skip While` clause differs from the `Where` clause in that the `Where` clause can be used to exclude all elements from a query that do not meet a particular condition. The `Skip While` clause excludes elements only until the first time that the condition is not satisfied. The `skip While` clause is most useful when you are working with an ordered query result.

You can bypass a specific number of results from the beginning of a query result by using the `skip` clause.

Example

The following code example uses the `Skip While` clause to bypass results until the first customer from the United States is found.

```
Public Sub SkipWhileSample()
    Dim customers = GetCustomerList()

    ' Return customers starting from the first U.S. customer encountered.
    Dim customerList = From cust In customers
        Order By cust.Country
        Skip While IsInternationalCustomer(cust)

    For Each cust In customerList
        Console.WriteLine(cust.CompanyName & vbTab & cust.Country)
    Next
End Sub

Public Function IsInternationalCustomer(ByVal cust As Customer) As Boolean
    If cust.Country = "USA" Then Return False

    Return True
End Function
```

Take Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Returns a specified number of contiguous elements from the start of a collection.

Syntax

```
Take count
```

Parts

count

Required. A value or an expression that evaluates to the number of elements of the sequence to return.

Remarks

The `Take` clause causes a query to include a specified number of contiguous elements from the start of a results list. The number of elements to include is specified by the `count` parameter.

You can use the `Take` clause with the `skip` clause to return a range of data from any segment of a query. To do this, pass the index of the first element of the range to the `skip` clause and the size of the range to the `Take` clause. In this case, the `Take` clause must be specified after the `skip` clause.

When you use the `Take` clause in a query, you may also need to ensure that the results are returned in an order that will enable the `Take` clause to include the intended results. For more information about ordering query results, see [Order By Clause](#).

You can use the `TakeWhile` clause to specify that only certain elements be returned, depending on a supplied condition.

Example

The following code example uses the `Take` clause together with the `skip` clause to return data from a query in pages. The `GetCustomers` function uses the `skip` clause to bypass the customers in the list until the supplied starting index value, and uses the `Take` clause to return a page of customers starting from that index value.

```

Public Sub PagingSample()
    Dim pageNumber As Integer = 0
    Dim pageSize As Integer = 10

    Dim customersPage = GetCustomers(pageNumber * pageSize, pageSize)

    Do While customersPage IsNot Nothing
        Console.WriteLine(vbCrLf & "Page: " & pageNumber + 1 & vbCrLf)

        For Each cust In customersPage
            Console.WriteLine(cust.CustomerID & ", " & cust.CompanyName)
        Next

        Console.WriteLine(vbCrLf)

        pageNumber += 1
        customersPage = GetCustomers(pageNumber * pageSize, pageSize)
    Loop
End Sub

Public Function GetCustomers(ByVal startIndex As Integer,
                            ByVal pageSize As Integer) As List(Of Customer)

    Dim customers = GetCustomerList()

    Dim returnCustomers = From cust In customers
                           Skip startIndex Take pageSize

    If returnCustomers.Count = 0 Then Return Nothing

    Return returnCustomers
End Function

Take While Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

The `Take While` clause includes elements only until the first time that the condition is not satisfied. The `Take While` clause is most useful when you are working with an ordered query result.

```
Public Sub TakeWhileSample()
    Dim customers = GetCustomerList()

    ' Return customers until the first customer with no orders is found.
    Dim customersWithOrders = From cust In customers

Where Clause (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies the filtering condition for a query.

Syntax

```
Where condition
```

Parts

`condition`

Required. An expression that determines whether the values for the current item in the collection are included in the output collection. The expression must evaluate to a `Boolean` value or the equivalent of a `Boolean` value. If the condition evaluates to `True`, the element is included in the query result; otherwise, the element is excluded from the query result.

Remarks

The `Where` clause enables you to filter query data by selecting only elements that meet certain criteria. Elements whose values cause the `Where` clause to evaluate to `True` are included in the query result; other elements are excluded. The expression that is used in a `Where` clause must evaluate to a `Boolean` or the equivalent of a `Boolean`, such as an `Integer` that evaluates to `False` when its value is zero. You can combine multiple expressions in a `Where` clause by using logical operators such as `And`, `Or`, `AndAlso`, `OrElse`, `Is`, and `IsNot`.

By default, query expressions are not evaluated until they are accessed—for example, when they are data-bound or iterated through in a `For` loop. As a result, the `Where` clause is not evaluated until the query is accessed. If you have values external to the query that are used in the `Where` clause, ensure that the appropriate value is used in the `Where` clause at the time the query is executed. For more information about query execution, see [Writing Your First LINQ Query](#).

You can call functions within a `Where` clause to perform a calculation or operation on a value from the current element in the collection. Calling a function in a `Where` clause can cause the query to be executed immediately when it is defined instead of when it is accessed. For more information about query execution, see [Writing Your First LINQ Query](#).

Example

The following query expression uses a `From` clause to declare a range variable `cust` for each `Customer` object in the `customers` collection. The `Where` clause uses the range variable to restrict the output to customers from the specified region. The `For Each` loop displays the company name for each customer in the query result.

```

Sub DisplayCustomersForRegion(ByVal customers As List(Of Customer),
                             ByVal region As String)

    Dim customersForRegion = From cust In customers
                             Where cust.Region = region

    For Each cust In customersForRegion
        Console.WriteLine(cust.CompanyName)
    Next
End Sub

```

Example

The following example uses `And` and `or` logical operators in the `Where` clause.

```

Private Sub DisplayElements()
    Dim elements As List(Of Element) = BuildList()

    ' Get a list of elements that have an atomic number from 12 to 14,
    ' or that have a name that ends in "r".
    Dim subset = From theElement In elements
                 Where (theElement.AtomicNumber >= 12 And theElement.AtomicNumber < 15) _
                 Or theElement.Name.EndsWith("r")
                 Order By theElement.Name

    For Each theElement In subset
        Console.WriteLine(theElement.Name & " " & theElement.AtomicNumber)
    Next

    ' Output:
    ' Aluminum 13
    ' Magnesium 12
    ' Silicon 14
    ' Sulfur 16
End Sub

Private Function BuildList() As List(Of Element)
    Return New List(Of Element) From
    {
        {New Element With {.Name = "Sodium", .AtomicNumber = 11}},
        {New Element With {.Name = "Magnesium", .AtomicNumber = 12}},
        {New Element With {.Name = "Aluminum", .AtomicNumber = 13}},
        {New Element With {.Name = "Silicon", .AtomicNumber = 14}},
        {New Element With {.Name = "Phosphorous", .AtomicNumber = 15}},
        {New Element With {.Name = "Sulfur", .AtomicNumber = 16}}
    }
End Function

Public Class Element
    Public Property Name As String
    Public Property AtomicNumber As Integer
End Class

AddHandler Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Associates an event with an event handler at run time.

Syntax

```
AddHandler event, AddressOf eventhandler
```

Parts

event	The name of the event to handle.
eventhandler	The name of a procedure that handles the event.

Remarks

The `AddHandler` and `RemoveHandler` statements allow you to start and stop event handling at any time during program execution.

The signature of the `eventhandler` procedure must match the signature of the event `event`.

The `Handles` keyword and the `AddHandler` statement both allow you to specify that particular procedures handle particular events, but there are differences. The `AddHandler` statement connects procedures to events at run time. Use the `Handles` keyword when defining a procedure to specify that it handles a particular event. For more information, see [Handles](#).

NOTE

For custom events, the `AddHandler` statement invokes the event's `AddHandler` accessor. For more information on custom events, see [Event Statement](#).

Example

```
Sub TestEvents()
    Dim Obj As New Class1
    ' Associate an event handler with an event.
    AddHandler Obj.Ev_Event, AddressOf EventHandler
    ' Call the method to raise the event.
    Obj.CauseSomeEvent()
    ' Stop handling events.
    RemoveHandler Obj.Ev_Event, AddressOf EventHandler
    ' This event will not be handled.
    Obj.CauseSomeEvent()
End Sub

Sub EventHandler()
    ' Handle the event.
    MsgBox("EventHandler caught event.")
End Sub

Public Class Class1
    ' Declare an event.
    Public Event Ev_Event()
    Sub CauseSomeEvent()
        ' Raise an event.
        RaiseEvent Ev_Event()
    End Sub
End Class
```

Call Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Transfers control to a `Function`, `Sub`, or dynamic-link library (DLL) procedure.

Syntax

```
[ Call ] procedureName [ (argumentList) ]
```

Parts

<code>procedureName</code>	Required. Name of the procedure to call.
<code>argumentList</code>	Optional. List of variables or expressions representing arguments that are passed to the procedure when it is called. Multiple arguments are separated by commas. If you include <code>argumentList</code> , you must enclose it in parentheses.

Remarks

You can use the `Call` keyword when you call a procedure. For most procedure calls, you aren't required to use this keyword.

You typically use the `Call` keyword when the called expression doesn't start with an identifier. Use of the `Call` keyword for other uses isn't recommended.

If the procedure returns a value, the `Call` statement discards it.

Example

The following code shows two examples where the `Call` keyword is necessary to call a procedure. In both examples, the called expression doesn't start with an identifier.

```
Sub TestCall()
    Call (Sub() Console.WriteLine("Hello"))()

    Call New TheClass().ShowText()
End Sub

Class TheClass
    Public Sub ShowText()
        Console.WriteLine(" World")
    End Sub
End Class
```

Class Statement (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Declares the name of a class and introduces the definition of the variables, properties, events, and procedures that the class comprises.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ Shadows ] [ MustInherit | NotInheritable ] [ Partial ] _  
Class name [ ( Of typelist ) ]  
    [ Inherits classname ]  
    [ Implements interfacenames ]  
    [ statements ]  
End Class
```

Parts

TERM	DEFINITION
<code>attributelist</code>	Optional. See Attribute List .
<code>accessmodifier</code>	Optional. Can be one of the following: <ul style="list-style-type: none">- Public- Protected- Friend- Private- Protected Friend- Private Protected See Access levels in Visual Basic .
<code>Shadows</code>	Optional. See Shadows .
<code>MustInherit</code>	Optional. See MustInherit .
<code>NotInheritable</code>	Optional. See NotInheritable .
<code>Partial</code>	Optional. Indicates a partial definition of the class. See Partial .
<code>name</code>	Required. Name of this class. See Declared Element Names .
<code>Of</code>	Optional. Specifies that this is a generic class.
<code>typelist</code>	Required if you use the <code>Of</code> keyword. List of type parameters for this class. See Type List .
<code>Inherits</code>	Optional. Indicates that this class inherits the members of another class. See Inherits Statement .

TERM	DEFINITION
<code>classname</code>	Required if you use the Inherits statement . The name of the class from which this class derives.
<code>Implements</code>	Optional. Indicates that this class implements the members of one or more interfaces. See Implements Statement .
<code>interfacenames</code>	Required if you use the Implements statement . The names of the interfaces this class implements.
<code>statements</code>	Optional. Statements which define the members of this class.
<code>End Class</code>	Required. Terminates the Class definition .

Remarks

A `Class` statement defines a new data type. A *class* is a fundamental building block of object-oriented programming (OOP). For more information, see [Objects and Classes](#).

You can use `Class` only at namespace or module level. This means the *declaration context* for a class must be a source file, namespace, class, structure, module, or interface, and cannot be a procedure or block. For more information, see [Declaration Contexts and Default Access Levels](#).

Each instance of a class has a lifetime independent of all other instances. This lifetime begins when it is created by a [New Operator](#) clause or by a function such as [CreateObject](#). It ends when all variables pointing to the instance have been set to [Nothing](#) or to instances of other classes.

Classes default to [Friend](#) access. You can adjust their access levels with the access modifiers. For more information, see [Access levels in Visual Basic](#).

Rules

- **Nesting.** You can define one class within another. The outer class is called the *containing class*, and the inner class is called a *nested class*.
- **Inheritance.** If the class uses the [Inherits Statement](#), you can specify only one base class or interface. A class cannot inherit from more than one element.

A class cannot inherit from another class with a more restrictive access level. For example, a `Public` class cannot inherit from a `Friend` class.

A class cannot inherit from a class nested within it.

- **Implementation.** If the class uses the [Implements Statement](#), you must implement every member defined by every interface you specify in `interfacenames`. An exception to this is reimplementation of a base class member. For more information, see "Reimplementation" in [Implements](#).
- **Default Property.** A class can specify at most one property as its *default property*. For more information, see [Default](#).

Behavior

- **Access Level.** Within a class, you can declare each member with its own access level. Class members

default to [Public](#) access, except variables and constants, which default to [Private](#) access. When a class has more restricted access than one of its members, the class access level takes precedence.

- **Scope.** A class is in scope throughout its containing namespace, class, structure, or module.

The scope of every class member is the entire class.

Lifetime. Visual Basic does not support static classes. The functional equivalent of a static class is provided by a module. For more information, see [Module Statement](#).

Class members have lifetimes depending on how and where they are declared. For more information, see [Lifetime in Visual Basic](#).

- **Qualification.** Code outside a class must qualify a member's name with the name of that class.

If code inside a nested class makes an unqualified reference to a programming element, Visual Basic searches for the element first in the nested class, then in its containing class, and so on out to the outermost containing element.

Classes and Modules

These elements have many similarities, but there are some important differences as well.

- **Terminology.** Previous versions of Visual Basic recognize two types of modules: *class modules* (.cls files) and *standard modules* (.bas files). The current version calls these *classes* and *modules*, respectively.
- **Shared Members.** You can control whether a member of a class is a shared or instance member.
- **Object Orientation.** Classes are object-oriented, but modules are not. You can create one or more instances of a class. For more information, see [Objects and Classes](#).

Example

The following example uses a `Class` statement to define a class and several members.

```
Class bankAccount
    Shared interestRate As Decimal
    Private accountNumber As String
    Private accountBalance As Decimal
    Public holdOnAccount As Boolean = False

    Public ReadOnly Property balance() As Decimal
        Get
            Return accountBalance
        End Get
    End Property

    Public Sub postInterest()
        accountBalance = accountBalance * (1 + interestRate)
    End Sub

    Public Sub postDeposit(ByVal amountIn As Decimal)
        accountBalance = accountBalance + amountIn
    End Sub

    Public Sub postWithdrawal(ByVal amountOut As Decimal)
        accountBalance = accountBalance - amountOut
    End Sub
End Class
```

Const Statement (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Declares and defines one or more constants.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ Shadows ]
Const constantlist
```

Parts

attributelist

Optional. List of attributes that apply to all the constants declared in this statement. See [Attribute List](#) in angle brackets ("<" and ">").

accessmodifier

Optional. Use this to specify what code can access these constants. Can be [Public](#), [Protected](#), [Friend](#), [Protected Friend](#), [Private](#), or [Private Protected](#).

Shadows

Optional. Use this to redeclare and hide a programming element in a base class. See [Shadows](#).

constantlist

Required. List of constants being declared in this statement.

```
constant [ , constant ... ]
```

Each `constant` has the following syntax and parts:

```
constantname [ As datatype ] = initializer
```

PART	DESCRIPTION
<code>constantname</code>	Required. Name of the constant. See Declared Element Names .
<code>datatype</code>	Required if <code>Option Strict</code> is <code>On</code> . Data type of the constant.
<code>initializer</code>	Required. Expression that is evaluated at compile time and assigned to the constant.

Remarks

If you have a value that never changes in your application, you can define a named constant and use it in place of a literal value. A name is easier to remember than a value. You can define the constant just once and use it in many places in your code. If in a later version you need to redefine the value, the `Const` statement is the only place you need to make a change.

You can use `Const` only at module or procedure level. This means the *declaration context* for a variable must

be a class, structure, module, procedure, or block, and cannot be a source file, namespace, or interface. For more information, see [Declaration Contexts and Default Access Levels](#).

Local constants (inside a procedure) default to public access, and you cannot use any access modifiers on them. Class and module member constants (outside any procedure) default to private access, and structure member constants default to public access. You can adjust their access levels with the access modifiers.

Rules

- **Declaration Context.** A constant declared at module level, outside any procedure, is a *member constant*; it is a member of the class, structure, or module that declares it.
A constant declared at procedure level is a *local constant*; it is local to the procedure or block that declares it.
- **Attributes.** You can apply attributes only to member constants, not to local constants. An attribute contributes information to the assembly's metadata, which is not meaningful for temporary storage such as local constants.
- **Modifiers.** By default, all constants are `Shared`, `Static`, and `ReadOnly`. You cannot use any of these keywords when declaring a constant.
At procedure level, you cannot use `Shadows` or any access modifiers to declare local constants.
- **Multiple Constants.** You can declare several constants in the same declaration statement, specifying the `constantname` part for each one. Multiple constants are separated by commas.

Data Type Rules

- **Data Types.** The `const` statement can declare the data type of a variable. You can specify any data type or the name of an enumeration.
- **Default Type.** If you do not specify `datatype`, the constant takes the data type of `initializer`. If you specify both `datatype` and `initializer`, the data type of `initializer` must be convertible to `datatype`. If neither `datatype` nor `initializer` is present, the data type defaults to `Object`.
- **Different Types.** You can specify different data types for different constants by using a separate `As` clause for each variable you declare. However, you cannot declare several constants to be of the same type by using a common `As` clause.
- **Initialization.** You must initialize the value of every constant in `constantlist`. You use `initializer` to supply an expression to be assigned to the constant. The expression can be any combination of literals, other constants that are already defined, and enumeration members that are already defined. You can use arithmetic and logical operators to combine such elements.

You cannot use variables or functions in `initializer`. However, you can use conversion keywords such as `CByte` and `CShort`. You can also use `AscW` if you call it with a constant `String` or `Char` argument, since that can be evaluated at compile time.

Behavior

- **Scope.** Local constants are accessible only from within their procedure or block. Member constants are accessible from anywhere within their class, structure, or module.
- **Qualification.** Code outside a class, structure, or module must qualify a member constant's name with the name of that class, structure, or module. Code outside a procedure or block cannot refer to any local constants within that procedure or block.

Example

The following example uses the `Const` statement to declare constants for use in place of literal values.

```
' The following statements declare constants.  
Const maximum As Long = 459  
Public Const helpString As String = "HELP"  
Private Const startValue As Integer = 5
```

Example

If you define a constant with data type `Object`, the Visual Basic compiler gives it the type of `initializer`, instead of `object`. In the following example, the constant `naturalLogBase` has the run-time type `Decimal`.

```
Const naturalLogBase As Object = CDec(2.7182818284)  
MsgBox("Run-time type of constant naturalLogBase is " &  
    naturalLogBase.GetType.ToString())
```

The preceding example uses the `ToString` method on the `Type` object returned by the `GetType Operator`, because `Type` cannot be converted to `String` using `cstr`.

Continue Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Transfers control immediately to the next iteration of a loop.

Syntax

```
Continue { Do | For | While }
```

Remarks

You can transfer from inside a `Do`, `For`, or `While` loop to the next iteration of that loop. Control passes immediately to the loop condition test, which is equivalent to transferring to the `For` or `While` statement, or to the `Do` or `Loop` statement that contains the `Until` or `While` clause.

You can use `Continue` at any location in the loop that allows transfers. The rules allowing transfer of control are the same as with the [GoTo Statement](#).

For example, if a loop is totally contained within a `Try` block, a `Catch` block, or a `Finally` block, you can use `Continue` to transfer out of the loop. If, on the other hand, the `Try ... End Try` structure is contained within the loop, you cannot use `Continue` to transfer control out of the `Finally` block, and you can use it to transfer out of a `Try` or `Catch` block only if you transfer completely out of the `Try ... End Try` structure.

If you have nested loops of the same type, for example a `Do` loop within another `Do` loop, a `Continue Do` statement skips to the next iteration of the innermost `Do` loop that contains it. You cannot use `Continue` to skip to the next iteration of a containing loop of the same type.

If you have nested loops of different types, for example a `Do` loop within a `For` loop, you can skip to the next iteration of either loop by using either `Continue Do` or `Continue For`.

Example

The following code example uses the `Continue While` statement to skip to the next column of an array if a divisor is zero. The `Continue While` is inside a `For` loop. It transfers to the `While col < lastcol` statement, which is the next iteration of the innermost `While` loop that contains the `For` loop.

```
Dim row, col As Integer
Dim lastrow As Integer = 6
Dim lastcol As Integer = 10
Dim a(,) As Double = New Double(lastrow, lastcol) {}
Dim b(7) As Double
row = -1
While row < lastrow
    row += 1
    col = -1
    While col < lastcol
        col += 1
        a(row, col) = 0
        For i As Integer = 0 To b.GetUpperBound(0)
            If b(i) = col Then
                Continue While
            Else
                a(row, col) += (row + b(i)) / (col - b(i))
            End If
        Next i
    End While
End While
```

Declare Statement

3/25/2019 • 8 minutes to read • [Edit Online](#)

Declares a reference to a procedure implemented in an external file.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ Shadows ] [ Overloads ] _
Declare [ charsetmodifier ] [ Sub ] name Lib "libname" _
[ Alias "aliasname" ] [ ([ parameterlist ]) ]
' -or-
[ <attributelist> ] [ accessmodifier ] [ Shadows ] [ Overloads ] _
Declare [ charsetmodifier ] [ Function ] name Lib "libname" _
[ Alias "aliasname" ] [ ([ parameterlist ]) ] [ As returntype ]
```

Parts

TERM	DEFINITION
<code>attributelist</code>	Optional. See Attribute List .
<code>accessmodifier</code>	Optional. Can be one of the following: <ul style="list-style-type: none">- Public- Protected- Friend- Private- Protected Friend- Private Protected See Access levels in Visual Basic .
<code>Shadows</code>	Optional. See Shadows .
<code>charsetmodifier</code>	Optional. Specifies character set and file search information. Can be one of the following: <ul style="list-style-type: none">- Ansi (default)- Unicode- Auto
<code>Sub</code>	Optional, but either <code>Sub</code> or <code>Function</code> must appear. Indicates that the external procedure does not return a value.
<code>Function</code>	Optional, but either <code>Sub</code> or <code>Function</code> must appear. Indicates that the external procedure returns a value.
<code>name</code>	Required. Name of this external reference. For more information, see Declared Element Names .

TERM	DEFINITION
<code>Lib</code>	Required. Introduces a <code>Lib</code> clause, which identifies the external file (DLL or code resource) that contains an external procedure.
<code>libname</code>	Required. Name of the file that contains the declared procedure.
<code>Alias</code>	Optional. Indicates that the procedure being declared cannot be identified within its file by the name specified in <code>name</code> . You specify its identification in <code>aliasname</code> .
<code>aliasname</code>	<p>Required if you use the <code>Alias</code> keyword. String that identifies the procedure in one of two ways:</p> <p>The entry point name of the procedure within its file, within quotes (<code>" "</code>)</p> <p>-or-</p> <p>A number sign (<code>#</code>) followed by an integer specifying the ordinal number of the procedure's entry point within its file</p>
<code>parameterlist</code>	Required if the procedure takes parameters. See Parameter List .
<code>returntype</code>	Required if <code>Function</code> is specified and <code>Option Strict</code> is <code>on</code> . Data type of the value returned by the procedure.

Remarks

Sometimes you need to call a procedure defined in a file (such as a DLL or code resource) outside your project. When you do this, the Visual Basic compiler does not have access to the information it needs to call the procedure correctly, such as where the procedure is located, how it is identified, its calling sequence and return type, and the string character set it uses. The `Declare` statement creates a reference to an external procedure and supplies this necessary information.

You can use `Declare` only at module level. This means the *declaration context* for an external reference must be a class, structure, or module, and cannot be a source file, namespace, interface, procedure, or block. For more information, see [Declaration Contexts and Default Access Levels](#).

External references default to `Public` access. You can adjust their access levels with the access modifiers.

Rules

- **Attributes.** You can apply attributes to an external reference. Any attribute you apply has effect only in your project, not in the external file.
- **Modifiers.** External procedures are implicitly `Shared`. You cannot use the `Shared` keyword when declaring an external reference, and you cannot alter its shared status.

An external procedure cannot participate in overriding, implement interface members, or handle events. Accordingly, you cannot use the `Overrides`, `Overridable`, `NotOverridable`, `MustOverride`, `Implements`, or `Handles` keyword in a `Declare` statement.

- **External Procedure Name.** You do not have to give this external reference the same name (in `name`) as the procedure's entry-point name within its external file (`aliasname`). You can use an `Alias` clause to specify the entry-point name. This can be useful if the external procedure has the same name as a Visual Basic reserved modifier or a variable, procedure, or any other programming element in the same scope.

NOTE

Entry-point names in most DLLs are case-sensitive.

- **External Procedure Number.** Alternatively, you can use an `Alias` clause to specify the ordinal number of the entry point within the export table of the external file. To do this, you begin `aliasname` with a number sign (#). This can be useful if any character in the external procedure name is not allowed in Visual Basic, or if the external file exports the procedure without a name.

Data Type Rules

- **Parameter Data Types.** If `Option Strict` is `on`, you must specify the data type of each parameter in `parameterlist`. This can be any data type or the name of an enumeration, structure, class, or interface. Within `parameterlist`, you use an `As` clause to specify the data type of the argument to be passed to each parameter.

NOTE

If the external procedure was not written for the .NET Framework, you must take care that the data types correspond. For example, if you declare an external reference to a Visual Basic 6.0 procedure with an `Integer` parameter (16 bits in Visual Basic 6.0), you must identify the corresponding argument as `Short` in the `Declare` statement, because that is the 16-bit integer type in Visual Basic. Similarly, `Long` has a different data width in Visual Basic 6.0, and `Date` is implemented differently.

- **Return Data Type.** If the external procedure is a `Function` and `option Strict` is `on`, you must specify the data type of the value returned to the calling code. This can be any data type or the name of an enumeration, structure, class, or interface.

NOTE

The Visual Basic compiler does not verify that your data types are compatible with those of the external procedure. If there is a mismatch, the common language runtime generates a `MarshalDirectiveException` exception at run time.

- **Default Data Types.** If `Option Strict` is `off` and you do not specify the data type of a parameter in `parameterlist`, the Visual Basic compiler converts the corresponding argument to the `Object` **Data Type**. Similarly, if you do not specify `returntype`, the compiler takes the return data type to be `Object`.

NOTE

Because you are dealing with an external procedure that might have been written on a different platform, it is dangerous to make any assumptions about data types or to allow them to default. It is much safer to specify the data type of every parameter and of the return value, if any. This also improves the readability of your code.

Behavior

- **Scope.** An external reference is in scope throughout its class, structure, or module.
- **Lifetime.** An external reference has the same lifetime as the class, structure, or module in which it is declared.
- **Calling an External Procedure.** You call an external procedure the same way you call a [Function](#) or [Sub](#) procedure—by using it in an expression if it returns a value, or by specifying it in a [Call Statement](#) if it does not return a value.

You pass arguments to the external procedure exactly as specified by [parameterlist](#) in the [Declare](#) statement. Do not take into account how the parameters were originally declared in the external file. Similarly, if there is a return value, use it exactly as specified by [returntype](#) in the [Declare](#) statement.

- **Character Sets.** You can specify in [charsetmodifier](#) how Visual Basic should marshal strings when it calls the external procedure. The [Ansi](#) modifier directs Visual Basic to marshal all strings to ANSI values, and the [Unicode](#) modifier directs it to marshal all strings to Unicode values. The [Auto](#) modifier directs Visual Basic to marshal strings according to .NET Framework rules based on the external reference [name](#), or [aliasname](#) if specified. The default value is [Ansi](#).

[charsetmodifier](#) also specifies how Visual Basic should look up the external procedure within its external file. [Ansi](#) and [Unicode](#) both direct Visual Basic to look it up without modifying its name during the search. [Auto](#) directs Visual Basic to determine the base character set of the run-time platform and possibly modify the external procedure name, as follows:

- On an ANSI platform, such as Windows 95, Windows 98, or Windows Millennium Edition, first look up the external procedure with no name modification. If that fails, append "A" to the end of the external procedure name and look it up again.
 - On a Unicode platform, such as Windows NT, Windows 2000, or Windows XP, first look up the external procedure with no name modification. If that fails, append "W" to the end of the external procedure name and look it up again.
- **Mechanism.** Visual Basic uses the .NET Framework *platform invoke* (PInvoke) mechanism to resolve and access external procedures. The [Declare](#) statement and the [DllImportAttribute](#) class both use this mechanism automatically, and you do not need any knowledge of PInvoke. For more information, see [Walkthrough: Calling Windows APIs](#).

IMPORTANT

If the external procedure runs outside the common language runtime (CLR), it is *unmanaged code*. When you call such a procedure, for example a Windows API function or a COM method, you might expose your application to security risks. For more information, see [Secure Coding Guidelines for Unmanaged Code](#).

Example

The following example declares an external reference to a [Function](#) procedure that returns the current user name. It then calls the external procedure [GetUserNameA](#) as part of the [getUser](#) procedure.

```

Declare Function getUserName Lib "advapi32.dll" Alias "GetUserNameA" (
    ByVal lpBuffer As String, ByRef nSize As Integer) As Integer
Sub getUser()
    Dim buffer As String = New String(CChar(" "), 25)
    Dim retVal As Integer = getUserName(buffer, 25)
    Dim userName As String = Strings.Left(buffer, InStr(buffer, Chr(0)) - 1)
    MsgBox(userName)
End Sub

```

Example

The [DllImportAttribute](#) provides an alternative way of using functions in unmanaged code. The following example declares an imported function without using a `Declare` statement.

```

' Add an Imports statement at the top of the class, structure, or
' module that uses the DllImport attribute.
Imports System.Runtime.InteropServices

```

```

<DllImportAttribute("kernel32.dll", EntryPoint:="MoveFileW",
    SetLastError:=True, CharSet:=CharSet.Unicode,
    ExactSpelling:=True,
    CallingConvention:=CallingConvention.StdCall)>
Public Shared Function moveFile(ByVal src As String,
    ByVal dst As String) As Boolean
    ' This function copies a file from the path src to the path dst.
    ' Leave this function empty. The DllImport attribute forces calls
    ' to moveFile to be forwarded to MoveFileW in KERNEL32.DLL.
End Function

```

Delegate Statement

2/28/2019 • 4 minutes to read • [Edit Online](#)

Used to declare a delegate. A delegate is a reference type that refers to a `Shared` method of a type or to an instance method of an object. Any procedure with matching parameter and return types can be used to create an instance of this delegate class. The procedure can then later be invoked by means of the delegate instance.

Syntax

```
[ <attrlist> ] [ accessmodifier ] _  
[ Shadows ] Delegate [ Sub | Function ] name [( Of typeparamlist )] [([ parameterlist ]) ] [ As type ]
```

Parts

TERM	DEFINITION
<code>attrlist</code>	Optional. List of attributes that apply to this delegate. Multiple attributes are separated by commas. You must enclose the Attribute List in angle brackets ("`<`" and "`>`").
<code>accessmodifier</code>	Optional. Specifies what code can access the delegate. Can be one of the following: <ul style="list-style-type: none">- Public. Any code that can access the element that declares the delegate can access it.- Protected. Only code within the delegate's class or a derived class can access it.- Friend. Only code within the same assembly can access the delegate.- Private. Only code within the element that declares the delegate can access it.- Protected Friend Only code within the delegate's class, a derived class, or the same assembly can access the delegate.- Private Protected Only code within the delegate's class or in a derived class in the same assembly can access the delegate.
<code>Shadows</code>	Optional. Indicates that this delegate redeclares and hides an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, except from where the shadowing element is inaccessible. For example, if a <code>Private</code> element shadows a base class element, code that does not have permission to access the <code>Private</code> element accesses the base class element instead.
<code>Sub</code>	Optional, but either <code>Sub</code> or <code>Function</code> must appear. Declares this procedure as a delegate <code>Sub</code> procedure that does not return a value.

TERM	DEFINITION
<code>Function</code>	Optional, but either <code>Sub</code> or <code>Function</code> must appear. Declares this procedure as a delegate <code>Function</code> procedure that returns a value.
<code>name</code>	Required. Name of the delegate type; follows standard variable naming conventions.
<code>typeparamlist</code>	Optional. List of type parameters for this delegate. Multiple type parameters are separated by commas. Optionally, each type parameter can be declared variant by using <code>In</code> and <code>out</code> generic modifiers. You must enclose the Type List in parentheses and introduce it with the <code>of</code> keyword.
<code>parameterlist</code>	Optional. List of parameters that are passed to the procedure when it is called. You must enclose the Parameter List in parentheses.
<code>type</code>	Required if you specify a <code>Function</code> procedure. Data type of the return value.

Remarks

The `Delegate` statement defines the parameter and return types of a delegate class. Any procedure with matching parameters and return types can be used to create an instance of this delegate class. The procedure can then later be invoked by means of the delegate instance, by calling the delegate's `Invoke` method.

Delegates can be declared at the namespace, module, class, or structure level, but not within a procedure.

Each delegate class defines a constructor that is passed the specification of an object method. An argument to a delegate constructor must be a reference to a method, or a lambda expression.

To specify a reference to a method, use the following syntax:

```
AddressOf [ expression ] methodname
```

The compile-time type of the `expression` must be the name of a class or an interface that contains a method of the specified name whose signature matches the signature of the delegate class. The `methodname` can be either a shared method or an instance method. The `methodname` is not optional, even if you create a delegate for the default method of the class.

To specify a lambda expression, use the following syntax:

```
Function ([ parm As type , parm2 As type2 , ...]) expression
```

The signature of the function must match that of the delegate type. For more information about lambda expressions, see [Lambda Expressions](#).

For more information about delegates, see [Delegates](#).

Example

The following example uses the `Delegate` statement to declare a delegate for operating on two numbers and returning a number. The `DelegateTest` method takes an instance of a delegate of this type and uses it to operate on pairs of numbers.

```

Delegate Function MathOperator(
    ByVal x As Double,
    ByVal y As Double
) As Double

Function AddNumbers(
    ByVal x As Double,
    ByVal y As Double
) As Double
    Return x + y
End Function

Function SubtractNumbers(
    ByVal x As Double,
    ByVal y As Double
) As Double
    Return x - y
End Function

Sub DelegateTest(
    ByVal x As Double,
    ByVal op As MathOperator,
    ByVal y As Double
)
    Dim ret As Double
    ret = op.Invoke(x, y) ' Call the method.
    MsgBox(ret)
End Sub

Protected Sub Test()
    DelegateTest(5, AddressOf AddNumbers, 3)
    DelegateTest(9, AddressOf SubtractNumbers, 3)
End Sub

Dim Statement (Visual Basic)

3/5/2019 • 12 minutes to read • [Edit Online](#)

Declares and allocates storage space for one or more variables.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [[ Shared ] [ Shadows ] | [ Static ]] [ ReadOnly ]
Dim [ WithEvents ] variablelist
```

Parts

- `attributelist`

Optional. See [Attribute List](#).

- `accessmodifier`

Optional. Can be one of the following:

- [Public](#)
- [Protected](#)
- [Friend](#)
- [Private](#)
- [Protected Friend](#)
- [Private Protected](#)

See [Access levels in Visual Basic](#).

- `Shared`

Optional. See [Shared](#).

- `Shadows`

Optional. See [Shadows](#).

- `Static`

Optional. See [Static](#).

- `ReadOnly`

Optional. See [ReadOnly](#).

- `WithEvents`

Optional. Specifies that these are object variables that refer to instances of a class that can raise events. See [WithEvents](#).

- `variablelist`

Required. List of variables being declared in this statement.

```
variable [ , variable ... ]
```

Each `variable` has the following syntax and parts:

```
variablename [ ( [ boundslist ] ) ] [ As [ New ] datatype [ With {  
[ .propertynname = propinitializer [ , ... ] ] } ] ] [ = initializer ]
```

PART	DESCRIPTION
<code>variablename</code>	Required. Name of the variable. See Declared Element Names .
<code>boundslist</code>	Optional. List of bounds of each dimension of an array variable.
<code>New</code>	Optional. Creates a new instance of the class when the <code>Dim</code> statement runs.
<code>datatype</code>	Optional. Data type of the variable.
<code>With</code>	Optional. Introduces the object initializer list.
<code>propertynname</code>	Optional. The name of a property in the class you are making an instance of.
<code>propinitializer</code>	Required after <code>propertynname</code> =. The expression that is evaluated and assigned to the property name.
<code>initializer</code>	Optional if <code>New</code> is not specified. Expression that is evaluated and assigned to the variable when it is created.

Remarks

The Visual Basic compiler uses the `Dim` statement to determine the variable's data type and other information, such as what code can access the variable. The following example declares a variable to hold an `Integer` value.

```
Dim numberOfStudents As Integer
```

You can specify any data type or the name of an enumeration, structure, class, or interface.

```
Dim finished As Boolean  
Dim monitorBox As System.Windows.Forms.Form
```

For a reference type, you use the `New` keyword to create a new instance of the class or structure that is specified by the data type. If you use `New`, you do not use an initializer expression. Instead, you supply arguments, if they are required, to the constructor of the class from which you are creating the variable.

```
Dim bottomLabel As New System.Windows.Forms.Label
```

You can declare a variable in a procedure, block, class, structure, or module. You cannot declare a variable in a source file, namespace, or interface. For more information, see [Declaration Contexts and Default Access Levels](#).

A variable that is declared at module level, outside any procedure, is a *member variable* or *field*. Member variables are in scope throughout their class, structure, or module. A variable that is declared at procedure level is a *local variable*. Local variables are in scope only within their procedure or block.

The following access modifiers are used to declare variables outside a procedure: `Public`, `Protected`, `Friend`, `Protected Friend`, and `Private`. For more information, see [Access levels in Visual Basic](#).

The `Dim` keyword is optional and usually omitted if you specify any of the following modifiers: `Public`, `Protected`, `Friend`, `Protected Friend`, `Private`, `Shared`, `Shadows`, `Static`, `ReadOnly`, or `WithEvents`.

```
Public maximumAllowed As Double
Protected Friend currentUserName As String
Private salary As Decimal
Static runningTotal As Integer
```

If `Option Explicit` is on (the default), the compiler requires a declaration for every variable you use. For more information, see [Option Explicit Statement](#).

Specifying an Initial Value

You can assign a value to a variable when it is created. For a value type, you use an *initializer* to supply an expression to be assigned to the variable. The expression must evaluate to a constant that can be calculated at compile time.

```
Dim quantity As Integer = 10
Dim message As String = "Just started"
```

If an initializer is specified and a data type is not specified in an `As` clause, *type inference* is used to infer the data type from the initializer. In the following example, both `num1` and `num2` are strongly typed as integers. In the second declaration, type inference infers the type from the value 3.

```
' Use explicit typing.
Dim num1 As Integer = 3

' Use local type inference.
Dim num2 = 3
```

Type inference applies at the procedure level. It does not apply outside a procedure in a class, structure, module, or interface. For more information about type inference, see [Option Infer Statement](#) and [Local Type Inference](#).

For information about what happens when a data type or initializer is not specified, see [Default Data Types and Values](#) later in this topic.

You can use an *object initializer* to declare instances of named and anonymous types. The following code creates an instance of a `Student` class and uses an object initializer to initialize properties.

```
Dim student1 As New Student With {.First = "Michael",
                                  .Last = "Tucker"}
```

For more information about object initializers, see [How to: Declare an Object by Using an Object](#)

Declaring Multiple Variables

You can declare several variables in one declaration statement, specifying the variable name for each one, and following each array name with parentheses. Multiple variables are separated by commas.

```
Dim lastTime, nextTime, allTimes() As Date
```

If you declare more than one variable with one `As` clause, you cannot supply an initializer for that group of variables.

You can specify different data types for different variables by using a separate `As` clause for each variable you declare. Each variable takes the data type specified in the first `As` clause encountered after its `variablename` part.

```
Dim a, b, c As Single, x, y As Double, i As Integer  
' a, b, and c are all Single; x and y are both Double
```

Arrays

You can declare a variable to hold an *array*, which can hold multiple values. To specify that a variable holds an array, follow its `variablename` immediately with parentheses. For more information about arrays, see [Arrays](#).

You can specify the lower and upper bound of each dimension of an array. To do this, include a `boundslist` inside the parentheses. For each dimension, the `boundslist` specifies the upper bound and optionally the lower bound. The lower bound is always zero, whether you specify it or not. Each index can vary from zero through its upper bound value.

The following two statements are equivalent. Each statement declares an array of 21 `Integer` elements. When you access the array, the index can vary from 0 through 20.

```
Dim totals(20) As Integer  
Dim totals(0 To 20) As Integer
```

The following statement declares a two-dimensional array of type `Double`. The array has 4 rows (3 + 1) of 6 columns (5 + 1) each. Note that an upper bound represents the highest possible value for the index, not the length of the dimension. The length of the dimension is the upper bound plus one.

```
Dim matrix2(3, 5) As Double
```

An array can have from 1 to 32 dimensions.

You can leave all the bounds blank in an array declaration. If you do this, the array has the number of dimensions you specify, but it is uninitialized. It has a value of `Nothing` until you initialize at least some of its elements. The `Dim` statement must specify bounds either for all dimensions or for no dimensions.

```
' Declare an array with blank array bounds.  
Dim messages() As String  
' Initialize the array.  
ReDim messages(4)
```

If the array has more than one dimension, you must include commas between the parentheses to indicate the number of dimensions.

```
Dim oneDimension(), twoDimensions(,), threeDimensions(,,) As Byte
```

You can declare a *zero-length array* by declaring one of the array's dimensions to be -1. A variable that holds a zero-length array does not have the value `Nothing`. Zero-length arrays are required by certain common language runtime functions. If you try to access such an array, a runtime exception occurs. For more information, see [Arrays](#).

You can initialize the values of an array by using an array literal. To do this, surround the initialization values with braces (`{}`).

```
Dim longArray() As Long = {0, 1, 2, 3}
```

For multidimensional arrays, the initialization for each separate dimension is enclosed in braces in the outer dimension. The elements are specified in row-major order.

```
Dim twoDimensions(,) As Integer = {{0, 1, 2}, {10, 11, 12}}
```

For more information about array literals, see [Arrays](#).

Default Data Types and Values

The following table describes the results of various combinations of specifying the data type and initializer in a `Dim` statement.

DATA TYPE SPECIFIED?	INITIALIZER SPECIFIED?	EXAMPLE	RESULT
No	No	<code>Dim qty</code>	If <code>Option Strict</code> is off (the default), the variable is set to <code>Nothing</code> . If <code>Option Strict</code> is on, a compile-time error occurs.
No	Yes	<code>Dim qty = 5</code>	If <code>Option Infer</code> is on (the default), the variable takes the data type of the initializer. See Local Type Inference . If <code>Option Infer</code> is off and <code>Option Strict</code> is off, the variable takes the data type of <code>Object</code> . If <code>Option Infer</code> is off and <code>Option Strict</code> is on, a compile-time error occurs.

DATA TYPE SPECIFIED?	INITIALIZER SPECIFIED?	EXAMPLE	RESULT
Yes	No	Dim qty As Integer	The variable is initialized to the default value for the data type. See the table later in this section.
Yes	Yes	Dim qty As Integer = 5	If the data type of the initializer is not convertible to the specified data type, a compile-time error occurs.

If you specify a data type but do not specify an initializer, Visual Basic initializes the variable to the default value for its data type. The following table shows the default initialization values.

DATA TYPE	DEFAULT VALUE
All numeric types (including <code>Byte</code> and <code>SByte</code>)	0
<code>Char</code>	Binary 0
All reference types (including <code>Object</code> , <code>String</code> , and all arrays)	<code>Nothing</code>
<code>Boolean</code>	<code>False</code>
<code>Date</code>	12:00 AM of January 1 of the year 1 (01/01/0001 12:00:00 AM)

Each element of a structure is initialized as if it were a separate variable. If you declare the length of an array but do not initialize its elements, each element is initialized as if it were a separate variable.

Static Local Variable Lifetime

A `Static` local variable has a longer lifetime than that of the procedure in which it is declared. The boundaries of the variable's lifetime depend on where the procedure is declared and whether it is `Shared`.

PROCEDURE DECLARATION	VARIABLE INITIALIZED	VARIABLE STOPS EXISTING
In a module	The first time the procedure is called	When your program stops execution
In a class or structure, procedure is <code>Shared</code>	The first time the procedure is called either on a specific instance or on the class or structure itself	When your program stops execution
In a class or structure, procedure isn't <code>Shared</code>	The first time the procedure is called on a specific instance	When the instance is released for garbage collection (GC)

Attributes and Modifiers

You can apply attributes only to member variables, not to local variables. An attribute contributes information to the assembly's metadata, which is not meaningful for temporary storage such as local

variables.

At module level, you cannot use the `Static` modifier to declare member variables. At procedure level, you cannot use `Shared`, `Shadows`, `ReadOnly`, `WithEvents`, or any access modifiers to declare local variables.

You can specify what code can access a variable by supplying an `accessmodifier`. Class and module member variables (outside any procedure) default to private access, and structure member variables default to public access. You can adjust their access levels with the access modifiers. You cannot use access modifiers on local variables (inside a procedure).

You can specify `WithEvents` only on member variables, not on local variables inside a procedure. If you specify `WithEvents`, the data type of the variable must be a specific class type, not `Object`. You cannot declare an array with `WithEvents`. For more information about events, see [Events](#).

NOTE

Code outside a class, structure, or module must qualify a member variable's name with the name of that class, structure, or module. Code outside a procedure or block cannot refer to any local variables within that procedure or block.

Releasing Managed Resources

The .NET Framework garbage collector disposes of managed resources without any extra coding on your part. However, you can force the disposal of a managed resource instead of waiting for the garbage collector.

If a class holds onto a particularly valuable and scarce resource (such as a database connection or file handle), you might not want to wait until the next garbage collection to clean up a class instance that's no longer in use. A class may implement the [IDisposable](#) interface to provide a way to release resources before a garbage collection. A class that implements that interface exposes a `Dispose` method that can be called to force valuable resources to be released immediately.

The `Using` statement automates the process of acquiring a resource, executing a set of statements, and then disposing of the resource. However, the resource must implement the [IDisposable](#) interface. For more information, see [Using Statement](#).

Example

The following example declares variables by using the `Dim` statement with various options.

```
' Declare and initialize a Long variable.  
Dim startingAmount As Long = 500  
  
' Declare a variable that refers to a Button object,  
' create a Button object, and assign the Button object  
' to the variable.  
Dim switchButton As New System.Windows.Forms.Button  
  
' Declare a local variable that always retains its value,  
' even after its procedure returns to the calling code.  
Static totalSales As Double  
  
' Declare a variable that refers to an array.  
Dim highTemperature(31) As Integer  
  
' Declare and initialize an array variable that  
' holds four Boolean check values.  
Dim checkValues() As Boolean = {False, False, True, False}
```

Example

The following example lists the prime numbers between 1 and 30. The scope of local variables is described in code comments.

```

Public Sub ListPrimes()
    ' The sb variable can be accessed only
    ' within the ListPrimes procedure.
    Dim sb As New System.Text.StringBuilder()

    ' The number variable can be accessed only
    ' within the For...Next block. A different
    ' variable with the same name could be declared
    ' outside of the For...Next block.
    For number As Integer = 1 To 30
        If CheckIfPrime(number) = True Then
            sb.Append(number.ToString & " ")
        End If
    Next

    Debug.WriteLine(sb.ToString)
    ' Output: 2 3 5 7 11 13 17 19 23 29
End Sub

Private Function CheckIfPrime(ByVal number As Integer) As Boolean
    If number < 2 Then
        Return False
    Else
        ' The root and highCheck variables can be accessed
        ' only within the Else block. Different variables
        ' with the same names could be declared outside of
        ' the Else block.
        Dim root As Double = Math.Sqrt(number)
        Dim highCheck As Integer = Convert.ToInt32(Math.Truncate(root))

        ' The div variable can be accessed only within
        ' the For...Next block.
        For div As Integer = 2 To highCheck
            If number Mod div = 0 Then
                Return False
            End If
        Next

        Return True
    End If
End Function

```

Example

In the following example, the `speedValue` variable is declared at the class level. The `Private` keyword is used to declare the variable. The variable can be accessed by any procedure in the `Car` class.

```

' Create a new instance of a Car.
Dim theCar As New Car()
theCar.Accelerate(30)
theCar.Accelerate(20)
theCar.Accelerate(-5)

Debug.WriteLine(theCar.Speed.ToString)
' Output: 45

```

```
Public Class Car
    ' The speedValue variable can be accessed by
    ' any procedure in the Car class.
    Private speedValue As Integer = 0

    Public ReadOnly Property Speed() As Integer
        Get
            Return speedValue
        End Get
    End Property

    Public Sub Accelerate(ByVal speedIncrease As Integer)
        speedValue += speedIncrease
    End Sub
End Class
```

Do...Loop Statement (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Repeats a block of statements while a `Boolean` condition is `True` or until the condition becomes `True`.

Syntax

```
Do { While | Until } condition
    [ statements ]
    [ Continue Do ]
    [ statements ]
    [ Exit Do ]
    [ statements ]
Loop
-or-
Do
    [ statements ]
    [ Continue Do ]
    [ statements ]
    [ Exit Do ]
    [ statements ]
Loop { While | Until } condition
```

Parts

TERM	DEFINITION
<code>Do</code>	Required. Starts the definition of the <code>Do</code> loop.
<code>While</code>	Required unless <code>Until</code> is used. Repeat the loop until <code>condition</code> is <code>False</code> .
<code>Until</code>	Required unless <code>While</code> is used. Repeat the loop until <code>condition</code> is <code>True</code> .
<code>condition</code>	Optional. <code>Boolean</code> expression. If <code>condition</code> is <code>Nothing</code> , Visual Basic treats it as <code>False</code> .
<code>statements</code>	Optional. One or more statements that are repeated while, or until, <code>condition</code> is <code>True</code> .
<code>Continue Do</code>	Optional. Transfers control to the next iteration of the <code>Do</code> loop.
<code>Exit Do</code>	Optional. Transfers control out of the <code>Do</code> loop.
<code>Loop</code>	Required. Terminates the definition of the <code>Do</code> loop.

Remarks

Use a `Do...Loop` structure when you want to repeat a set of statements an indefinite number of times, until a

condition is satisfied. If you want to repeat the statements a set number of times, the [For...Next Statement](#) is usually a better choice.

You can use either `While` or `Until` to specify `condition`, but not both.

You can test `condition` only one time, at either the start or the end of the loop. If you test `condition` at the start of the loop (in the `Do` statement), the loop might not run even one time. If you test at the end of the loop (in the `Loop` statement), the loop always runs at least one time.

The condition usually results from a comparison of two values, but it can be any expression that evaluates to a [Boolean Data Type](#) value (`True` or `False`). This includes values of other data types, such as numeric types, that have been converted to `Boolean`.

You can nest `Do` loops by putting one loop within another. You can also nest different kinds of control structures within each other. For more information, see [Nested Control Structures](#).

NOTE

The `Do...Loop` structure gives you more flexibility than the [While...End While Statement](#) because it enables you to decide whether to end the loop when `condition` stops being `True` or when it first becomes `True`. It also enables you to test `condition` at either the start or the end of the loop.

Exit Do

The [Exit Do](#) statement can provide an alternative way to exit a `Do...Loop`. `Exit Do` transfers control immediately to the statement that follows the `Loop` statement.

`Exit Do` is often used after some condition is evaluated, for example in an `If...Then...Else` structure. You might want to exit a loop if you detect a condition that makes it unnecessary or impossible to continue iterating, such as an erroneous value or a termination request. One use of `Exit Do` is to test for a condition that could cause an *endless loop*, which is a loop that could run a large or even infinite number of times. You can use `Exit Do` to escape the loop.

You can include any number of `Exit Do` statements anywhere in a `Do...Loop`.

When used within nested `Do` loops, `Exit Do` transfers control out of the innermost loop and into the next higher level of nesting.

Example

In the following example, the statements in the loop continue to run until the `index` variable is greater than 10. The `Until` clause is at the end of the loop.

```
Dim index As Integer = 0
Do
    Debug.WriteLine(index.ToString & " ")
    index += 1
Loop Until index > 10

Debug.WriteLine("")
' Output: 0 1 2 3 4 5 6 7 8 9 10
```

Example

The following example uses a `While` clause instead of an `Until` clause, and `condition` is tested at the start of

the loop instead of at the end.

```
Dim index As Integer = 0
Do While index <= 10
    Debug.WriteLine(index.ToString & " ")
    index += 1
Loop

Debug.WriteLine("")
' Output: 0 1 2 3 4 5 6 7 8 9 10
```

Example

In the following example, `condition` stops the loop when the `index` variable is greater than 100. The `If` statement in the loop, however, causes the `Exit Do` statement to stop the loop when the `index` variable is greater than 10.

```
Dim index As Integer = 0
Do While index <= 100
    If index > 10 Then
        Exit Do
    End If

    Debug.WriteLine(index.ToString & " ")
    index += 1
Loop

Debug.WriteLine("")
' Output: 0 1 2 3 4 5 6 7 8 9 10
```

Example

The following example reads all lines in a text file. The `OpenText` method opens the file and returns a `StreamReader` that reads the characters. In the `Do...Loop` condition, the `Peek` method of the `StreamReader` determines whether there are any additional characters.

```
Private Sub ShowText(ByVal textFilePath As String)
    If System.IO.File.Exists(textFilePath) = False Then
        Debug.WriteLine("File Not Found: " & textFilePath)
    Else
        Dim sr As System.IO.StreamReader = System.IO.File.OpenText(textFilePath)

        Do While sr.Peek() >= 0
            Debug.WriteLine(sr.ReadLine())
        Loop

        sr.Close()
    End If
End Sub
```

Else Statement (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Introduces a group of statements to be run or compiled if no other conditional group of statements has been run or compiled.

Remarks

The `Else` keyword can be used in these contexts:

[If...Then...Else Statement](#)

[Select...Case Statement](#)

[#If...Then...#Else Directive](#)

See also

- [Keywords](#)

End Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Terminates execution immediately.

Syntax

```
End
```

Remarks

You can place the `End` statement anywhere in a procedure to force the entire application to stop running. `End` closes any files opened with an `Open` statement and clears all the application's variables. The application closes as soon as there are no other programs holding references to its objects and none of its code is running.

NOTE

The `End` statement stops code execution abruptly, and does not invoke the `Dispose` or `Finalize` method, or any other Visual Basic code. Object references held by other programs are invalidated. If an `End` statement is encountered within a `Try` or `Catch` block, control does not pass to the corresponding `Finally` block.

The `Stop` statement suspends execution, but unlike `End`, it does not close any files or clear any variables, unless it is encountered in a compiled executable (.exe) file.

Because `End` terminates your application without attending to any resources that might be open, you should try to close down cleanly before using it. For example, if your application has any forms open, you should close them before control reaches the `End` statement.

You should use `End` sparingly, and only when you need to stop immediately. The normal ways to terminate a procedure ([Return Statement](#) and [Exit Statement](#)) not only close down the procedure cleanly but also give the calling code the opportunity to close down cleanly. A console application, for example, can simply `Return` from the `Main` procedure.

IMPORTANT

The `End` statement calls the `Exit` method of the `Environment` class in the `System` namespace. `Exit` requires that you have `UnmanagedCode` permission. If you do not, a `SecurityException` error occurs.

When followed by an additional keyword, `End <keyword> Statement` delineates the end of the definition of the appropriate procedure or block. For example, `End Function` terminates the definition of a `Function` procedure.

Example

The following example uses the `End` statement to terminate code execution if the user requests it.

```
Sub Form_Load()
    Dim answer As MsgBoxResult
    answer = MsgBox("Do you want to quit now?", MsgBoxStyle.YesNo)
    If answer = MsgBoxResult.Yes Then
        MsgBox("Terminating program")
    End
End If
End Sub
```

End <keyword> Statement (Visual Basic)

1/30/2019 • 2 minutes to read • [Edit Online](#)

When followed by an additional keyword, terminates the definition of the statement block introduced by that keyword.

Syntax

```
End AddHandler  
End Class  
End Enum  
End Event  
End Function  
End Get  
End If  
End Interface  
End Module  
End Namespace

End RaiseEvent  
End RemoveHandler  
End Select  
End Set  
End Structure  
End Sub  
End SyncLock  
End Try  
End While  
End With
```

Parts

PART	DESCRIPTION
<code>End</code>	Required. Terminates the definition of the programming element.
<code>AddHandler</code>	Required to terminate an <code>AddHandler</code> accessor begun by a matching <code>AddHandler</code> statement in a custom Event Statement .
<code>Class</code>	Required to terminate a class definition begun by a matching Class Statement .
<code>Enum</code>	Required to terminate an enumeration definition begun by a matching Enum Statement .
<code>Event</code>	Required to terminate a <code>Custom</code> event definition begun by a matching Event Statement .

PART	DESCRIPTION
Function	Required to terminate a <code>Function</code> procedure definition begun by a matching Function Statement . If execution encounters an <code>End Function</code> statement, control returns to the calling code.
Get	Required to terminate a <code>Property</code> procedure definition begun by a matching Get Statement . If execution encounters an <code>End Get</code> statement, control returns to the statement requesting the property's value.
If	Required to terminate an <code>If ... Then ... Else</code> block definition begun by a matching <code>If</code> statement. See If...Then...Else Statement .
Interface	Required to terminate an interface definition begun by a matching Interface Statement .
Module	Required to terminate a module definition begun by a matching Module Statement .
Namespace	Required to terminate a namespace definition begun by a matching Namespace Statement .
Operator	Required to terminate an operator definition begun by a matching Operator Statement .
Property	Required to terminate a property definition begun by a matching Property Statement .
RaiseEvent	Required to terminate a <code>RaiseEvent</code> accessor begun by a matching <code>RaiseEvent</code> statement in a custom Event Statement .
RemoveHandler	Required to terminate a <code>RemoveHandler</code> accessor begun by a matching <code>RemoveHandler</code> statement in a custom Event Statement .
Select	Required to terminate a <code>Select ... Case</code> block definition begun by a matching <code>Select</code> statement. See Select...Case Statement .
Set	Required to terminate a <code>Property</code> procedure definition begun by a matching Set Statement . If execution encounters an <code>End Set</code> statement, control returns to the statement setting the property's value.
Structure	Required to terminate a structure definition begun by a matching Structure Statement .
Sub	Required to terminate a <code>Sub</code> procedure definition begun by a matching Sub Statement . If execution encounters an <code>End Sub</code> statement, control returns to the calling code.

PART	DESCRIPTION
SyncLock	Required to terminate a <code>SyncLock</code> block definition begun by a matching <code>SyncLock</code> statement. See SyncLock Statement .
Try	Required to terminate a <code>Try ... Catch ... Finally</code> block definition begun by a matching <code>Try</code> statement. See Try...Catch...Finally Statement .
While	Required to terminate a <code>While</code> loop definition begun by a matching <code>While</code> statement. See While...End While Statement .
With	Required to terminate a <code>With</code> block definition begun by a matching <code>With</code> statement. See With...End With Statement .

Directives

When preceded by a number sign (#), the `End` keyword terminates a preprocessing block introduced by the corresponding directive.

```
#End ExternalSource
#End If
#End Region
```

PART	DESCRIPTION
#End	Required. Terminates the definition of the preprocessing block.
ExternalSource	Required to terminate an external source block begun by a matching #ExternalSource Directive .
If	Required to terminate a conditional compilation block begun by a matching <code>#If</code> directive. See #If...Then...#Else Directives .
Region	Required to terminate a source region block begun by a matching #Region Directive .

Remarks

The [End Statement](#), without an additional keyword, terminates execution immediately.

Smart Device Developer Notes

The `End` statement, without an additional keyword, is not supported.

Enum Statement (Visual Basic)

2/28/2019 • 7 minutes to read • [Edit Online](#)

Declares an enumeration and defines the values of its members.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ Shadows ]
Enum enumerationname [ As datatype ]
    memberlist
End Enum
```

Parts

- **attributelist**

Optional. List of attributes that apply to this enumeration. You must enclose the [attribute list](#) in angle brackets ("<" and ">").

The [FlagsAttribute](#) attribute indicates that the value of an instance of the enumeration can include multiple enumeration members, and that each member represents a bit field in the enumeration value.

- **accessmodifier**

Optional. Specifies what code can access this enumeration. Can be one of the following:

- [Public](#)
- [Protected](#)
- [Friend](#)
- [Private](#)
- [Protected Friend](#)
- [Private Protected](#)

- **Shadows**

Optional. Specifies that this enumeration redeclares and hides an identically named programming element, or set of overloaded elements, in a base class. You can specify [Shadows](#) only on the enumeration itself, not on any of its members.

- **enumerationname**

Required. Name of the enumeration. For information on valid names, see [Declared Element Names](#).

- **datatype**

Optional. Data type of the enumeration and all its members.

- **memberlist**

Required. List of member constants being declared in this statement. Multiple members appear on individual source code lines.

Each `member` has the following syntax and parts: [`<attribute list>` `member name` [= `initializer`]]

PART	DESCRIPTION
<code>membername</code>	Required. Name of this member.
<code>initializer</code>	Optional. Expression that is evaluated at compile time and assigned to this member.

- `End` `Enum`

Terminates the `Enum` block.

Remarks

If you have a set of unchanging values that are logically related to each other, you can define them together in an enumeration. This provides meaningful names for the enumeration and its members, which are easier to remember than their values. You can then use the enumeration members in many places in your code.

The benefits of using enumerations include the following:

- Reduces errors caused by transposing or mistyping numbers.
- Makes it easy to change values in the future.
- Makes code easier to read, which means it is less likely that errors will be introduced.
- Ensures forward compatibility. If you use enumerations, your code is less likely to fail if in the future someone changes the values corresponding to the member names.

An enumeration has a name, an underlying data type, and a set of members. Each member represents a constant.

An enumeration declared at class, structure, module, or interface level, outside any procedure, is a *member enumeration*. It is a member of the class, structure, module, or interface that declares it.

Member enumerations can be accessed from anywhere within their class, structure, module, or interface. Code outside a class, structure, or module must qualify a member enumeration's name with the name of that class, structure, or module. You can avoid the need to use fully qualified names by adding an [Imports](#) statement to the source file.

An enumeration declared at namespace level, outside any class, structure, module, or interface, is a member of the namespace in which it appears.

The *declaration context* for an enumeration must be a source file, namespace, class, structure, module, or interface, and cannot be a procedure. For more information, see [Declaration Contexts and Default Access Levels](#).

You can apply attributes to an enumeration as a whole, but not to its members individually. An attribute contributes information to the assembly's metadata.

Data Type

The `Enum` statement can declare the data type of an enumeration. Each member takes the enumeration's data type. You can specify `Byte`, `Integer`, `Long`, `SByte`, `Short`, `UInteger`, `ULong`, or `UShort`.

If you do not specify `datatype` for the enumeration, each member takes the data type of its `initializer`. If you specify both `datatype` and `initializer`, the data type of `initializer` must be convertible to `datatype`.

If neither `datatype` nor `initializer` is present, the data type defaults to `Integer`.

Initializing Members

The `Enum` statement can initialize the contents of selected members in `memberlist`. You use `initializer` to supply an expression to be assigned to the member.

If you do not specify `initializer` for a member, Visual Basic initializes it either to zero (if it is the first `member` in `memberlist`), or to a value greater by one than that of the immediately preceding `member`.

The expression supplied in each `initializer` can be any combination of literals, other constants that are already defined, and enumeration members that are already defined, including a previous member of this enumeration. You can use arithmetic and logical operators to combine such elements.

You cannot use variables or functions in `initializer`. However, you can use conversion keywords such as `CByte` and `CShort`. You can also use `AscW` if you call it with a constant `String` or `Char` argument, since that can be evaluated at compile time.

Enumerations cannot have floating-point values. If a member is assigned a floating-point value and `Option Strict` is set to on, a compiler error occurs. If `Option Strict` is off, the value is automatically converted to the `Enum` type.

If the value of a member exceeds the allowable range for the underlying data type, or if you initialize any member to the maximum value allowed by the underlying data type, the compiler reports an error.

Modifiers

Class, structure, module, and interface member enumerations default to public access. You can adjust their access levels with the access modifiers. Namespace member enumerations default to friend access. You can adjust their access levels to public, but not to private or protected. For more information, see [Access levels in Visual Basic](#).

All enumeration members have public access, and you cannot use any access modifiers on them. However, if the enumeration itself has a more restricted access level, the specified enumeration access level takes precedence.

By default, all enumerations are types and their fields are constants. Therefore the `Shared`, `Static`, and `ReadOnly` keywords cannot be used when declaring an enumeration or its members.

Assigning Multiple Values

Enumerations typically represent mutually exclusive values. By including the `FlagsAttribute` attribute in the `Enum` declaration, you can instead assign multiple values to an instance of the enumeration. The `FlagsAttribute` attribute specifies that the enumeration be treated as a bit field, that is, a set of flags. These are called *bitwise* enumerations.

When you declare an enumeration by using the `FlagsAttribute` attribute, we recommend that you use powers of 2, that is, 1, 2, 4, 8, 16, and so on, for the values. We also recommend that "None" be the name of a member whose value is 0. For additional guidelines, see [FlagsAttribute](#) and [Enum](#).

Example

The following example shows how to use the `Enum` statement. Note that the member is referred to as `EggSizeEnum.Medium`, and not as `Medium`.

```

Public Class Egg
    Enum EggSizeEnum
        Jumbo
        ExtraLarge
        Large
        Medium
        Small
    End Enum

    Public Sub Poach()
        Dim size As EggSizeEnum

        size = EggSizeEnum.Medium
        ' Continue processing...
    End Sub
End Class

```

Example

The method in the following example is outside the `Egg` class. Therefore, `EggSizeEnum` is fully qualified as `Egg.EggSizeEnum`.

```

Public Sub Scramble(ByVal size As Egg.EggSizeEnum)
    ' Process for the three largest sizes.
    ' Throw an exception for any other size.
    Select Case size
        Case Egg.EggSizeEnum.Jumbo
            ' Process.
        Case Egg.EggSizeEnum.ExtraLarge
            ' Process.
        Case Egg.EggSizeEnum.Large
            ' Process.
        Case Else
            Throw New ApplicationException("size is invalid: " & size.ToString)
    End Select
End Sub

```

Example

The following example uses the `Enum` statement to define a related set of named constant values. In this case, the values are colors you might choose to design data entry forms for a database.

```

Public Enum InterfaceColors
    MistyRose = &HE1E4FF&
    SlateGray = &H908070&
    DodgerBlue = &HFF901E&
    DeepSkyBlue = &HFFBF00&
    SpringGreen = &H7FFF00&
    ForestGreen = &H228B22&
    Goldenrod = &H20A5DA&
    Firebrick = &H2222B2&
End Enum

```

Example

The following example shows values that include both positive and negative numbers.

```
Enum SecurityLevel
    IllegalEntry = -1
    MinimumSecurity = 0
    MaximumSecurity = 1
End Enum
```

Example

In the following example, an `As` clause is used to specify the `datatype` of an enumeration.

```
Public Enum MyEnum As Byte
    Zero
    One
    Two
End Enum
```

Example

The following example shows how to use a bitwise enumeration. Multiple values can be assigned to an instance of a bitwise enumeration. The `Enum` declaration includes the `FlagsAttribute` attribute, which indicates that the enumeration can be treated as a set of flags.

```
' Apply the Flags attribute, which allows an instance
' of the enumeration to have multiple values.
<Flags()> Public Enum FilePermissions As Integer
    None = 0
    Create = 1
    Read = 2
    Update = 4
    Delete = 8
End Enum

Public Sub ShowBitwiseEnum()

    ' Declare the non-exclusive enumeration object and
    ' set it to multiple values.
    Dim perm As FilePermissions
    perm = FilePermissions.Read Or FilePermissions.Update

    ' Show the values in the enumeration object.
    Console.WriteLine(perm.ToString)
    ' Output: Read, Update

    ' Show the total integer value of all values
    ' in the enumeration object.
    Console.WriteLine(CInt(perm))
    ' Output: 6

    ' Show whether the enumeration object contains
    ' the specified flag.
    Console.WriteLine(perm.HasFlag(FilePermissions.Update))
    ' Output: True
End Sub
```

Example

The following example iterates through an enumeration. It uses the `GetNames` method to retrieve an array of member names from the enumeration, and `GetValues` to retrieve an array of member values.

```
Enum EggSizeEnum
    Jumbo
    ExtraLarge
    Large
    Medium
    Small
End Enum

Public Sub Iterate()
    Dim names = [Enum].GetNames(GetType(EggSizeEnum))
    For Each name In names
        Console.WriteLine(name & " ")
    Next
    Console.WriteLine()
    ' Output: Jumbo ExtraLarge Large Medium Small

    Dim values = [Enum].GetValues(GetType(EggSizeEnum))
    For Each value In values
        Console.WriteLine(value & " ")
    Next
    Console.WriteLine()
    ' Output: 0 1 2 3 4
End Sub
```

Erase Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Used to release array variables and deallocate the memory used for their elements.

Syntax

```
Erase arraylist
```

Parts

arraylist

Required. List of array variables to be erased. Multiple variables are separated by commas.

Remarks

The `Erase` statement can appear only at procedure level. This means you can release arrays inside a procedure but not at class or module level.

The `Erase` statement is equivalent to assigning `Nothing` to each array variable.

Example

The following example uses the `Erase` statement to clear two arrays and free their memory (1000 and 100 storage elements, respectively). The `ReDim` statement then assigns a new array instance to the three-dimensional array.

```
Dim threeDimArray(9, 9, 9), twoDimArray(9, 9) As Integer
Erase threeDimArray, twoDimArray
ReDim threeDimArray(4, 4, 9)
```

Error Statement

1/23/2019 • 2 minutes to read • [Edit Online](#)

Simulates the occurrence of an error.

Syntax

```
Error errornumber
```

Parts

`errornumber`

Required. Can be any valid error number.

Remarks

The `Error` statement is supported for backward compatibility. In new code, especially when creating objects, use the `Err` object's `Raise` method to generate run-time errors.

If `errornumber` is defined, the `Error` statement calls the error handler after the properties of the `Err` object are assigned the following default values:

PROPERTY	VALUE
<code>Number</code>	Value specified as argument to <code>Error</code> statement. Can be any valid error number.
<code>Source</code>	Name of the current Visual Basic project.
<code>Description</code>	String expression corresponding to the return value of the <code>Error</code> function for the specified <code>Number</code> , if this string exists. If the string does not exist, <code>Description</code> contains a zero-length string ("").
<code>HelpFile</code>	The fully qualified drive, path, and file name of the appropriate Visual Basic Help file.
<code>HelpContext</code>	The appropriate Visual Basic Help file context ID for the error corresponding to the <code>Number</code> property.
<code>LastDLLError</code>	Zero.

If no error handler exists, or if none is enabled, an error message is created and displayed from the `Err` object properties.

NOTE

Some Visual Basic host applications cannot create objects. See your host application's documentation to determine whether it can create classes and objects.

Example

This example uses the `Error` statement to generate error number 11.

```
On Error Resume Next    ' Defer error handling.  
Error 11    ' Simulate the "Division by zero" error.
```

Event Statement

2/28/2019 • 6 minutes to read • [Edit Online](#)

Declares a user-defined event.

Syntax

```
[ <attrlist> ] [ accessmodifier ] _
[ Shared ] [ Shadows ] Event eventname[(parameterlist)] _
[ Implements implementslist ]
' -or-
[ <attrlist> ] [ accessmodifier ] _
[ Shared ] [ Shadows ] Event eventname As delegatename _
[ Implements implementslist ]
' -or-
[ <attrlist> ] [ accessmodifier ] _
[ Shared ] [ Shadows ] Custom Event eventname As delegatename _
[ Implements implementslist ]
    [ <attrlist> ] AddHandler(ByName value As delegatename)
        [ statements ]
    End AddHandler
    [ <attrlist> ] RemoveHandler(ByName value As delegatename)
        [ statements ]
    End RemoveHandler
    [ <attrlist> ] RaiseEvent(delegatesignature)
        [ statements ]
    End RaiseEvent
End Event
```

Parts

PART	DESCRIPTION
<code>attrlist</code>	Optional. List of attributes that apply to this event. Multiple attributes are separated by commas. You must enclose the Attribute List in angle brackets ("<" and ">").
<code>accessmodifier</code>	Optional. Specifies what code can access the event. Can be one of the following: <ul style="list-style-type: none">- Public—any code that can access the element that declares it can access it.- Protected—only code within its class or a derived class can access it.- Friend—only code in the same assembly can access it.- Private—only code in the element that declares it can access it.- Protected Friend—only code in the event's class, a derived class, or the same assembly can access it.- Private Protected—only code in the event's class or a derived class in the same assembly can access it.
<code>Shared</code>	Optional. Specifies that this event is not associated with a specific instance of a class or structure.

PART	DESCRIPTION
<code>Shadows</code>	<p>Optional. Indicates that this event redeclares and hides an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind.</p> <p>A shadowed element is unavailable from within the derived class that shadows it, except from where the shadowing element is inaccessible. For example, if a <code>Private</code> element shadows a base-class element, code that does not have permission to access the <code>Private</code> element accesses the base-class element instead.</p>
<code>eventname</code>	Required. Name of the event; follows standard variable naming conventions.
<code>parameterlist</code>	Optional. List of local variables that represent the parameters of this event. You must enclose the Parameter List in parentheses.
<code>Implements</code>	Optional. Indicates that this event implements an event of an interface.
<code>implementslist</code>	<p>Required if <code>Implements</code> is supplied. List of <code>Sub</code> procedures being implemented. Multiple procedures are separated by commas:</p> <p><i>implementedprocedure</i> [, <i>implementedprocedure</i> ...]</p> <p>Each <code>implementedprocedure</code> has the following syntax and parts:</p> <p style="text-align: center;"><code>interface</code> . <code>definedname</code></p> <ul style="list-style-type: none"> - <code>interface</code> - Required. Name of an interface that this procedure's containing class or structure is implementing. - <code>Definedname</code> - Required. Name by which the procedure is defined in <code>interface</code>. This does not have to be the same as <code>name</code>, the name that this procedure is using to implement the defined procedure.
<code>Custom</code>	Required. Events declared as <code>Custom</code> must define custom <code>AddHandler</code> , <code>RemoveHandler</code> , and <code>RaiseEvent</code> accessors.
<code>delegatename</code>	Optional. The name of a delegate that specifies the event-handler signature.
<code>AddHandler</code>	Required. Declares an <code>AddHandler</code> accessor, which specifies the statements to execute when an event handler is added, either explicitly by using the <code>AddHandler</code> statement or implicitly by using the <code>Handles</code> clause.
<code>End AddHandler</code>	Required. Terminates the <code>AddHandler</code> block.
<code>value</code>	Required. Parameter name.

PART	DESCRIPTION
<code>RemoveHandler</code>	Required. Declares a <code>RemoveHandler</code> accessor, which specifies the statements to execute when an event handler is removed using the <code>RemoveHandler</code> statement.
<code>End RemoveHandler</code>	Required. Terminates the <code>RemoveHandler</code> block.
<code>RaiseEvent</code>	Required. Declares a <code>RaiseEvent</code> accessor, which specifies the statements to execute when the event is raised using the <code>RaiseEvent</code> statement. Typically, this invokes a list of delegates maintained by the <code>AddHandler</code> and <code>RemoveHandler</code> accessors.
<code>End RaiseEvent</code>	Required. Terminates the <code>RaiseEvent</code> block.
<code>delegatesignature</code>	Required. List of parameters that matches the parameters required by the <code>delegatename</code> delegate. You must enclose the Parameter List in parentheses.
<code>statements</code>	Optional. Statements that contain the bodies of the <code>AddHandler</code> , <code>RemoveHandler</code> , and <code>RaiseEvent</code> methods.
<code>End Event</code>	Required. Terminates the <code>Event</code> block.

Remarks

Once the event has been declared, use the `RaiseEvent` statement to raise the event. A typical event might be declared and raised as shown in the following fragments:

```
Public Class EventSource
    ' Declare an event.
    Public Event LogonCompleted(ByVal UserName As String)
    Sub CauseEvent()
        ' Raise an event on successful logon.
        RaiseEvent LogonCompleted("AustinSteele")
    End Sub
End Class
```

NOTE

You can declare event arguments just as you do arguments of procedures, with the following exceptions: events cannot have named arguments, `ParamArray` arguments, or `Optional` arguments. Events do not have return values.

To handle an event, you must associate it with an event handler subroutine using either the `Handles` or `AddHandler` statement. The signatures of the subroutine and the event must match. To handle a shared event, you must use the `AddHandler` statement.

You can use `Event` only at module level. This means the *declaration context* for an event must be a class, structure, module, or interface, and cannot be a source file, namespace, procedure, or block. For more information, see [Declaration Contexts and Default Access Levels](#).

In most circumstances, you can use the first syntax in the Syntax section of this topic for declaring events. However, some scenarios require that you have more control over the detailed behavior of the event. The last syntax in the Syntax section of this topic, which uses the `Custom` keyword, provides that control by enabling you to define custom events. In a custom event, you specify exactly what occurs when code adds or removes an event handler to or from the event, or when code raises the event. For examples, see [How to: Declare Custom Events To Conserve Memory](#) and [How to: Declare Custom Events To Avoid Blocking](#).

Example

The following example uses events to count down seconds from 10 to 0. The code illustrates several of the event-related methods, properties, and statements. This includes the `RaiseEvent` statement.

The class that raises an event is the event source, and the methods that process the event are the event handlers. An event source can have multiple handlers for the events it generates. When the class raises the event, that event is raised on every class that has elected to handle events for that instance of the object.

The example also uses a form (`Form1`) with a button (`Button1`) and a text box (`TextBox1`). When you click the button, the first text box displays a countdown from 10 to 0 seconds. When the full time (10 seconds) has elapsed, the first text box displays "Done".

The code for `Form1` specifies the initial and terminal states of the form. It also contains the code executed when events are raised.

To use this example, open a new Windows Forms project. Then add a button named `Button1` and a text box named `TextBox1` to the main form, named `Form1`. Then right-click the form and click **View Code** to open the code editor.

Add a `WithEvents` variable to the declarations section of the `Form1` class:

```
Private WithEvents mText As TimerState
```

Add the following code to the code for `Form1`. Replace any duplicate procedures that may exist, such as `Form_Load` or `Button_Click`.

```

Private Sub Form1_Load() Handles MyBase.Load
    Button1.Text = "Start"
    mText = New TimerState
End Sub
Private Sub Button1_Click() Handles Button1.Click
    mText.StartCountdown(10.0, 0.1)
End Sub

Private Sub mText_ChangeText() Handles mText.Finished
    TextBox1.Text = "Done"
End Sub

Private Sub mTextUpdateTime(ByVal Countdown As Double
) Handles mText.UpdateTime

    TextBox1.Text = Format(Countdown, "##0.0")
    ' Use DoEvents to allow the display to refresh.
    My.Application.DoEvents()
End Sub

Class TimerState
    Public Event UpdateTime(ByVal Countdown As Double)
    Public Event Finished()
    Public Sub StartCountdown(ByVal Duration As Double,
        ByVal Increment As Double)
        Dim Start As Double = DateAndTime.Timer
        Dim ElapsedTime As Double = 0

        Dim SoFar As Double = 0
        Do While ElapsedTime < Duration
            If ElapsedTime > SoFar + Increment Then
                SoFar += Increment
                RaiseEvent UpdateTime(Duration - SoFar)
            End If
            ElapsedTime = DateAndTime.Timer - Start
        Loop
        RaiseEvent Finished()
    End Sub
End Class

```

Press F5 to run the previous example, and click the button labeled **Start**. The first text box starts to count down the seconds. When the full time (10 seconds) has elapsed, the first text box displays "Done".

NOTE

The `My.Application.DoEvents` method does not process events in the same way the form does. To enable the form to handle the events directly, you can use multithreading. For more information, see [Managed Threading](#).

Exit Statement (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Exits a procedure or block and transfers control immediately to the statement following the procedure call or the block definition.

Syntax

```
Exit { Do | For | Function | Property | Select | Sub | Try | While }
```

Statements

Exit Do

Immediately exits the `Do` loop in which it appears. Execution continues with the statement following the `Loop` statement. `Exit Do` can be used only inside a `Do` loop. When used within nested `Do` loops, `Exit Do` exits the innermost loop and transfers control to the next higher level of nesting.

Exit For

Immediately exits the `For` loop in which it appears. Execution continues with the statement following the `Next` statement. `Exit For` can be used only inside a `For ... Next` or `For Each ... Next` loop. When used within nested `For` loops, `Exit For` exits the innermost loop and transfers control to the next higher level of nesting.

Exit Function

Immediately exits the `Function` procedure in which it appears. Execution continues with the statement following the statement that called the `Function` procedure. `Exit Function` can be used only inside a `Function` procedure.

To specify a return value, you can assign the value to the function name on a line before the `Exit Function` statement. To assign the return value and exit the function in one statement, you can instead use the [Return Statement](#).

Exit Property

Immediately exits the `Property` procedure in which it appears. Execution continues with the statement that called the `Property` procedure, that is, with the statement requesting or setting the property's value.

`Exit Property` can be used only inside a property's `Get` or `Set` procedure.

To specify a return value in a `Get` procedure, you can assign the value to the function name on a line before the `Exit Property` statement. To assign the return value and exit the `Get` procedure in one statement, you can instead use the `Return` statement.

In a `Set` procedure, the `Exit Property` statement is equivalent to the `Return` statement.

Exit Select

Immediately exits the `Select Case` block in which it appears. Execution continues with the statement following the `End Select` statement. `Exit Select` can be used only inside a `Select Case` statement.

Exit Sub

Immediately exits the `Sub` procedure in which it appears. Execution continues with the statement following the statement that called the `Sub` procedure. `Exit Sub` can be used only inside a `Sub` procedure.

In a `Sub` procedure, the `Exit Sub` statement is equivalent to the `Return` statement.

`Exit Try`

Immediately exits the `Try` or `Catch` block in which it appears. Execution continues with the `Finally` block if there is one, or with the statement following the `End Try` statement otherwise. `Exit Try` can be used only inside a `Try` or `Catch` block, and not inside a `Finally` block.

`Exit While`

Immediately exits the `While` loop in which it appears. Execution continues with the statement following the `End While` statement. `Exit While` can be used only inside a `While` loop. When used within nested `While` loops, `Exit While` transfers control to the loop that is one nested level above the loop where `Exit While` occurs.

Remarks

Do not confuse `Exit` statements with `End` statements. `Exit` does not define the end of a statement.

Example

In the following example, the loop condition stops the loop when the `index` variable is greater than 100. The `If` statement in the loop, however, causes the `Exit Do` statement to stop the loop when the `index` variable is greater than 10.

```
Dim index As Integer = 0
Do While index <= 100
    If index > 10 Then
        Exit Do
    End If

    Debug.WriteLine(index.ToString & " ")
    index += 1
Loop

Debug.WriteLine("")
' Output: 0 1 2 3 4 5 6 7 8 9 10
```

Example

The following example assigns the return value to the function name `myFunction`, and then uses `Exit Function` to return from the function.

```
Function myFunction(ByVal j As Integer) As Double
    myFunction = 3.87 * j
    Exit Function
End Function
```

Example

The following example uses the [Return Statement](#) to assign the return value and exit the function.

```
Function myFunction(ByVal j As Integer) As Double
    Return 3.87 * j
End Function
```

For Each...Next Statement (Visual Basic)

2/28/2019 • 12 minutes to read • [Edit Online](#)

Repeats a group of statements for each element in a collection.

Syntax

```
For Each element [ As datatype ] In group
    [ statements ]
    [ Continue For ]
    [ statements ]
    [ Exit For ]
    [ statements ]
Next [ element ]
```

Parts

TERM	DEFINITION
<code>element</code>	Required in the <code>For Each</code> statement. Optional in the <code>Next</code> statement. Variable. Used to iterate through the elements of the collection.
<code>datatype</code>	Required if <code>element</code> isn't already declared. Data type of <code>element</code> .
<code>group</code>	Required. A variable with a type that's a collection type or Object. Refers to the collection over which the <code>statements</code> are to be repeated.
<code>statements</code>	Optional. One or more statements between <code>For Each</code> and <code>Next</code> that run on each item in <code>group</code> .
<code>Continue For</code>	Optional. Transfers control to the start of the <code>For Each</code> loop.
<code>Exit For</code>	Optional. Transfers control out of the <code>For Each</code> loop.
<code>Next</code>	Required. Terminates the definition of the <code>For Each</code> loop.

Simple Example

Use a `For Each ... Next` loop when you want to repeat a set of statements for each element of a collection or array.

TIP

A [For...Next Statement](#) works well when you can associate each iteration of a loop with a control variable and determine that variable's initial and final values. However, when you are dealing with a collection, the concept of initial and final values isn't meaningful, and you don't necessarily know how many elements the collection has. In this kind of case, a [For Each ... Next](#) loop is often a better choice.

In the following example, the [For Each ... Next](#) statement iterates through all the elements of a List collection.

```
' Create a list of strings by using a
' collection initializer.
Dim lst As New List(Of String) _
    From {"abc", "def", "ghi"}

' Iterate through the list.
For Each item As String In lst
    Debug.WriteLine(item & " ")
Next
Debug.WriteLine("")
'Output: abc def ghi
```

For more examples, see [Collections and Arrays](#).

Nested Loops

You can nest [For Each](#) loops by putting one loop within another.

The following example demonstrates nested [For Each ... Next](#) structures.

```
' Create lists of numbers and letters
' by using array initializers.
Dim numbers() As Integer = {1, 4, 7}
Dim letters() As String = {"a", "b", "c"}

' Iterate through the list by using nested loops.
For Each number As Integer In numbers
    For Each letter As String In letters
        Debug.WriteLine(number.ToString & letter & " ")
    Next
Next
Debug.WriteLine("")
'Output: 1a 1b 1c 4a 4b 4c 7a 7b 7c
```

When you nest loops, each loop must have a unique [element](#) variable.

You can also nest different kinds of control structures within each other. For more information, see [Nested Control Structures](#).

Exit For and Continue For

The [Exit For](#) statement causes execution to exit the [For ... Next](#) loop and transfers control to the statement that follows the [Next](#) statement.

The [Continue For](#) statement transfers control immediately to the next iteration of the loop. For more information, see [Continue Statement](#).

The following example shows how to use the [Continue For](#) and [Exit For](#) statements.

```

Dim numberSeq() As Integer =
    {1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12}

For Each number As Integer In numberSeq
    ' If number is between 5 and 7, continue
    ' with the next iteration.
    If number >= 5 And number <= 8 Then
        Continue For
    End If

    ' Display the number.
    Debug.Write(number.ToString & " ")

    ' If number is 10, exit the loop.
    If number = 10 Then
        Exit For
    End If
Next
Debug.WriteLine("")
' Output: 1 2 3 4 9 10

```

You can put any number of `Exit For` statements in a `For Each` loop. When used within nested `For Each` loops, `Exit For` causes execution to exit the innermost loop and transfers control to the next higher level of nesting.

`Exit For` is often used after an evaluation of some condition, for example, in an `If ... Then ... Else` structure. You might want to use `Exit For` for the following conditions:

- Continuing to iterate is unnecessary or impossible. This might be caused by an erroneous value or a termination request.
- An exception is caught in a `Try ... Catch ... Finally`. You might use `Exit For` at the end of the `Finally` block.
- There is an endless loop, which is a loop that could run a large or even infinite number of times. If you detect such a condition, you can use `Exit For` to escape the loop. For more information, see [Do...Loop Statement](#).

Iterators

You use an *iterator* to perform a custom iteration over a collection. An iterator can be a function or a `Get` accessor. It uses a `Yield` statement to return each element of the collection one at a time.

You call an iterator by using a `For Each...Next` statement. Each iteration of the `For Each` loop calls the iterator. When a `Yield` statement is reached in the iterator, the expression in the `Yield` statement is returned, and the current location in code is retained. Execution is restarted from that location the next time that the iterator is called.

The following example uses an iterator function. The iterator function has a `Yield` statement that's inside a `For...Next` loop. In the `ListEvenNumbers` method, each iteration of the `For Each` statement body creates a call to the iterator function, which proceeds to the next `Yield` statement.

```

Public Sub ListEvenNumbers()
    For Each number As Integer In EvenSequence(5, 18)
        Debug.WriteLine(number & " ")
    Next
    Debug.WriteLine("")
    ' Output: 6 8 10 12 14 16 18
End Sub

Private Iterator Function EvenSequence(
    ByVal firstNumber As Integer, ByVal lastNumber As Integer) _
As System.Collections.Generic.IEnumerable(Of Integer)

    ' Yield even numbers in the range.
    For number = firstNumber To lastNumber
        If number Mod 2 = 0 Then
            Yield number
        End If
    Next
End Function

```

For more information, see [Iterators](#), [Yield Statement](#), and [Iterator](#).

Technical Implementation

When a `For Each ... Next` statement runs, Visual Basic evaluates the collection only one time, before the loop starts. If your statement block changes `element` or `group`, these changes don't affect the iteration of the loop.

When all the elements in the collection have been successively assigned to `element`, the `For Each` loop stops and control passes to the statement following the `Next` statement.

If `element` hasn't been declared outside this loop, you must declare it in the `For Each` statement. You can declare the type of `element` explicitly by using an `As` statement, or you can rely on type inference to assign the type. In either case, the scope of `element` is the body of the loop. However, you cannot declare `element` both outside and inside the loop.

You can optionally specify `element` in the `Next` statement. This improves the readability of your program, especially if you have nested `For Each` loops. You must specify the same variable as the one that appears in the corresponding `For Each` statement.

You might want to avoid changing the value of `element` inside a loop. Doing this can make it more difficult to read and debug your code. Changing the value of `group` doesn't affect the collection or its elements, which were determined when the loop was first entered.

When you're nesting loops, if a `Next` statement of an outer nesting level is encountered before the `Next` of an inner level, the compiler signals an error. However, the compiler can detect this overlapping error only if you specify `element` in every `Next` statement.

If your code depends on traversing a collection in a particular order, a `For Each ... Next` loop isn't the best choice, unless you know the characteristics of the enumerator object the collection exposes. The order of traversal isn't determined by Visual Basic, but by the `MoveNext` method of the enumerator object.

Therefore, you might not be able to predict which element of the collection is the first to be returned in `element`, or which is the next to be returned after a given element. You might achieve more reliable results using a different loop structure, such as `For ... Next` or `Do ... Loop`.

The data type of `element` must be such that the data type of the elements of `group` can be converted to it.

The data type of `group` must be a reference type that refers to a collection or an array that's enumerable.

Most commonly this means that `group` refers to an object that implements the `IEnumerable` interface of the `System.Collections` namespace or the `IEnumerable<T>` interface of the `System.Collections.Generic` namespace. `System.Collections.IEnumerable` defines the `GetEnumerator` method, which returns an enumerator object for the collection. The enumerator object implements the `System.Collections.IEnumerator` interface of the `System.Collections` namespace and exposes the `Current` property and the `Reset` and `MoveNext` methods. Visual Basic uses these to traverse the collection.

Narrowing Conversions

When `Option Strict` is set to `On`, narrowing conversions ordinarily cause compiler errors. In a `For Each` statement, however, conversions from the elements in `group` to `element` are evaluated and performed at run time, and compiler errors caused by narrowing conversions are suppressed.

In the following example, the assignment of `m` as the initial value for `n` doesn't compile when `Option Strict` is on because the conversion of a `Long` to an `Integer` is a narrowing conversion. In the `For Each` statement, however, no compiler error is reported, even though the assignment to `number` requires the same conversion from `Long` to `Integer`. In the `For Each` statement that contains a large number, a run-time error occurs when `ToInteger` is applied to the large number.

```
Option Strict On

Module Module1
    Sub Main()
        ' The assignment of m to n causes a compiler error when
        ' Option Strict is on.
        Dim m As Long = 987
        'Dim n As Integer = m

        ' The For Each loop requires the same conversion but
        ' causes no errors, even when Option Strict is on.
        For Each number As Integer In New Long() {45, 3, 987}
            Console.Write(number & " ")
        Next
        Console.WriteLine()
        ' Output: 45 3 987

        ' Here a run-time error is raised because 9876543210
        ' is too large for type Integer.
        'For Each number As Integer In New Long() {45, 3, 9876543210}
        '    Console.Write(number & " ")
        'Next

        Console.ReadKey()
    End Sub
End Module
```

IEnumerator Calls

When execution of a `For Each ... Next` loop starts, Visual Basic verifies that `group` refers to a valid collection object. If not, it throws an exception. Otherwise, it calls the `MoveNext` method and the `Current` property of the enumerator object to return the first element. If `MoveNext` indicates that there is no next element, that is, if the collection is empty, the `For Each` loop stops and control passes to the statement following the `Next` statement. Otherwise, Visual Basic sets `element` to the first element and runs the statement block.

Each time Visual Basic encounters the `Next` statement, it returns to the `For Each` statement. Again it calls `MoveNext` and `Current` to return the next element, and again it either runs the block or stops the loop depending on the result. This process continues until `MoveNext` indicates that there is no next element or an `Exit For` statement is encountered.

Modifying the Collection. The enumerator object returned by `GetEnumerator` normally doesn't let you

change the collection by adding, deleting, replacing, or reordering any elements. If you change the collection after you have initiated a `For Each ... Next` loop, the enumerator object becomes invalid, and the next attempt to access an element causes an `InvalidOperationException` exception.

However, this blocking of modification isn't determined by Visual Basic, but rather by the implementation of the `IEnumerable` interface. It is possible to implement `IEnumerable` in a way that allows for modification during iteration. If you are considering doing such dynamic modification, make sure that you understand the characteristics of the `IEnumerable` implementation on the collection you are using.

Modifying Collection Elements. The `Current` property of the enumerator object is `ReadOnly`, and it returns a local copy of each collection element. This means that you cannot modify the elements themselves in a `For Each ... Next` loop. Any modification you make affects only the local copy from `Current` and isn't reflected back into the underlying collection. However, if an element is a reference type, you can modify the members of the instance to which it points. The following example modifies the `BackColor` member of each `thisControl` element. You cannot, however, modify `thisControl` itself.

```
Sub lightBlueBackground(ByVal thisForm As System.Windows.Forms.Form)
    For Each thisControl As System.Windows.Forms.Control In thisForm.Controls
        thisControl.BackColor = System.Drawing.Color.LightBlue
    Next thisControl
End Sub
```

The previous example can modify the `BackColor` member of each `thisControl` element, although it cannot modify `thisControl` itself.

Traversing Arrays. Because the `Array` class implements the `IEnumerable` interface, all arrays expose the `GetEnumerator` method. This means that you can iterate through an array with a `For Each ... Next` loop. However, you can only read the array elements. You cannot change them.

Example

The following example lists all the folders in the C:\ directory by using the `DirectoryInfo` class.

```
Dim dInfo As New System.IO.DirectoryInfo("c:\")
For Each dir As System.IO.DirectoryInfo In dInfo.GetDirectories()
    Debug.WriteLine(dir.Name)
Next
```

Example

The following example illustrates a procedure for sorting a collection. The example sorts instances of a `Car` class that are stored in a `List<T>`. The `Car` class implements the `IComparable<T>` interface, which requires that the `CompareTo` method be implemented.

Each call to the `CompareTo` method makes a single comparison that's used for sorting. User-written code in the `CompareTo` method returns a value for each comparison of the current object with another object. The value returned is less than zero if the current object is less than the other object, greater than zero if the current object is greater than the other object, and zero if they are equal. This enables you to define in code the criteria for greater than, less than, and equal.

In the `ListCars` method, the `cars.Sort()` statement sorts the list. This call to the `Sort` method of the `List<T>` causes the `CompareTo` method to be called automatically for the `Car` objects in the `List`.

```
Public Sub ListCars()
```

```

' Create some new cars.
Dim cars As New List(Of Car) From
{
    New Car With {.Name = "car1", .Color = "blue", .Speed = 20},
    New Car With {.Name = "car2", .Color = "red", .Speed = 50},
    New Car With {.Name = "car3", .Color = "green", .Speed = 10},
    New Car With {.Name = "car4", .Color = "blue", .Speed = 50},
    New Car With {.Name = "car5", .Color = "blue", .Speed = 30},
    New Car With {.Name = "car6", .Color = "red", .Speed = 60},
    New Car With {.Name = "car7", .Color = "green", .Speed = 50}
}

' Sort the cars by color alphabetically, and then by speed
' in descending order.
cars.Sort()

' View all of the cars.
For Each thisCar As Car In cars
    Debug.Write(thisCar.Color.PadRight(5) & " ")
    Debug.Write(thisCar.Speed.ToString & " ")
    Debug.Write(thisCar.Name)
    Debug.WriteLine("")
Next

' Output:
' blue 50 car4
' blue 30 car5
' blue 20 car1
' green 50 car7
' green 10 car3
' red 60 car6
' red 50 car2
End Sub

Public Class Car
    Implements IComparable(Of Car)

        Public Property Name As String
        Public Property Speed As Integer
        Public Property Color As String

        Public Function CompareTo(ByVal other As Car) As Integer _
            Implements System.IComparable(Of Car).CompareTo
            ' A call to this method makes a single comparison that is
            ' used for sorting.

            ' Determine the relative order of the objects being compared.
            ' Sort by color alphabetically, and then by speed in
            ' descending order.

            ' Compare the colors.
            Dim compare As Integer

            ' If the colors are the same, compare the speeds.
            If compare = 0 Then
                compare = Me.Speed.CompareTo(other.Speed)

                ' Use descending order for speed.
                compare = -compare
            End If

For...Next Statement (Visual Basic)

3/5/2019 • 9 minutes to read • [Edit Online](#)

Repeats a group of statements a specified number of times.

Syntax

```
For counter [ As datatype ] = start To end [ Step step ]
    [ statements ]
    [ Continue For ]
    [ statements ]
    [ Exit For ]
    [ statements ]
Next [ counter ]
```

Parts

PART	DESCRIPTION
counter	Required in the <code>For</code> statement. Numeric variable. The control variable for the loop. For more information, see Counter Argument later in this topic.
datatype	Optional. Data type of <code>counter</code> . For more information, see Counter Argument later in this topic.
start	Required. Numeric expression. The initial value of <code>counter</code> .
end	Required. Numeric expression. The final value of <code>counter</code> .
step	Optional. Numeric expression. The amount by which <code>counter</code> is incremented each time through the loop.
statements	Optional. One or more statements between <code>For</code> and <code>Next</code> that run the specified number of times.
Continue For	Optional. Transfers control to the next loop iteration.
Exit For	Optional. Transfers control out of the <code>For</code> loop.
Next	Required. Terminates the definition of the <code>For</code> loop.

NOTE

The `To` keyword is used in this statement to specify the range for the counter. You can also use this keyword in the [Select...Case Statement](#) and in array declarations. For more information about array declarations, see [Dim Statement](#).

Simple Examples

You use a `For ... Next` structure when you want to repeat a set of statements a set number of times.

In the following example, the `index` variable starts with a value of 1 and is incremented with each iteration of the loop, ending after the value of `index` reaches 5.

```
For index As Integer = 1 To 5
    Debug.WriteLine(index.ToString & " ")
Next
Debug.WriteLine("")
' Output: 1 2 3 4 5
```

In the following example, the `number` variable starts at 2 and is reduced by 0.25 on each iteration of the loop, ending after the value of `number` reaches 0. The `Step` argument of `- .25` reduces the value by 0.25 on each iteration of the loop.

```
For number As Double = 2 To 0 Step -0.25
    Debug.WriteLine(number.ToString & " ")
Next
Debug.WriteLine("")
' Output: 2 1.75 1.5 1.25 1 0.75 0.5 0.25 0
```

TIP

A [While...End While Statement](#) or [Do...Loop Statement](#) works well when you don't know in advance how many times to run the statements in the loop. However, when you expect to run the loop a specific number of times, a `For ... Next` loop is a better choice. You determine the number of iterations when you first enter the loop.

Nesting Loops

You can nest `For` loops by putting one loop within another. The following example demonstrates nested `For ... Next` structures that have different step values. The outer loop creates a string for every iteration of the loop. The inner loop decrements a loop counter variable for every iteration of the loop.

```
For indexA = 1 To 3
    ' Create a new StringBuilder, which is used
    ' to efficiently build strings.
    Dim sb As New System.Text.StringBuilder()

    ' Append to the StringBuilder every third number
    ' from 20 to 1 descending.
    For indexB = 20 To 1 Step -3
        sb.Append(indexB.ToString)
        sb.Append(" ")
    Next indexB

    ' Display the line.
    Debug.WriteLine(sb.ToString)
Next indexA
' Output:
' 20 17 14 11 8 5 2
' 20 17 14 11 8 5 2
' 20 17 14 11 8 5 2
```

When nesting loops, each loop must have a unique `counter` variable.

You can also nest different kinds control structures within each other. For more information, see [Nested Control Structures](#).

Exit For and Continue For

The `Exit For` statement immediately exits the `For ... Next` loop and transfers control to the statement that follows the `Next` statement.

The `Continue For` statement transfers control immediately to the next iteration of the loop. For more information, see [Continue Statement](#).

The following example illustrates the use of the `Continue For` and `Exit For` statements.

```
For index As Integer = 1 To 100000
    ' If index is between 5 and 7, continue
    ' with the next iteration.
    If index >= 5 AndAlso index <= 8 Then
        Continue For
    End If

    ' Display the index.
    Debug.WriteLine(index.ToString & " ")

    ' If index is 10, exit the loop.
    If index = 10 Then
        Exit For
    End If
Next
Debug.WriteLine("")
' Output: 1 2 3 4 9 10
```

You can put any number of `Exit For` statements in a `For ... Next` loop. When used within nested `For ... Next` loops, `Exit For` exits the innermost loop and transfers control to the next higher level of nesting.

`Exit For` is often used after you evaluate some condition (for example, in an `If ... Then ... Else` structure). You might want to use `Exit For` for the following conditions:

- Continuing to iterate is unnecessary or impossible. An erroneous value or a termination request might create this condition.
- A `Try ... Catch ... Finally` statement catches an exception. You might use `Exit For` at the end of the `Finally` block.
- You have an endless loop, which is a loop that could run a large or even infinite number of times. If you detect such a condition, you can use `Exit For` to escape the loop. For more information, see [Do...Loop Statement](#).

Technical Implementation

When a `For ... Next` loop starts, Visual Basic evaluates `start`, `end`, and `step`. Visual Basic evaluates these values only at this time and then assigns `start` to `counter`. Before the statement block runs, Visual Basic compares `counter` to `end`. If `counter` is already larger than the `end` value (or smaller if `step` is negative), the `For` loop ends and control passes to the statement that follows the `Next` statement. Otherwise, the statement block runs.

Each time Visual Basic encounters the `Next` statement, it increments `counter` by `step` and returns to the `For` statement. Again it compares `counter` to `end`, and again it either runs the block or exits the loop, depending on the result. This process continues until `counter` passes `end` or an `Exit For` statement is

encountered.

The loop doesn't stop until `counter` has passed `end`. If `counter` is equal to `end`, the loop continues. The comparison that determines whether to run the block is `counter <= end` if `step` is positive and `counter >= end` if `step` is negative.

If you change the value of `counter` while inside a loop, your code might be more difficult to read and debug. Changing the value of `start`, `end`, or `step` doesn't affect the iteration values that were determined when the loop was first entered.

If you nest loops, the compiler signals an error if it encounters the `Next` statement of an outer nesting level before the `Next` statement of an inner level. However, the compiler can detect this overlapping error only if you specify `counter` in every `Next` statement.

Step Argument

The value of `step` can be either positive or negative. This parameter determines loop processing according to the following table:

STEP VALUE	LOOP EXECUTES IF
Positive or zero	<code>counter <= end</code>
Negative	<code>counter >= end</code>

The default value of `step` is 1.

Counter Argument

The following table indicates whether `counter` defines a new local variable that's scoped to the entire `For...Next` loop. This determination depends on whether `datatype` is present and whether `counter` is already defined.

IS DATATYPE PRESENT?	IS COUNTER ALREADY DEFINED?	RESULT (WHETHER COUNTER DEFINES A NEW LOCAL VARIABLE THAT'S SCOPED TO THE ENTIRE FOR...NEXT LOOP)
No	Yes	No, because <code>counter</code> is already defined. If the scope of <code>counter</code> isn't local to the procedure, a compile-time warning occurs.
No	No	Yes. The data type is inferred from the <code>start</code> , <code>end</code> , and <code>step</code> expressions. For information about type inference, see Option Infer Statement and Local Type Inference .
Yes	Yes	Yes, but only if the existing <code>counter</code> variable is defined outside the procedure. That variable remains separate. If the scope of the existing <code>counter</code> variable is local to the procedure, a compile-time error occurs.
Yes	No	Yes.

The data type of `counter` determines the type of the iteration, which must be one of the following types:

- A `Byte`, `SByte`, `UShort`, `Short`, `UInteger`, `Integer`, `ULong`, `Long`, `Decimal`, `Single`, or `Double`.
- An enumeration that you declare by using an [Enum Statement](#).
- An `Object`.
- A type `T` that has the following operators, where `B` is a type that can be used in a `Boolean` expression.

```
Public Shared Operator >= (op1 As T, op2 As T) As B
```

```
Public Shared Operator <= (op1 As T, op2 As T) As B
```

```
Public Shared Operator - (op1 As T, op2 As T) As T
```

```
Public Shared Operator + (op1 As T, op2 As T) As T
```

You can optionally specify the `counter` variable in the `Next` statement. This syntax improves the readability of your program, especially if you have nested `For` loops. You must specify the variable that appears in the corresponding `For` statement.

The `start`, `end`, and `step` expressions can evaluate to any data type that widens to the type of `counter`. If you use a user-defined type for `counter`, you might have to define the `CType` conversion operator to convert the types of `start`, `end`, or `step` to the type of `counter`.

Example

The following example removes all elements from a generic list. Instead of a [For Each...Next Statement](#), the example shows a `For ... Next` statement that iterates in descending order. The example uses this technique because the `removeAt` method causes elements after the removed element to have a lower index value.

```
Dim lst As New List(Of Integer) From {10, 20, 30, 40}

For index As Integer = lst.Count - 1 To 0 Step -1
    lst.RemoveAt(index)
Next

Debug.WriteLine(lst.Count.ToString)
' Output: 0
```

Example

The following example iterates through an enumeration that's declared by using an [Enum Statement](#).

```

Public Enum Mammals
    Buffalo
    Gazelle
    Mongoose
    Rhinoceros
    Whale
End Enum

Public Sub ListSomeMammals()
    For mammal As Mammals = Mammals.Gazelle To Mammals.Rhinoceros
        Debug.WriteLine(mammal.ToString & " ")
    Next
    Debug.WriteLine("")
    ' Output: Gazelle Mongoose Rhinoceros
End Sub

```

Example

In the following example, the statement parameters use a class that has operator overloads for the `+`, `-`, `>=`, and `<=` operators.

```

Private Class Distance
    Public Property Number() As Double

    Public Sub New(ByVal number As Double)
        Me.Number = number
    End Sub

    ' Define operator overloads to support For...Next statements.
    Public Shared Operator +(ByVal op1 As Distance, ByVal op2 As Distance) As Distance
        Return New Distance(op1.Number + op2.Number)
    End Operator

    Public Shared Operator -(ByVal op1 As Distance, ByVal op2 As Distance) As Distance
        Return New Distance(op1.Number - op2.Number)
    End Operator

    Public Shared Operator >=(ByVal op1 As Distance, ByVal op2 As Distance) As Boolean
        Return (op1.Number >= op2.Number)
    End Operator

    Public Shared Operator <=(ByVal op1 As Distance, ByVal op2 As Distance) As Boolean
        Return (op1.Number <= op2.Number)
    End Operator
End Class

Public Sub ListDistances()
    Dim distFrom As New Distance(10)
    Dim distTo As New Distance(25)
    Dim distStep As New Distance(4)

    For dist As Distance = distFrom To distTo Step distStep
        Debug.WriteLine(dist.Number.ToString & " ")
    Next
    Debug.WriteLine("")

    ' Output: 10 14 18 22
End Sub

```

Function Statement (Visual Basic)

2/28/2019 • 8 minutes to read • [Edit Online](#)

Declares the name, parameters, and code that define a `Function` procedure.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ proceduremodifiers ] [ Shared ] [ Shadows ] [ Async |  
Iterator ]  
Function name [ (Of typeparamlist) ] [ (parameterlist) ] [ As returntype ] [ Implements  
implementslist | Handles eventlist ]  
    [ statements ]  
    [ Exit Function ]  
    [ statements ]  
End Function
```

Parts

- `attributelist`

Optional. See [Attribute List](#).

- `accessmodifier`

Optional. Can be one of the following:

- [Public](#)
- [Protected](#)
- [Friend](#)
- [Private](#)
- [Protected Friend](#)
- [Private Protected](#)

See [Access levels in Visual Basic](#).

- `proceduremodifiers`

Optional. Can be one of the following:

- [Overloads](#)
- [Overrides](#)
- [Overridable](#)
- [NotOverridable](#)
- [MustOverride](#)
- `MustOverride Overrides`
- `NotOverridable Overrides`

- **Shared**

Optional. See [Shared](#).

- **Shadows**

Optional. See [Shadows](#).

- **Async**

Optional. See [Async](#).

- **Iterator**

Optional. See [Iterator](#).

- **name**

Required. Name of the procedure. See [Declared Element Names](#).

- **typeparamlist**

Optional. List of type parameters for a generic procedure. See [Type List](#).

- **parameterlist**

Optional. List of local variable names representing the parameters of this procedure. See [Parameter List](#).

- **returntype**

Required if `Option Strict` is `On`. Data type of the value returned by this procedure.

- **Implements**

Optional. Indicates that this procedure implements one or more `Function` procedures, each one defined in an interface implemented by this procedure's containing class or structure. See [Implements Statement](#).

- **implementslist**

Required if `Implements` is supplied. List of `Function` procedures being implemented.

`implementedprocedure [, implementedprocedure ...]`

Each `implementedprocedure` has the following syntax and parts:

`interface.definedname`

PART	DESCRIPTION
<code>interface</code>	Required. Name of an interface implemented by this procedure's containing class or structure.
<code>definedname</code>	Required. Name by which the procedure is defined in <code>interface</code> .

- **Handles**

Optional. Indicates that this procedure can handle one or more specific events. See [Handles](#).

- **eventlist**

Required if `Handles` is supplied. List of events this procedure handles.

`eventspecifier [, eventspecifier ...]`

Each `eventspecifier` has the following syntax and parts:

`eventvariable.event`

PART	DESCRIPTION
<code>eventvariable</code>	Required. Object variable declared with the data type of the class or structure that raises the event.
<code>event</code>	Required. Name of the event this procedure handles.

- `statements`

Optional. Block of statements to be executed within this procedure.

- `End Function`

Terminates the definition of this procedure.

Remarks

All executable code must be inside a procedure. Each procedure, in turn, is declared within a class, a structure, or a module that is referred to as the containing class, structure, or module.

To return a value to the calling code, use a `Function` procedure; otherwise, use a `Sub` procedure.

Defining a Function

You can define a `Function` procedure only at the module level. Therefore, the declaration context for a function must be a class, a structure, a module, or an interface and can't be a source file, a namespace, a procedure, or a block. For more information, see [Declaration Contexts and Default Access Levels](#).

`Function` procedures default to public access. You can adjust their access levels with the access modifiers.

A `Function` procedure can declare the data type of the value that the procedure returns. You can specify any data type or the name of an enumeration, a structure, a class, or an interface. If you don't specify the `returntype` parameter, the procedure returns `Object`.

If this procedure uses the `Implements` keyword, the containing class or structure must also have an `Implements` statement that immediately follows its `Class` or `Structure` statement. The `Implements` statement must include each interface that's specified in `implementslist`. However, the name by which an interface defines the `Function` (in `definedname`) doesn't need to match the name of this procedure (in `name`).

NOTE

You can use lambda expressions to define function expressions inline. For more information, see [Function Expression](#) and [Lambda Expressions](#).

Returning from a Function

When the `Function` procedure returns to the calling code, execution continues with the statement that follows the statement that called the procedure.

To return a value from a function, you can either assign the value to the function name or include it in a `Return` statement.

The `Return` statement simultaneously assigns the return value and exits the function, as the following example shows.

```
Function myFunction(ByVal j As Integer) As Double
    Return 3.87 * j
End Function
```

The following example assigns the return value to the function name `myFunction` and then uses the `Exit Function` statement to return.

```
Function myFunction(ByVal j As Integer) As Double
    myFunction = 3.87 * j
    Exit Function
End Function
```

The `Exit Function` and `Return` statements cause an immediate exit from a `Function` procedure. Any number of `Exit Function` and `Return` statements can appear anywhere in the procedure, and you can mix `Exit Function` and `Return` statements.

If you use `Exit Function` without assigning a value to `name`, the procedure returns the default value for the data type that's specified in `returntype`. If `returntype` isn't specified, the procedure returns `Nothing`, which is the default value for `Object`.

Calling a Function

You call a `Function` procedure by using the procedure name, followed by the argument list in parentheses, in an expression. You can omit the parentheses only if you aren't supplying any arguments. However, your code is more readable if you always include the parentheses.

You call a `Function` procedure the same way that you call any library function such as `Sqr`, `Cos`, or `ChrW`.

You can also call a function by using the `Call` keyword. In that case, the return value is ignored. Use of the `Call` keyword isn't recommended in most cases. For more information, see [Call Statement](#).

Visual Basic sometimes rearranges arithmetic expressions to increase internal efficiency. For that reason, you shouldn't use a `Function` procedure in an arithmetic expression when the function changes the value of variables in the same expression.

Async Functions

The `Async` feature allows you to invoke asynchronous functions without using explicit callbacks or manually splitting your code across multiple functions or lambda expressions.

If you mark a function with the `Async` modifier, you can use the `Await` operator in the function. When control reaches an `Await` expression in the `Async` function, control returns to the caller, and progress in the function is suspended until the awaited task completes. When the task is complete, execution can resume in the function.

NOTE

An `Async` procedure returns to the caller when either it encounters the first awaited object that's not yet complete, or it gets to the end of the `Async` procedure, whichever occurs first.

An `Async` function can have a return type of `Task<TResult>` or `Task`. An example of an `Async` function that has a return type of `Task<TResult>` is provided below.

An `Async` function cannot declare any `ByRef` parameters.

A `Sub Statement` can also be marked with the `Async` modifier. This is primarily used for event handlers, where a value cannot be returned. An `Async Sub` procedure can't be awaited, and the caller of an `Async Sub` procedure can't catch exceptions that are thrown by the `Sub` procedure.

For more information about `Async` functions, see [Asynchronous Programming with Async and Await](#), [Control Flow in Async Programs](#), and [Async Return Types](#).

Iterator Functions

An *iterator* function performs a custom iteration over a collection, such as a list or array. An iterator function uses the `Yield` statement to return each element one at a time. When a `Yield` statement is reached, the current location in code is remembered. Execution is restarted from that location the next time the iterator function is called.

You call an iterator from client code by using a `For Each...Next` statement.

The return type of an iterator function can be `IEnumerable`, `IEnumerable<T>`, `IEnumerator`, or `IEnumerator<T>`.

For more information, see [Iterators](#).

Example

The following example uses the `Function` statement to declare the name, parameters, and code that form the body of a `Function` procedure. The `ParamArray` modifier enables the function to accept a variable number of arguments.

```
Public Function calcSum(ByVal ParamArray args() As Double) As Double
    calcSum = 0
    If args.Length <= 0 Then Exit Function
    For i As Integer = 0 To UBound(args, 1)
        calcSum += args(i)
    Next i
End Function
```

Example

The following example invokes the function declared in the preceding example.

```

Module Module1

Sub Main()
    ' In the following function call, calcSum's local variables
    ' are assigned the following values: args(0) = 4, args(1) = 3,
    ' and so on. The displayed sum is 10.
    Dim returnedValue As Double = calcSum(4, 3, 2, 1)
    Console.WriteLine("Sum: " & returnedValue)
    ' Parameter args accepts zero or more arguments. The sum
    ' displayed by the following statements is 0.
    returnedValue = calcSum()
    Console.WriteLine("Sum: " & returnedValue)
End Sub

Public Function calcSum(ByVal ParamArray args() As Double) As Double
    calcSum = 0
    If args.Length <= 0 Then Exit Function
    For i As Integer = 0 To UBound(args, 1)
        calcSum += args(i)
    Next i
End Function

End Module

```

Example

In the following example, `DelayAsync` is an `Async Function` that has a return type of `Task<TResult>`. `DelayAsync` has a `Return` statement that returns an integer. Therefore the function declaration of `DelayAsync` needs to have a return type of `Task(Of Integer)`. Because the return type is `Task(Of Integer)`, the evaluation of the `Await` expression in `DoSomethingAsync` produces an integer. This is demonstrated in this statement: `Dim result As Integer = Await delayTask`.

The `startButton_Click` procedure is an example of an `Async Sub` procedure. Because `DoSomethingAsync` is an `Async` function, the task for the call to `DoSomethingAsync` must be awaited, as the following statement demonstrates: `Await DoSomethingAsync()`. The `startButton_Click` `Sub` procedure must be defined with the `Async` modifier because it has an `Await` expression.

```
' Imports System.Diagnostics
' Imports System.Threading.Tasks

' This Click event is marked with the Async modifier.
Private Async Sub startButton_Click(sender As Object, e As RoutedEventArgs) Handles
startButton.Click
    Await DoSomethingAsync()
End Sub

Private Async Function DoSomethingAsync() As Task
    Dim delayTask As Task(Of Integer) = DelayAsync()
    Dim result As Integer = Await delayTask

    ' The previous two statements may be combined into

Get Statement

2/28/2019 • 3 minutes to read • [Edit Online](#)

Declares a `Get` property procedure used to retrieve the value of a property.

Syntax

```
[ <attributelist> ] [ accessmodifier ] Get()
    [ statements ]
End Get
```

Parts

TERM	DEFINITION
<code>attributelist</code>	Optional. See Attribute List .
<code>accessmodifier</code>	Optional on at most one of the <code>Get</code> and <code>Set</code> statements in this property. Can be one of the following: <ul style="list-style-type: none">- Protected- Friend- Private- <code>Protected Friend</code> See Access levels in Visual Basic .
<code>statements</code>	Optional. One or more statements that run when the <code>Get</code> property procedure is called.
<code>End Get</code>	Required. Terminates the definition of the <code>Get</code> property procedure.

Remarks

Every property must have a `Get` property procedure unless the property is marked `WriteOnly`. The `Get` procedure is used to return the current value of the property.

Visual Basic automatically calls a property's `Get` procedure when an expression requests the property's value.

The body of the property declaration can contain only the property's `Get` and `Set` procedures between the [Property Statement](#) and the `End Property` statement. It cannot store anything other than those procedures. In particular, it cannot store the property's current value. You must store this value outside the property, because if you store it inside either of the property procedures, the other property procedure cannot access it. The usual approach is to store the value in a [Private](#) variable declared at the same level as the property. You must define a `Get` procedure inside the property to which it applies.

The `Get` procedure defaults to the access level of its containing property unless you use `accessmodifier` in the `Get` statement.

Rules

- **Mixed Access Levels.** If you are defining a read-write property, you can optionally specify a different access level for either the `Get` or the `Set` procedure, but not both. If you do this, the procedure access level must be more restrictive than the property's access level. For example, if the property is declared `Friend`, you can declare the `Get` procedure `Private`, but not `Public`.

If you are defining a `ReadOnly` property, the `Get` procedure represents the entire property. You cannot declare a different access level for `Get`, because that would set two access levels for the property.

- **Return Type.** The [Property Statement](#) can declare the data type of the value it returns. The `Get` procedure automatically returns that data type. You can specify any data type or the name of an enumeration, structure, class, or interface.

If the `Property` statement does not specify `returntype`, the procedure returns `Object`.

Behavior

- **Returning from a Procedure.** When the `Get` procedure returns to the calling code, execution continues within the statement that requested the property value.

`Get` property procedures can return a value using either the [Return Statement](#) or by assigning the return value to the property name. For more information, see "Return Value" in [Function Statement](#).

The `Exit Property` and `Return` statements cause an immediate exit from a property procedure. Any number of `Exit Property` and `Return` statements can appear anywhere in the procedure, and you can mix `Exit Property` and `Return` statements.

- **Return Value.** To return a value from a `Get` procedure, you can either assign the value to the property name or include it in a [Return Statement](#). The `Return` statement simultaneously assigns the `Get` procedure return value and exits the procedure.

If you use `Exit Property` without assigning a value to the property name, the `Get` procedure returns the default value for the property's data type. For more information, see "Return Value" in [Function Statement](#).

The following example illustrates two ways the read-only property `quoteForTheDay` can return the value held in the private variable `quoteValue`.

```
Private quoteValue As String = "No quote assigned yet."
```

```
ReadOnly Property quoteForTheDay() As String
    Get
        quoteForTheDay = quoteValue
        Exit Property
    End Get
End Property
```

```
ReadOnly Property quoteForTheDay() As String
    Get
        Return quoteValue
    End Get
End Property
```

Example

The following example uses the `Get` statement to return the value of a property.

```
Class propClass
    ' Define a private local variable to store the property value.
    Private currentTime As String
    ' Define the read-only property.
    Public ReadOnly Property dateAndTime() As String
        Get
            ' The Get procedure is called automatically when the
            ' value of the property is retrieved.
            currentTime = CStr(Now)
            ' Return the date and time As a string.
            Return currentTime
        End Get
    End Property
End Class
```

GoTo Statement

3/16/2019 • 2 minutes to read • [Edit Online](#)

Branches unconditionally to a specified line in a procedure.

Syntax

```
GoTo line
```

Part

line

Required. Any line label.

Remarks

The `GoTo` statement can branch only to lines in the procedure in which it appears. The line must have a line label that `GoTo` can refer to. For more information, see [How to: Label Statements](#).

NOTE

`GoTo` statements can make code difficult to read and maintain. Whenever possible, use a control structure instead. For more information, see [Control Flow](#).

You cannot use a `GoTo` statement to branch from outside a `For ... Next`, `For Each ... Next`, `SyncLock ... End SyncLock`, `Try ... Catch ... Finally`, `With ... End With`, or `Using ... End Using` construction to a label inside.

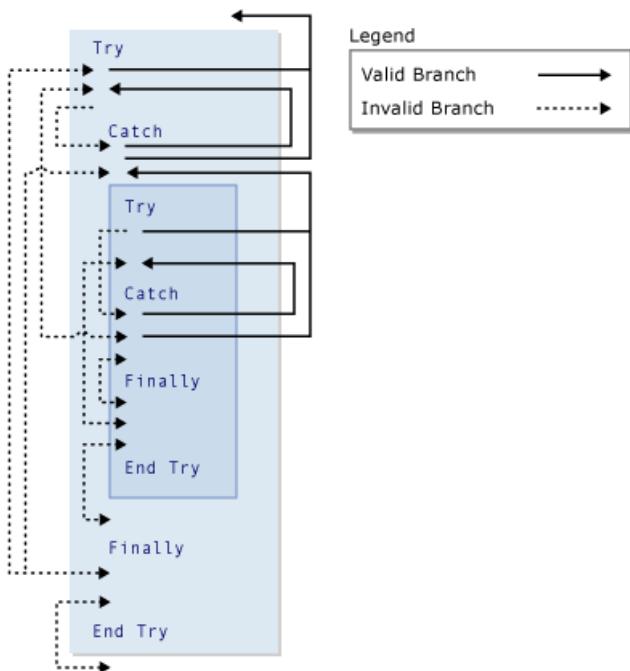

Branching and Try Constructors

Within a `Try ... Catch ... Finally` construction, the following rules apply to branching with the `GoTo` statement.

BLOCK OR REGION	BRANCHING IN FROM OUTSIDE	BRANCHING OUT FROM INSIDE
<code>Try</code> block	Only from a <code>Catch</code> block of the same construction <sup>1</sup>	Only to outside the whole construction
<code>Catch</code> block	Never allowed	Only to outside the whole construction, or to the <code>Try</code> block of the same construction <sup>1</sup>
<code>Finally</code> block	Never allowed	Never allowed

<sup>1</sup> If one `Try ... Catch ... Finally` construction is nested within another, a `Catch` block can branch into the `Try` block at its own nesting level, but not into any other `Try` block. A nested `Try ... Catch ... Finally` construction must be contained completely in a `Try` or `Catch` block of the construction within which it is nested.

The following illustration shows one `Try` construction nested within another. Various branches among the blocks of the two constructions are indicated as valid or invalid.

Example

The following example uses the `GoTo` statement to branch to line labels in a procedure.

```

Sub gotoStatementDemo()
    Dim number As Integer = 1
    Dim sampleString As String
    ' Evaluate number and branch to appropriate label.
    If number = 1 Then GoTo Line1 Else GoTo Line2
Line1:
    sampleString = "Number equals 1"
    GoTo LastLine
Line2:
    ' The following statement never gets executed because number = 1.
    sampleString = "Number equals 2"
LastLine:
    ' Write "Number equals 1" in the Debug window.
    Debug.WriteLine(sampleString)
End Sub

```

If...Then...Else Statement (Visual Basic)

3/1/2019 • 5 minutes to read • [Edit Online](#)

Conditionally executes a group of statements, depending on the value of an expression.

Syntax

```
' Multiline syntax:  
If condition [ Then ]  
    [ statements ]  
[ ElseIf elseifcondition [ Then ]  
    [ elseifstatements ] ]  
[ Else  
    [ elsestatements ] ]  
End If  
  
' Single-line syntax:  
If condition Then [ statements ] [ Else [ elsestatements ] ]
```

Quick links to example code

This article includes several examples that illustrate uses of the `If ... Then ... Else` statement:

- [Multiline syntax example](#)
- [Nested syntax example](#)
- [Single-line syntax example](#)

Parts

`condition`

Required. Expression. Must evaluate to `True` or `False`, or to a data type that is implicitly convertible to `Boolean`.

If the expression is a `Nullable Boolean` variable that evaluates to `Nothing`, the condition is treated as if the expression is `False` and the `Else` block is executed.

`Then`

Required in the single-line syntax; optional in the multiline syntax.

`statements`

Optional. One or more statements following `If ... Then` that are executed if `condition` evaluates to `True`.

`elseifcondition`

Required if `ElseIf` is present. Expression. Must evaluate to `True` or `False`, or to a data type that is implicitly convertible to `Boolean`.

`elseifstatements`

Optional. One or more statements following `ElseIf ... Then` that are executed if `elseifcondition` evaluates to `True`.

`elsestatements`

Optional. One or more statements that are executed if no previous `condition` or `elseifcondition` expression

evaluates to `True`.

`End If`

Terminates the multiline version of `If ... Then ... Else` block.

Remarks

Multiline syntax

When an `If ... Then ... Else` statement is encountered, `condition` is tested. If `condition` is `True`, the statements following `Then` are executed. If `condition` is `False`, each `ElseIf` statement (if there are any) is evaluated in order. When a `True` `elseifcondition` is found, the statements immediately following the associated `ElseIf` are executed. If no `elseifcondition` evaluates to `True`, or if there are no `ElseIf` statements, the statements following `Else` are executed. After executing the statements following `Then`, `ElseIf`, or `Else`, execution continues with the statement following `End If`.

The `ElseIf` and `Else` clauses are both optional. You can have as many `ElseIf` clauses as you want in an `If ... Then ... Else` statement, but no `ElseIf` clause can appear after an `Else` clause. `If ... Then ... Else` statements can be nested within each other.

In the multiline syntax, the `If` statement must be the only statement on the first line. The `ElseIf`, `Else`, and `End If` statements can be preceded only by a line label. The `If ... Then ... Else` block must end with an `End If` statement.

TIP

The [Select...Case Statement](#) might be more useful when you evaluate a single expression that has several possible values.

Single-Line syntax

You can use the single-line syntax for a single condition with code to execute if it's true. However, the multiple-line syntax provides more structure and flexibility and is easier to read, maintain, and debug.

What follows the `Then` keyword is examined to determine whether a statement is a single-line `If`. If anything other than a comment appears after `Then` on the same line, the statement is treated as a single-line `If` statement. If `Then` is absent, it must be the start of a multiple-line `If ... Then ... Else`.

In the single-line syntax, you can have multiple statements executed as the result of an `If ... Then` decision. All statements must be on the same line and be separated by colons.

Multiline syntax example

The following example illustrates the use of the multiline syntax of the `If ... Then ... Else` statement.

```

Module Multiline
    Public Sub Main()
        'Create a Random object to seed our starting value
        Dim randomizer As New Random()
        'set our variable
        Dim count As Integer = randomizer.Next(0, 5)

        Dim message As String

        'If count is zero, output will be no items
        If count = 0 Then
            message = "There are no items."
        'If count is 1, output will be "There is 1 item.".
        ElseIf count = 1 Then
            message = "There is 1 item."
        'If count is greater than 1, output will be "There are {count} items.", where {count} is replaced by
        'the value of count.
        Else
            message = $"There are {count} items."
        End If

        Console.WriteLine(message)
    End Sub
End Module
'This example displays output like the following:
' There are 4 items.

```

Nested syntax example

The following example contains nested `If ... Then ... Else` statements.

```

Module Nested
    Public Sub Main()
        ' Run the function as part of the WriteLine output.
        Console.WriteLine("Time Check is " & CheckIfTime() & ".")
    End Sub

    Private Function CheckIfTime() As Boolean
        ' Determine the current day of week and hour of day.
        Dim dayW As DayOfWeek = DateTime.Now.DayOfWeek
        Dim hour As Integer = DateTime.Now.Hour

        ' Return True if Wednesday from 2 to 3:59 P.M.,
        ' or if Thursday from noon to 12:59 P.M.
        If dayW = DayOfWeek.Wednesday Then
            If hour = 14 Or hour = 15 Then
                Return True
            Else
                Return False
            End If
        ElseIf dayW = DayOfWeek.Thursday Then
            If hour = 12 Then
                Return True
            Else
                Return False
            End If
        Else
            Return False
        End If
    End Function
End Module
'This example displays output like the following:
'Time Check is False.

```

Single-Line syntax example

The following example illustrates the use of the single-line syntax.

```
Module SingleLine
    Public Sub Main()

        'Create a Random object to seed our starting values
        Dim randomizer As New Random()

        Dim A As Integer = randomizer.Next(10, 20)
        Dim B As Integer = randomizer.Next(0, 20)
        Dim C As Integer = randomizer.Next(0, 5)

        'Let's display the initial values for comparison
        Console.WriteLine($"A value before If: {A}")
        Console.WriteLine($"B value before If: {B}")
        Console.WriteLine($"C value before If: {C}")

        ' If A > 10, execute the three colon-separated statements in the order
        ' that they appear
        If A > 10 Then A = A + 1 : B = B + A : C = C + B

        'If the condition is true, the values will be different
        Console.WriteLine($"A value after If: {A}")
        Console.WriteLine($"B value after If: {B}")
        Console.WriteLine($"C value after If: {C}")

    End Sub
End Module

'This example displays output like the following:
'A value before If: 11
'B value before If: 6
'C value before If: 3
'A value after If: 12
'B value after If: 17
'C value after If: 21

Implements Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies one or more interfaces, or interface members, that must be implemented in the class or structure definition in which it appears.

Syntax

```
Implements interfacename [, ...]  
-or-  
Implements interfacename.interfacemember [, ...]
```

Parts

`interfacename`

Required. An interface whose properties, procedures, and events are to be implemented by corresponding members in the class or structure.

`interfacemember`

Required. The member of an interface that is being implemented.

Remarks

An interface is a collection of prototypes representing the members (properties, procedures, and events) the interface encapsulates. Interfaces contain only the declarations for members; classes and structures implement these members. For more information, see [Interfaces](#).

The `Implements` statement must immediately follow the `Class` or `Structure` statement.

When you implement an interface, you must implement all the members declared in the interface. Omitting any member is considered to be a syntax error. To implement an individual member, you specify the `Implements` keyword (which is separate from the `Implements` statement) when you declare the member in the class or structure. For more information, see [Interfaces](#).

Classes can use `Private` implementations of properties and procedures, but these members are accessible only by casting an instance of the implementing class into a variable declared to be of the type of the interface.

Example

The following example shows how to use the `Implements` statement to implement members of an interface. It defines an interface named `ICustomerInfo` with an event, a property, and a procedure. The class `customerInfo` implements all the members defined in the interface.

```

Public Interface ICustomerInfo
    Event updateComplete()
    Property customerName() As String
    Sub updateCustomerStatus()
End Interface

Public Class customerInfo
    Implements ICustomerInfo
    ' Storage for the property value.
    Private customerNameValue As String
    Public Event updateComplete() Implements ICustomerInfo.updateComplete
    Public Property CustomerName() As String _
        Implements ICustomerInfo.customerName
        Get
            Return customerNameValue
        End Get
        Set(ByVal value As String)
            ' The value parameter is passed to the Set procedure
            ' when the contents of this property are modified.
            customerNameValue = value
        End Set
    End Property

    Public Sub updateCustomerStatus() _
        Implements ICustomerInfo.updateCustomerStatus
        ' Add code here to update the status of this account.
        ' Raise an event to indicate that this procedure is done.
        RaiseEvent updateComplete()
    End Sub
End Class

```

Note that the class `customerInfo` uses the `Implements` statement on a separate source code line to indicate that the class implements all the members of the `ICustomerInfo` interface. Then each member in the class uses the `Implements` keyword as part of its member declaration to indicate that it implements that interface member.

Example

The following two procedures show how you could use the interface implemented in the preceding example. To test the implementation, add these procedures to your project and call the `testImplements` procedure.

```

Public Sub testImplements()
    ' This procedure tests the interface implementation by
    ' creating an instance of the class that implements ICustomerInfo.
    Dim cust As ICustomerInfo = New customerInfo()
    ' Associate an event handler with the event that is raised by
    ' the cust object.
    AddHandler cust.updateComplete, AddressOf handleUpdateComplete
    ' Set the customerName Property
    cust.customerName = "Fred"
    ' Retrieve and display the customerName property.
    MsgBox("Customer name is: " & cust.customerName)
    ' Call the updateCustomerStatus procedure, which raises the
    ' updateComplete event.
    cust.updateCustomerStatus()
End Sub

Sub handleUpdateComplete()
    ' This is the event handler for the updateComplete event.
    MsgBox("Update is complete.")
End Sub

Imports Statement (.NET Namespace and Type)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Enables type names to be referenced without namespace qualification.

Syntax

```
Imports [ aliasname = ] namespace  
-or-  
Imports [ aliasname = ] namespace.element
```

Parts

TERM	DEFINITION
aliasname	Optional. An <i>import alias</i> or name by which code can refer to namespace instead of the full qualification string. See Declared Element Names .
namespace	Required. The fully qualified name of the namespace being imported. Can be a string of namespaces nested to any level.
element	Optional. The name of a programming element declared in the namespace. Can be any container element.

Remarks

The `Imports` statement enables types that are contained in a given namespace to be referenced directly.

You can supply a single namespace name or a string of nested namespaces. Each nested namespace is separated from the next higher level namespace by a period (`.`), as the following example illustrates.

```
Imports System.Collections.Generic
```

Each source file can contain any number of `Imports` statements. These must follow any option declarations, such as the `Option Strict` statement, and they must precede any programming element declarations, such as `Module` or `Class` statements.

You can use `Imports` only at file level. This means the declaration context for importation must be a source file, and cannot be a namespace, class, structure, module, interface, procedure, or block.

Note that the `Imports` statement does not make elements from other projects and assemblies available to your project. Importing does not take the place of setting a reference. It only removes the need to qualify names that are already available to your project. For more information, see "Importing Containing Elements" in [References to Declared Elements](#).

NOTE

You can define implicit `Imports` statements by using the [References Page, Project Designer \(Visual Basic\)](#). For more information, see [How to: Add or Remove Imported Namespaces \(Visual Basic\)](#).

Import Aliases

An *import alias* defines the alias for a namespace or type. Import aliases are useful when you need to use items with the same name that are declared in one or more namespaces. For more information and an example, see "Qualifying an Element Name" in [References to Declared Elements](#).

You should not declare a member at module level with the same name as `aliasname`. If you do, the Visual Basic compiler uses `aliasname` only for the declared member and no longer recognizes it as an import alias.

Although the syntax used for declaring an import alias is like that used for importing an XML namespace prefix, the results are different. An import alias can be used as an expression in your code, whereas an XML namespace prefix can be used only in XML literals or XML axis properties as the prefix for a qualified element or attribute name.

Element Names

If you supply `element`, it must represent a *container element*, that is, a programming element that can contain other elements. Container elements include classes, structures, modules, interfaces, and enumerations.

The scope of the elements made available by an `Imports` statement depends on whether you specify `element`. If you specify only `namespace`, all uniquely named members of that namespace, and members of container elements within that namespace, are available without qualification. If you specify both `namespace` and `element`, only the members of that element are available without qualification.

Example

The following example returns all the folders in the C:\ directory by using the `DirectoryInfo` class.

The code has no `Imports` statements at the top of the file. Therefore, the `DirectoryInfo`, `StringBuilder`, and `CrLf` references are all fully qualified with the namespaces.

```
Public Function GetFolders() As String
    ' Create a new StringBuilder, which is used
    ' to efficiently build strings.
    Dim sb As New System.Text.StringBuilder

    Dim dInfo As New System.IO.DirectoryInfo("c:\\")

    ' Obtain an array of directories, and iterate through
    ' the array.
    For Each dir As System.IO.DirectoryInfo In dInfo.GetDirectories()
        sb.Append(dir.Name)
        sb.Append(Microsoft.VisualBasic.ControlChars.CrLf)
    Next

    Return sb.ToString
End Function
```

Example

The following example includes `Imports` statements for the referenced namespaces. Therefore, the types do not have to be fully qualified with the namespaces.

```
' Place Imports statements at the top of your program.  
Imports System.Text  
Imports System.IO  
Imports Microsoft.VisualBasic.ControlChars
```

```
Public Function GetFolders() As String  
    Dim sb As New StringBuilder  
  
    Dim dInfo As New DirectoryInfo("c:\")  
    For Each dir As DirectoryInfo In dInfo.GetDirectories()  
        sb.Append(dir.Name)  
        sb.Append(CrLf)  
    Next  
  
    Return sb.ToString  
End Function
```

Example

The following example includes `Imports` statements that create aliases for the referenced namespaces. The types are qualified with the aliases.

```
Imports systxt = System.Text  
Imports sysio = System.IO  
Imports ch = Microsoft.VisualBasic.ControlChars
```

```
Public Function GetFolders() As String  
    Dim sb As New systxt.StringBuilder  
  
    Dim dInfo As New sysio.DirectoryInfo("c:\")  
    For Each dir As sysio.DirectoryInfo In dInfo.GetDirectories()  
        sb.Append(dir.Name)  
        sb.Append(ch.CrLf)  
    Next  
  
    Return sb.ToString  
End Function
```

Example

The following example includes `Imports` statements that create aliases for the referenced types. Aliases are used to specify the types.

```
Imports strbld = System.Text.StringBuilder  
Imports dirinf = System.IO.DirectoryInfo
```

```
Public Function GetFolders() As String
    Dim sb As New StrBld

    Dim dInfo As New DirInf("c:\")
    For Each dir As DirInf In dInfo.GetDirectories()
        sb.Append(dir.Name)
        sb.Append(ControlChars.CrLf)
    Next

    Return sb.ToString
End Function
```

Imports Statement (XML Namespace)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Imports XML namespace prefixes for use in XML literals and XML axis properties.

Syntax

```
Imports <xmlns:xmlNamespacePrefix = "xmlNamespaceName">
```

Parts

`xmlNamespacePrefix`

Optional. The string by which XML elements and attributes can refer to `xmlNamespaceName`. If no `xmlNamespacePrefix` is supplied, the imported XML namespace is the default XML namespace. Must be a valid XML identifier. For more information, see [Names of Declared XML Elements and Attributes](#).

`xmlNamespaceName`

Required. The string identifying the XML namespace being imported.

Remarks

You can use the `Imports` statement to define global XML namespaces that you can use with XML literals and XML axis properties, or as parameters passed to the `GetXmlNamespace` operator. (For information about using the `Imports` statement to import an alias that can be used where type names are used in your code, see [Imports Statement \(.NET Namespace and Type\)](#).) The syntax for declaring an XML namespace by using the `Imports` statement is identical to the syntax used in XML. Therefore, you can copy a namespace declaration from an XML file and use it in an `Imports` statement.

XML namespace prefixes are useful when you want to repeatedly create XML elements that are from the same namespace. The XML namespace prefix declared with the `Imports` statement is global in the sense that it is available to all code in the file. You can use it when you create XML element literals and when you access XML axis properties. For more information, see [XML Element Literal](#) and [XML Axis Properties](#).

If you define a global XML namespace without a namespace prefix (for example,

```
Imports <xmlns="http://SomeNameSpace"> ), that namespace is considered the default XML namespace. The default XML namespace is used for any XML element literals or XML attribute axis properties that do not explicitly specify a namespace. The default namespace is also used if the specified namespace is the empty namespace (that is, xmlns="" ). The default XML namespace does not apply to XML attributes in XML literals or to XML attribute axis properties that do not have a namespace.
```

XML namespaces that are defined in an XML literal, which are called *local XML namespaces*, take precedence over XML namespaces that are defined by the `Imports` statement as global. XML namespaces that are defined by the `Imports` statement take precedence over XML namespaces imported for a Visual Basic project. If an XML literal defines an XML namespace, that local namespace does not apply to embedded expressions.

Global XML namespaces follow the same scoping and definition rules as .NET Framework namespaces. As a result, you can include an `Imports` statement to define a global XML namespace anywhere you can import a .NET Framework namespace. This includes both code files and project-level imported namespaces. For information about project-level imported namespaces, see [References Page, Project Designer \(Visual Basic\)](#).

Each source file can contain any number of `Imports` statements. These must follow option declarations, such as the `Option Strict` statement, and they must precede programming element declarations, such as `Module` or `Class` statements.

Example

The following example imports a default XML namespace and an XML namespace identified with the prefix `ns`. It then creates XML literals that use both namespaces.

```
' Place Imports statements at the top of your program.
Imports <xmlns="http://DefaultNamespace">
Imports <xmlns:ns="http://NewNamespace">

Module Module1

    Sub Main()
        ' Create element by using the default global XML namespace.
        Dim inner = <innerElement/>

        ' Create element by using both the default global XML namespace
        ' and the namespace identified with the "ns" prefix.
        Dim outer = <ns:outer>
            <ns:innerElement></ns:innerElement>
            <siblingElement></siblingElement>
            <%= inner %>
        </ns:outer>

        ' Display element to see its final form.
        Console.WriteLine(outer)
    End Sub

End Module
```

This code displays the following text:

```
<ns:outer xmlns="http://DefaultNamespace"
           xmlns:ns="http://NewNamespace">
    <ns:innerElement></ns:innerElement>
    <siblingElement></siblingElement>
    <innerElement />
</ns:outer>
```

Example

The following example imports the XML namespace prefix `ns`. It then creates an XML literal that uses the namespace prefix and displays the element's final form.

```

' Place Imports statements at the top of your program.
Imports <xmlns:ns="http://SomeNamespace">

Class TestClass1

    Shared Sub TestPrefix()
        ' Create test using a global XML namespace prefix.
        Dim inner2 = <ns:inner2/>

        Dim test =
            <ns:outer>
                <ns:middle xmlns:ns="http://NewNamespace">
                    <ns:inner1/>
                    <%= inner2 %>
                </ns:middle>
            </ns:outer>

        ' Display test to see its final form.
        Console.WriteLine(test)
    End Sub

End Class

```

This code displays the following text:

```

<ns:outer xmlns:ns="http://SomeNamespace">
    <ns:middle xmlns:ns="http://NewNamespace">
        <ns:inner1 />
        <inner2 xmlns="http://SomeNamespace" />
    </ns:middle>
</ns:outer>

```

Notice that the compiler converted the XML namespace prefix from a global prefix to a local prefix definition.

Example

The following example imports the XML namespace prefix `ns`. It then uses the prefix of the namespace to create an XML literal and access the first child node with the qualified name `ns:name`.

```

Imports <xmlns:ns = "http://SomeNamespace">

Class TestClass4

    Shared Sub TestPrefix()
        Dim contact = <ns:contact>
            <ns:name>Patrick Hines</ns:name>
        </ns:contact>
        Console.WriteLine(contact.<ns:name>.Value)
    End Sub

End Class

```

This code displays the following text:

`Patrick Hines`

Inherits Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Causes the current class or interface to inherit the attributes, variables, properties, procedures, and events from another class or set of interfaces.

Syntax

```
Inherits basetypenames
```

Parts

TERM	DEFINITION
<code>basetypenames</code>	Required. The name of the class from which this class derives. -or- The names of the interfaces from which this interface derives. Use commas to separate multiple names.

Remarks

If used, the `Inherits` statement must be the first non-blank, non-comment line in a class or interface definition. It should immediately follow the `Class` or `Interface` statement.

You can use `Inherits` only in a class or interface. This means the declaration context for an inheritance cannot be a source file, namespace, structure, module, procedure, or block.

Rules

- **Class Inheritance.** If a class uses the `Inherits` statement, you can specify only one base class.

A class cannot inherit from a class nested within it.

- **Interface Inheritance.** If an interface uses the `Inherits` statement, you can specify one or more base interfaces. You can inherit from two interfaces even if they each define a member with the same name. If you do so, the implementing code must use name qualification to specify which member it is implementing.

An interface cannot inherit from another interface with a more restrictive access level. For example, a `Public` interface cannot inherit from a `Friend` interface.

An interface cannot inherit from an interface nested within it.

An example of class inheritance in the .NET Framework is the `ArgumentException` class, which inherits from the `SystemException` class. This provides to `ArgumentException` all the predefined properties and procedures required by system exceptions, such as the `Message` property and the `ToString` method.

An example of interface inheritance in the .NET Framework is the `ICollection` interface, which inherits from the

[IEnumerable](#) interface. This causes [ICollection](#) to inherit the definition of the enumerator required to traverse a collection.

Example

The following example uses the `Inherits` statement to show how a class named `thisClass` can inherit all the members of a base class named `anotherClass`.

```
Public Class thisClass
    Inherits anotherClass
    ' Add code to override, overload, or extend members
    ' inherited from the base class.
    ' Add new variable, property, procedure, and event declarations.
End Class
```

Example

The following example shows inheritance of multiple interfaces.

```
Public Interface thisInterface
    Inherits IComparable, IDisposable, IFormattable
    ' Add new property, procedure, and event definitions.
End Interface
```

The interface named `thisInterface` now includes all the definitions in the [IComparable](#), [IDisposable](#), and [IFormattable](#) interfaces. The inherited members provide respectively for type-specific comparison of two objects, releasing allocated resources, and expressing the value of an object as a `String`. A class that implements `thisInterface` must implement every member of every base interface.

Interface Statement (Visual Basic)

2/28/2019 • 5 minutes to read • [Edit Online](#)

Declares the name of an interface and introduces the definitions of the members that the interface comprises.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ Shadows ] _  
Interface name [ ( Of typelist ) ]  
    [ Inherits interfacenames ]  
    [ [ modifiers ] Property membername ]  
    [ [ modifiers ] Function membername ]  
    [ [ modifiers ] Sub membername ]  
    [ [ modifiers ] Event membername ]  
    [ [ modifiers ] Interface membername ]  
    [ [ modifiers ] Class membername ]  
    [ [ modifiers ] Structure membername ]  
End Interface
```

Parts

TERM	DEFINITION
<code>attributelist</code>	Optional. See Attribute List .
<code>accessmodifier</code>	Optional. Can be one of the following: <ul style="list-style-type: none">- Public- Protected- Friend- Private- Protected Friend- Private Protected See Access levels in Visual Basic .
<code>Shadows</code>	Optional. See Shadows .
<code>name</code>	Required. Name of this interface. See Declared Element Names .
<code>of</code>	Optional. Specifies that this is a generic interface.
<code>typelist</code>	Required if you use the <code>Of</code> keyword. List of type parameters for this interface. Optionally, each type parameter can be declared variant by using <code>In</code> and <code>out</code> generic modifiers. See Type List .
<code>Inherits</code>	Optional. Indicates that this interface inherits the attributes and members of another interface or interfaces. See Inherits Statement .

TERM	DEFINITION
<code>interfacenames</code>	Required if you use the <code>Inherits</code> statement. The names of the interfaces from which this interface derives.
<code>modifiers</code>	Optional. Appropriate modifiers for the interface member being defined.
<code>Property</code>	Optional. Defines a property that is a member of the interface.
<code>Function</code>	Optional. Defines a <code>Function</code> procedure that is a member of the interface.
<code>Sub</code>	Optional. Defines a <code>Sub</code> procedure that is a member of the interface.
<code>Event</code>	Optional. Defines an event that is a member of the interface.
<code>Interface</code>	Optional. Defines an interface that is a nested within this interface. The nested interface definition must terminate with an <code>End Interface</code> statement.
<code>Class</code>	Optional. Defines a class that is a member of the interface. The member class definition must terminate with an <code>End Class</code> statement.
<code>Structure</code>	Optional. Defines a structure that is a member of the interface. The member structure definition must terminate with an <code>End Structure</code> statement.
<code>membername</code>	Required for each property, procedure, event, interface, class, or structure defined as a member of the interface. The name of the member.
<code>End Interface</code>	Terminates the <code>Interface</code> definition.

Remarks

An *interface* defines a set of members, such as properties and procedures, that classes and structures can implement. The interface defines only the signatures of the members and not their internal workings.

A class or structure implements the interface by supplying code for every member defined by the interface. Finally, when the application creates an instance from that class or structure, an object exists and runs in memory. For more information, see [Objects and Classes](#) and [Interfaces](#).

You can use `Interface` only at namespace or module level. This means the *declaration context* for an interface must be a source file, namespace, class, structure, module, or interface, and cannot be a procedure or block. For more information, see [Declaration Contexts and Default Access Levels](#).

Interfaces default to [Friend](#) access. You can adjust their access levels with the access modifiers. For more information, see [Access levels in Visual Basic](#).

Rules

- **Nesting Interfaces.** You can define one interface within another. The outer interface is called the *containing interface*, and the inner interface is called a *nested interface*.
- **Member Declaration.** When you declare a property or procedure as a member of an interface, you are defining only the *signature* of that property or procedure. This includes the element type (property or procedure), its parameters and parameter types, and its return type. Because of this, the member definition uses only one line of code, and terminating statements such as `End Function` or `End Property` are not valid in an interface.

In contrast, when you define an enumeration or structure, or a nested class or interface, it is necessary to include their data members.

- **Member Modifiers.** You cannot use any access modifiers when defining module members, nor can you specify `Shared` or any procedure modifier except `Overloads`. You can declare any member with `Shadows`, and you can use `Default` when defining a property, as well as `ReadOnly` or `WriteOnly`.
- **Inheritance.** If the interface uses the [Inherits Statement](#), you can specify one or more base interfaces. You can inherit from two interfaces even if they each define a member with the same name. If you do so, the implementing code must use name qualification to specify which member it is implementing.

An interface cannot inherit from another interface with a more restrictive access level. For example, a `Public` interface cannot inherit from a `Friend` interface.

An interface cannot inherit from an interface nested within it.

- **Implementation.** When a class uses the [Implements](#) statement to implement this interface, it must implement every member defined within the interface. Furthermore, each signature in the implementing code must exactly match the corresponding signature defined in this interface. However, the name of the member in the implementing code does not have to match the member name as defined in the interface.

When a class is implementing a procedure, it cannot designate the procedure as `Shared`.

- **Default Property.** An interface can specify at most one property as its *default property*, which can be referenced without using the property name. You specify such a property by declaring it with the `Default` modifier.

Notice that this means that an interface can define a default property only if it inherits none.

Behavior

- **Access Level.** All interface members implicitly have `Public` access. You cannot use any access modifier when defining a member. However, a class implementing the interface can declare an access level for each implemented member.

If you assign a class instance to a variable, the access level of its members can depend on whether the data type of the variable is the underlying interface or the implementing class. The following example illustrates this.

```

Public Interface IDemo
    Sub doSomething()
End Interface
Public Class implementIDemo
    Implements IDemo
    Private Sub doSomething() Implements IDemo.doSomething
    End Sub
End Class
Dim varAsInterface As IDemo = New implementIDemo()
Dim varAsClass As implementIDemo = New implementIDemo()

```

If you access class members through `varAsInterface`, they all have public access. However, if you access members through `varAsClass`, the `Sub` procedure `doSomething` has private access.

- **Scope.** An interface is in scope throughout its namespace, class, structure, or module.

The scope of every interface member is the entire interface.

- **Lifetime.** An interface does not itself have a lifetime, nor do its members. When a class implements an interface and an object is created as an instance of that class, the object has a lifetime within the application in which it is running. For more information, see "Lifetime" in [Class Statement](#).

Example

The following example uses the `Interface` statement to define an interface named `thisInterface`, which must be implemented with a `Property` statement and a `Function` statement.

```

Public Interface thisInterface
    Property thisProp(ByVal thisStr As String) As Char
    Function thisFunc(ByVal thisInt As Integer) As Integer
End Interface

```

Note that the `Property` and `Function` statements do not introduce blocks ending with `End Property` and `End Function` within the interface. The interface defines only the signatures of its members. The full `Property` and `Function` blocks appear in a class that implements `thisInterface`.

Mid Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Replaces a specified number of characters in a `String` variable with characters from another string.

Syntax

```
Mid( _
    ByRef Target As String, _
    ByVal Start As Integer, _
    Optional ByVal Length As Integer _
) = StringExpression
```

Parts

`Target`

Required. Name of the `String` variable to modify.

`Start`

Required. `Integer` expression. Character position in `Target` where the replacement of text begins. `Start` uses a one-based index.

`Length`

Optional. `Integer` expression. Number of characters to replace. If omitted, all of `String` is used.

`StringExpression`

Required. `String` expression that replaces part of `Target`.

Exceptions

EXCEPTION TYPE	CONDITION
<code>ArgumentException</code>	<code>Start</code> <= 0 or <code>Length</code> < 0.

Remarks

The number of characters replaced is always less than or equal to the number of characters in `Target`.

Visual Basic has a `Mid` function and a `Mid` statement. These elements both operate on a specified number of characters in a string, but the `Mid` function returns the characters while the `Mid` statement replaces the characters. For more information, see [Mid](#).

NOTE

The `MidB` statement of earlier versions of Visual Basic replaces a substring in bytes, rather than characters. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic strings are in Unicode, and `MidB` is no longer supported.

Example

This example uses the `Mid` statement to replace a specified number of characters in a string variable with characters from another string.

```
Dim TestString As String
' Initializes string.
TestString = "The dog jumps"
' Returns "The fox jumps".
Mid(TestString, 5, 3) = "fox"
' Returns "The cow jumps".
Mid(TestString, 5) = "cow"
' Returns "The cow jumpe".
Mid(TestString, 5) = "cow jumped over"
' Returns "The duc jumpe".
Mid(TestString, 5, 3) = "duck"
```

Module Statement

2/28/2019 • 3 minutes to read • [Edit Online](#)

Declares the name of a module and introduces the definition of the variables, properties, events, and procedures that the module comprises.

Syntax

```
[ <attributelist> ] [ accessmodifier ] Module name  
[ statements ]  
End Module
```

Parts

`attributelist`

Optional. See [Attribute List](#).

`accessmodifier`

Optional. Can be one of the following:

- [Public](#)
- [Friend](#)

See [Access levels in Visual Basic](#).

`name`

Required. Name of this module. See [Declared Element Names](#).

`statements`

Optional. Statements which define the variables, properties, events, procedures, and nested types of this module.

`End Module`

Terminates the `Module` definition.

Remarks

A `Module` statement defines a reference type available throughout its namespace. A *module* (sometimes called a *standard module*) is similar to a class but with some important distinctions. Every module has exactly one instance and does not need to be created or assigned to a variable. Modules do not support inheritance or implement interfaces. Notice that a module is not a *type* in the sense that a class or structure is — you cannot declare a programming element to have the data type of a module.

You can use `Module` only at namespace level. This means the *declaration context* for a module must be a source file or namespace, and cannot be a class, structure, module, interface, procedure, or block. You cannot nest a module within another module, or within any type. For more information, see [Declaration Contexts and Default Access Levels](#).

A module has the same lifetime as your program. Because its members are all `Shared`, they also have lifetimes equal to that of the program.

Modules default to [Friend](#) access. You can adjust their access levels with the access modifiers. For more information, see [Access levels in Visual Basic](#).

All members of a module are implicitly [Shared](#).

Classes and Modules

These elements have many similarities, but there are some important differences as well.

- **Terminology.** Previous versions of Visual Basic recognize two types of modules: *class modules* (.cls files) and *standard modules* (.bas files). The current version calls these *classes* and *modules*, respectively.
- **Shared Members.** You can control whether a member of a class is a shared or instance member.
- **Object Orientation.** Classes are object-oriented, but modules are not. So only classes can be instantiated as objects. For more information, see [Objects and Classes](#).

Rules

- **Modifiers.** All module members are implicitly [Shared](#). You cannot use the [Shared](#) keyword when declaring a member, and you cannot alter the shared status of any member.
- **Inheritance.** A module cannot inherit from any type other than [Object](#), from which all modules inherit. In particular, one module cannot inherit from another.
You cannot use the [Inherits Statement](#) in a module definition, even to specify [Object](#).
- **Default Property.** You cannot define any default properties in a module. For more information, see [Default](#).

Behavior

- **Access Level.** Within a module, you can declare each member with its own access level. Module members default to [Public](#) access, except variables and constants, which default to [Private](#) access. When a module has more restricted access than one of its members, the specified module access level takes precedence.
- **Scope.** A module is in scope throughout its namespace.

The scope of every module member is the entire module. Notice that all members undergo *type promotion*, which causes their scope to be promoted to the namespace containing the module. For more information, see [Type Promotion](#).

- **Qualification.** You can have multiple modules in a project, and you can declare members with the same name in two or more modules. However, you must qualify any reference to such a member with the appropriate module name if the reference is from outside that module. For more information, see [References to Declared Elements](#).

Example

```
Public Module thisModule
    Sub Main()
        Dim userName As String = InputBox("What is your name?")
        MsgBox("User name is" & userName)
    End Sub
    ' Insert variable, property, procedure, and event declarations.
End Module
```

Namespace Statement

2/28/2019 • 4 minutes to read • [Edit Online](#)

Declares the name of a namespace and causes the source code that follows the declaration to be compiled within that namespace.

Syntax

```
Namespace [Global.] { name | name.name }
    [ componenttypes ]
End Namespace
```

Parts

Global

Optional. Allows you to define a namespace out of the root namespace of your project. See [Namespaces in Visual Basic](#).

name

Required. A unique name that identifies the namespace. Must be a valid Visual Basic identifier. For more information, see [Declared Element Names](#).

componenttypes

Optional. Elements that make up the namespace. These include, but are not limited to, enumerations, structures, interfaces, classes, modules, delegates, and other namespaces.

End Namespace

Terminates a `Namespace` block.

Remarks

Namespaces are used as an organizational system. They provide a way to classify and present programming elements that are exposed to other programs and applications. Note that a namespace is not a *type* in the sense that a class or structure is—you cannot declare a programming element to have the data type of a namespace.

All programming elements declared after a `Namespace` statement belong to that namespace. Visual Basic continues to compile elements into the last declared namespace until it encounters either an `End Namespace` statement or another `Namespace` statement.

If a namespace is already defined, even outside your project, you can add programming elements to it. To do this, you use a `Namespace` statement to direct Visual Basic to compile elements into that namespace.

You can use a `Namespace` statement only at the file or namespace level. This means the *declaration context* for a namespace must be a source file or another namespace, and cannot be a class, structure, module, interface, or procedure. For more information, see [Declaration Contexts and Default Access Levels](#).

You can declare one namespace within another. There is no strict limit to the levels of nesting you can declare, but remember that when other code accesses the elements declared in the innermost namespace, it must use a qualification string that contains all the namespace names in the nesting hierarchy.

Access Level

Namespaces are treated as if they have a `Public` access level. A namespace can be accessed from code anywhere in the same project, from other projects that reference the project, and from any assembly built from the project.

Programming elements declared at namespace level, meaning in a namespace but not inside any other element, can have `Public` or `Friend` access. If unspecified, the access level of such an element uses `Friend` by default. Elements you can declare at namespace level include classes, structures, modules, interfaces, enumerations, and delegates. For more information, see [Declaration Contexts and Default Access Levels](#).

Root Namespace

All namespace names in your project are based on a *root namespace*. Visual Studio assigns your project name as the default root namespace for all code in your project. For example, if your project is named `Payroll`, its programming elements belong to namespace `Payroll`. If you declare `Namespace funding`, the full name of that namespace is `Payroll.funding`.

If you want to specify an existing namespace in a `Namespace` statement, such as in the generic list class example, you can set your root namespace to a null value. To do this, click **Project Properties** from the **Project** menu and then clear the **Root namespace** entry so that the box is empty. If you did not do this in the generic list class example, the Visual Basic compiler would take `System.Collections.Generic` as a new namespace within project `Payroll`, with the full name of `Payroll.System.Collections.Generic`.

Alternatively, you can use the `Global` keyword to refer to elements of namespaces defined outside your project. Doing so lets you retain your project name as the root namespace. This reduces the chance of unintentionally merging your programming elements together with those of existing namespaces. For more information, see the "Global Keyword in Fully Qualified Names" section in [Namespaces in Visual Basic](#).

The `Global` keyword can also be used in a Namespace statement. This lets you define a namespace out of the root namespace of your project. For more information, see the "Global Keyword in Namespace Statements" section in [Namespaces in Visual Basic](#).

Troubleshooting. The root namespace can lead to unexpected concatenations of namespace names. If you make reference to namespaces defined outside your project, the Visual Basic compiler can construe them as nested namespaces in the root namespace. In such a case, the compiler does not recognize any types that have been already defined in the external namespaces. To avoid this, either set your root namespace to a null value as described in "Root Namespace," or use the `Global` keyword to access elements of external namespaces.

Attributes and Modifiers

You cannot apply attributes to a namespace. An attribute contributes information to the assembly's metadata, which is not meaningful for source classifiers such as namespaces.

You cannot apply any access or procedure modifiers, or any other modifiers, to a namespace. Because it is not a type, these modifiers are not meaningful.

Example

The following example declares two namespaces, one nested in the other.

```
Namespace n1
    Namespace n2
        Class a
            ' Insert class definition.
        End Class
    End Namespace
End Namespace
```

Example

The following example declares multiple nested namespaces on a single line, and it is equivalent to the previous example.

```
Namespace n1.n2
    Class a
        ' Insert class definition.
    End Class
End Namespace
```

Example

The following example accesses the class defined in the previous examples.

```
Dim instance As New n1.n2.a
```

Example

The following example defines the skeleton of a new generic list class and adds it to the [System.Collections.Generic](#) namespace.

```
Namespace System.Collections.Generic
    Class specialSortedList(Of T)
        Inherits List(Of T)
        ' Insert code to define the special generic list class.
    End Class
End Namespace
```

On Error Statement (Visual Basic)

3/1/2019 • 7 minutes to read • [Edit Online](#)

Enables an error-handling routine and specifies the location of the routine within a procedure; can also be used to disable an error-handling routine.

Without error handling, any run-time error that occurs is fatal: an error message is displayed, and execution stops.

Whenever possible, we suggest you use structured exception handling in your code, rather than using unstructured exception handling and the `On Error` statement. For more information, see [Try...Catch...Finally Statement](#).

NOTE

The `Error` keyword is also used in the [Error Statement](#), which is supported for backward compatibility.

Syntax

```
On Error { GoTo [ line | 0 | -1 ] | Resume Next }
```

Parts

TERM	DEFINITION
<code>GoTo</code> <code>line</code>	Enables the error-handling routine that starts at the line specified in the required <code>line</code> argument. The <code>line</code> argument is any line label or line number. If a run-time error occurs, control branches to the specified line, making the error handler active. The specified line must be in the same procedure as the <code>On Error</code> statement, or a compile-time error will occur.
<code>GoTo</code> <code>0</code>	Disables enabled error handler in the current procedure and resets it to <code>Nothing</code> .
<code>GoTo</code> <code>-1</code>	Disables enabled exception in the current procedure and resets it to <code>Nothing</code> .
<code>Resume Next</code>	Specifies that when a run-time error occurs, control goes to the statement immediately following the statement where the error occurred, and execution continues from that point. Use this form rather than <code>On Error GoTo</code> when accessing objects.

Remarks

NOTE

We recommend that you use structured exception handling in your code whenever possible, rather than using unstructured exception handling and the `On Error` statement. For more information, see [Try...Catch...Finally Statement](#).

An "enabled" error handler is one that is turned on by an `On Error` statement. An "active" error handler is an enabled handler that is in the process of handling an error.

If an error occurs while an error handler is active (between the occurrence of the error and a `Resume`, `Exit Sub`, `Exit Function`, or `Exit Property` statement), the current procedure's error handler cannot handle the error. Control returns to the calling procedure.

If the calling procedure has an enabled error handler, it is activated to handle the error. If the calling procedure's error handler is also active, control passes back through previous calling procedures until an enabled, but inactive, error handler is found. If no such error handler is found, the error is fatal at the point at which it actually occurred.

Each time the error handler passes control back to a calling procedure, that procedure becomes the current procedure. Once an error is handled by an error handler in any procedure, execution resumes in the current procedure at the point designated by the `Resume` statement.

NOTE

An error-handling routine is not a `Sub` procedure or a `Function` procedure. It is a section of code marked by a line label or a line number.

Number Property

Error-handling routines rely on the value in the `Number` property of the `Err` object to determine the cause of the error. The routine should test or save relevant property values in the `Err` object before any other error can occur or before a procedure that might cause an error is called. The property values in the `Err` object reflect only the most recent error. The error message associated with `Err.Number` is contained in `Err.Description`.

Throw Statement

An error that is raised with the `Err.Raise` method sets the `Exception` property to a newly created instance of the `Exception` class. In order to support the raising of exceptions of derived exception types, a `Throw` statement is supported in the language. This takes a single parameter that is the exception instance to be thrown. The following example shows how these features can be used with the existing exception handling support:

```
On Error GoTo Handler
Throw New DivideByZeroException()
Handler:
  If (TypeOf Err.GetException() Is DivideByZeroException) Then
    ' Code for handling the error is entered here.
  End If
```

Notice that the `On Error GoTo` statement traps all errors, regardless of the exception class.

On Error Resume Next

`On Error Resume Next` causes execution to continue with the statement immediately following the statement that caused the run-time error, or with the statement immediately following the most recent call out of the procedure

containing the `On Error Resume Next` statement. This statement allows execution to continue despite a run-time error. You can place the error-handling routine where the error would occur rather than transferring control to another location within the procedure. An `On Error Resume Next` statement becomes inactive when another procedure is called, so you should execute an `On Error Resume Next` statement in each called routine if you want inline error handling within that routine.

NOTE

The `On Error Resume Next` construct may be preferable to `On Error GoTo` when handling errors generated during access to other objects. Checking `Err` after each interaction with an object removes ambiguity about which object was accessed by the code. You can be sure which object placed the error code in `Err.Number`, as well as which object originally generated the error (the object specified in `Err.Source`).

On Error GoTo 0

`On Error GoTo 0` disables error handling in the current procedure. It doesn't specify line 0 as the start of the error-handling code, even if the procedure contains a line numbered 0. Without an `On Error GoTo 0` statement, an error handler is automatically disabled when a procedure is exited.

On Error GoTo -1

`On Error GoTo -1` disables the exception in the current procedure. It does not specify line -1 as the start of the error-handling code, even if the procedure contains a line numbered -1. Without an `On Error GoTo -1` statement, an exception is automatically disabled when a procedure is exited.

To prevent error-handling code from running when no error has occurred, place an `Exit Sub`, `Exit Function`, or `Exit Property` statement immediately before the error-handling routine, as in the following fragment:

```
Public Sub InitializeMatrix(ByVal Var1 As Object, ByVal Var2 As Object)
    On Error GoTo ErrorHandler
    ' Insert code that might generate an error here
    Exit Sub
ErrorHandler:
    ' Insert code to handle the error here
    Resume Next
End Sub
```

Here, the error-handling code follows the `Exit Sub` statement and precedes the `End Sub` statement to separate it from the procedure flow. You can place error-handling code anywhere in a procedure.

Untrapped Errors

Untrapped errors in objects are returned to the controlling application when the object is running as an executable file. Within the development environment, untrapped errors are returned to the controlling application only if the proper options are set. See your host application's documentation for a description of which options should be set during debugging, how to set them, and whether the host can create classes.

If you create an object that accesses other objects, you should try to handle any unhandled errors they pass back. If you cannot, map the error codes in `Err.Number` to one of your own errors and then pass them back to the caller of your object. You should specify your error by adding your error code to the `vbObjectError` constant. For example, if your error code is 1052, assign it as follows:

```
Err.Number = vbObjectError + 1052
```

Caution

System errors during calls to Windows dynamic-link libraries (DLLs) do not raise exceptions and cannot be trapped with Visual Basic error trapping. When calling DLL functions, you should check each return value for success or failure (according to the API specifications), and in the event of a failure, check the value in the [Err](#) object's [LastDLError](#) property.

Example

This example first uses the [On Error GoTo](#) statement to specify the location of an error-handling routine within a procedure. In the example, an attempt to divide by zero generates error number 6. The error is handled in the error-handling routine, and control is then returned to the statement that caused the error. The [On Error GoTo 0](#) statement turns off error trapping. Then the [On Error Resume Next](#) statement is used to defer error trapping so that the context for the error generated by the next statement can be known for certain. Note that [Err.Clear](#) is used to clear the [Err](#) object's properties after the error is handled.

```
Public Sub OnErrorDemo()
    On Error GoTo ErrorHandler      ' Enable error-handling routine.
    Dim x As Integer = 32
    Dim y As Integer = 0
    Dim z As Integer
    z = x / y      ' Creates a divide by zero error
    On Error GoTo 0      ' Turn off error trapping.
    On Error Resume Next      ' Defer error trapping.
    z = x / y      ' Creates a divide by zero error again
    If Err.Number = 6 Then
        ' Tell user what happened. Then clear the Err object.
        Dim Msg As String
        Msg = "There was an error attempting to divide by zero!"
        MsgBox(Msg, , "Divide by zero error")
        Err.Clear() ' Clear Err object fields.
    End If
    Exit Sub      ' Exit to avoid handler.
ErrorHandler:  ' Error-handling routine.
    Select Case Err.Number      ' Evaluate error number.
        Case 6      ' Divide by zero error
            MsgBox("You attempted to divide by zero!")
            ' Insert code to handle this error
        Case Else
            ' Insert code to handle other situations here...
    End Select
    Resume Next      ' Resume execution at the statement immediately
                    ' following the statement where the error occurred.
End Sub
```

Operator Statement

2/28/2019 • 5 minutes to read • [Edit Online](#)

Declares the operator symbol, operands, and code that define an operator procedure on a class or structure.

Syntax

```
[ <attrlist> ] Public [ Overloads ] Shared [ Shadows ] [ Widening | Narrowing ]
Operator operatorsymbol ( operand1 [, operand2 ]) [ As [ <attrlist> ] type ]
    [ statements ]
    [ statements ]
    Return returnvalue
    [ statements ]
End Operator
```

Parts

attrlist

Optional. See [Attribute List](#).

Public

Required. Indicates that this operator procedure has [Public](#) access.

Overloads

Optional. See [Overloads](#).

Shared

Required. Indicates that this operator procedure is a [Shared](#) procedure.

Shadows

Optional. See [Shadows](#).

Widening

Required for a conversion operator unless you specify **Narrowing**. Indicates that this operator procedure defines a [Widening](#) conversion. See "Widening and Narrowing Conversions" on this Help page.

Narrowing

Required for a conversion operator unless you specify **Widening**. Indicates that this operator procedure defines a [Narrowing](#) conversion. See "Widening and Narrowing Conversions" on this Help page.

operatorsymbol

Required. The symbol or identifier of the operator that this operator procedure defines.

operand1

Required. The name and type of the single operand of a unary operator (including a conversion operator) or the left operand of a binary operator.

operand2

Required for binary operators. The name and type of the right operand of a binary operator.

operand1 and **operand2** have the following syntax and parts:

[**ByVal**] operandname [As operandtype]

PART	DESCRIPTION
<code>ByVal</code>	Optional, but the passing mechanism must be <code>ByVal</code> .
<code>operandname</code>	Required. Name of the variable representing this operand. See Declared Element Names .
<code>operandtype</code>	Optional unless <code>Option Strict</code> is <code>On</code> . Data type of this operand.

`type`

Optional unless `Option Strict` is `on`. Data type of the value the operator procedure returns.

`statements`

Optional. Block of statements that the operator procedure runs.

`returnValue`

Required. The value that the operator procedure returns to the calling code.

`End Operator`

Required. Terminates the definition of this operator procedure.

Remarks

You can use `Operator` only in a class or structure. This means the *declaration context* for an operator cannot be a source file, namespace, module, interface, procedure, or block. For more information, see [Declaration Contexts and Default Access Levels](#).

All operators must be `Public Shared`. You cannot specify `ByRef`, `Optional`, or `ParamArray` for either operand.

You cannot use the operator symbol or identifier to hold a return value. You must use the `Return` statement, and it must specify a value. Any number of `Return` statements can appear anywhere in the procedure.

Defining an operator in this way is called *operator overloading*, whether or not you use the `Overloads` keyword. The following table lists the operators you can define.

TYPE	OPERATORS
Unary	<code>+</code> , <code>-</code> , <code>IsFalse</code> , <code>IsTrue</code> , <code>Not</code>
Binary	<code>+</code> , <code>-</code> , <code>*</code> , <code>/</code> , <code>\</code> , <code>&</code> , <code>^</code> , <code>>></code> , <code><<</code> , <code>=</code> , <code><></code> , <code>></code> , <code>>=</code> , <code><</code> , <code><=</code> , <code>And</code> , <code>Like</code> , <code>Mod</code> , <code>Or</code> , <code>Xor</code>
Conversion (unary)	<code>CType</code>

Note that the `=` operator in the binary list is the comparison operator, not the assignment operator.

When you define `CType`, you must specify either `Widening` or `Narrowing`.

Matched Pairs

You must define certain operators as matched pairs. If you define either operator of such a pair, you must define the other as well. The matched pairs are the following:

- `=` and `<>`

- `>` and `<`
- `>=` and `<=`
- `IsTrue` and `IsFalse`

Data Type Restrictions

Every operator you define must involve the class or structure on which you define it. This means that the class or structure must appear as the data type of the following:

- The operand of a unary operator.
- At least one of the operands of a binary operator.
- Either the operand or the return type of a conversion operator.

Certain operators have additional data type restrictions, as follows:

- If you define the `IsTrue` and `IsFalse` operators, they must both return the `Boolean` type.
- If you define the `<<` and `>>` operators, they must both specify the `Integer` type for the `operandtype` of `operand2`.

The return type does not have to correspond to the type of either operand. For example, a comparison operator such as `=` or `<>` can return `Boolean` even if neither operand is `Boolean`.

Logical and Bitwise Operators

The `And`, `Or`, `Not`, and `Xor` operators can perform either logical or bitwise operations in Visual Basic. However, if you define one of these operators on a class or structure, you can define only its bitwise operation.

You cannot define the `AndAlso` operator directly with an `Operator` statement. However, you can use `AndAlso` if you have fulfilled the following conditions:

- You have defined `And` on the same operand types you want to use for `AndAlso`.
- Your definition of `And` returns the same type as the class or structure on which you have defined it.
- You have defined the `IsFalse` operator on the class or structure on which you have defined `And`.

Similarly, you can use `OrElse` if you have defined `or` on the same operands, with the return type of the class or structure, and you have defined `.IsTrue` on the class or structure.

Widening and Narrowing Conversions

A *widening conversion* always succeeds at run time, while a *narrowing conversion* can fail at run time. For more information, see [Widening and Narrowing Conversions](#).

If you declare a conversion procedure to be `Widening`, your procedure code must not generate any failures. This means the following:

- It must always return a valid value of type `type`.
- It must handle all possible exceptions and other error conditions.
- It must handle any error returns from any procedures it calls.

If there is any possibility that a conversion procedure might not succeed, or that it might cause an unhandled

exception, you must declare it to be [Narrowing](#).

Example

The following code example uses the `Operator` statement to define the outline of a structure that includes operator procedures for the `And`, `Or`, `IsFalse`, and `IsTrue` operators. `And` and `Or` each take two operands of type `abc` and return type `abc`. `IsFalse` and `IsTrue` each take a single operand of type `abc` and return `Boolean`. These definitions allow the calling code to use `And`, `AndAlso`, `Or`, and `OrElse` with operands of type `abc`.

```
Public Structure abc
    Dim d As Date
    Public Shared Operator And(ByVal x As abc, ByVal y As abc) As abc
        Dim r As New abc
        ' Insert code to calculate And of x and y.
        Return r
    End Operator
    Public Shared Operator Or(ByVal x As abc, ByVal y As abc) As abc
        Dim r As New abc
        ' Insert code to calculate Or of x and y.
        Return r
    End Operator
    Public Shared Operator IsFalse(ByVal z As abc) As Boolean
        Dim b As Boolean
        ' Insert code to calculate IsFalse of z.
        Return b
    End Operator
    Public Shared Operator IsTrue(ByVal z As abc) As Boolean
        Dim b As Boolean
        ' Insert code to calculate IsTrue of z.
        Return b
    End Operator
End Structure
```

Option <keyword> Statement

1/30/2019 • 2 minutes to read • [Edit Online](#)

Introduces a statement that specifies a compiler option that applies to the entire source file.

Remarks

The compiler options can control whether all variables must be explicitly declared, whether narrowing type conversions must be explicit, or whether strings should be compared as text or as binary quantities.

The `option` keyword can be used in these contexts:

[Option Explicit Statement](#)

[Option Infer Statement](#)

[Option Strict Statement](#)

Option Compare Statement

2/28/2019 • 3 minutes to read • [Edit Online](#)

Declares the default comparison method to use when comparing string data.

Syntax

```
Option Compare { Binary | Text }
```

Parts

TERM	DEFINITION
<code>Binary</code>	<p>Optional. Results in string comparisons based on a sort order derived from the internal binary representations of the characters.</p> <p>This type of comparison is useful especially if the strings can contain characters that are not to be interpreted as text. In this case, you do not want to bias comparisons with alphabetical equivalences, such as case insensitivity.</p>
<code>Text</code>	<p>Optional. Results in string comparisons based on a case-insensitive text sort order determined by your system's locale.</p> <p>This type of comparison is useful if your strings contain all text characters, and you want to compare them taking into account alphabetic equivalences such as case insensitivity and closely related letters. For example, you might want to consider <code>A</code> and <code>a</code> to be equal, and <code>Ä</code> and <code>ä</code> to come before <code>B</code> and <code>b</code>.</p>

Remarks

If used, the `Option Compare` statement must appear in a file before any other source code statements.

The `Option Compare` statement specifies the string comparison method (`Binary` or `Text`). The default text comparison method is `Binary`.

A `Binary` comparison compares the numeric Unicode value of each character in each string. A `Text` comparison compares each Unicode character based on its lexical meaning in the current culture.

In Microsoft Windows, sort order is determined by the code page. For more information, see [Code Pages](#).

In the following example, characters in the English/European code page (ANSI 1252) are sorted by using `Option Compare Binary`, which produces a typical binary sort order.

```
A < B < E < Z < a < b < e < z < Ä < Ê < Ø < à < ê < ø
```

When the same characters in the same code page are sorted by using `Option Compare Text`, the following text sort order is produced.

(A=a) < (À = à) < (B=b) < (E=e) < (Ê = ê) < (Z=z) < (Ø = ø)

When an Option Compare Statement Is Not Present

If the source code does not contain an `Option Compare` statement, the **Option Compare** setting on the [Compile Page, Project Designer \(Visual Basic\)](#) is used. If you use the command-line compiler, the setting specified by the `/optioncompare` compiler option is used.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To set Option Compare in the IDE

1. In **Solution Explorer**, select a project. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Set the value in the **Option Compare** box.

When you create a project, the **Option Compare** setting on the **Compile** tab is set to the **Option Compare** setting in the **Options** dialog box. To change this setting, on the **Tools** menu, click **Options**. In the **Options** dialog box, expand **Projects and Solutions**, and then click **VB Defaults**. The initial default setting in **VB Defaults** is **Binary**.

To set Option Compare on the command line

- Include the `/optioncompare` compiler option in the **vbc** command.

Example

The following example uses the `Option Compare` statement to set the binary comparison as the default string comparison method. To use this code, uncomment the `Option Compare Binary` statement, and put it at the top of the source file.

```
' Option Compare Binary  
  
Console.WriteLine("A" < "a")  
' Output: True
```

Example

The following example uses the `Option Compare` statement to set the case-insensitive text sort order as the default string comparison method. To use this code, uncomment the `Option Compare Text` statement, and put it at the top of the source file.

```
' Option Compare Text  
  
Console.WriteLine("A" = "a")  
' Output: True
```

Option Explicit Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Forces explicit declaration of all variables in a file, or allows implicit declarations of variables.

Syntax

```
Option Explicit { On | Off }
```

Parts

`On`

Optional. Enables `Option Explicit` checking. If `on` or `off` is not specified, the default is `on`.

`Off`

Optional. Disables `Option Explicit` checking.

Remarks

When `Option Explicit On` or `Option Explicit` appears in a file, you must explicitly declare all variables by using the `Dim` or `ReDim` statements. If you try to use an undeclared variable name, an error occurs at compile time.

The `Option Explicit Off` statement allows implicit declaration of variables.

If used, the `Option Explicit` statement must appear in a file before any other source code statements.

NOTE

Setting `Option Explicit` to `off` is generally not a good practice. You could misspell a variable name in one or more locations, which would cause unexpected results when the program is run.

When an Option Explicit Statement Is Not Present

If the source code does not contain an `Option Explicit` statement, the **Option Explicit** setting on the [Compile Page, Project Designer \(Visual Basic\)](#) is used. If the command-line compiler is used, the `/optionexplicit` compiler option is used.

To set Option Explicit in the IDE

1. In **Solution Explorer**, select a project. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Set the value in the **Option Explicit** box.

When you create a new project, the **Option Explicit** setting on the **Compile** tab is set to the **Option Explicit** setting in the **VB Defaults** dialog box. To access the **VB Defaults** dialog box, on the **Tools** menu, click **Options**. In the **Options** dialog box, expand **Projects and Solutions**, and then click **VB Defaults**. The initial default setting in **VB Defaults** is `On`.

To set Option Explicit on the command line

- Include the `/optionexplicit` compiler option in the **vbc** command.

Example

The following example uses the `Option Explicit` statement to force explicit declaration of all variables.

Attempting to use an undeclared variable causes an error at compile time.

```
' Force explicit variable declaration.  
Option Explicit On
```

```
Dim thisVar As Integer  
thisVar = 10  
' The following assignment produces a COMPILER ERROR because  
' the variable is not declared and Option Explicit is On.  
thisInt = 10 ' causes ERROR
```

Option Infer Statement

2/28/2019 • 4 minutes to read • [Edit Online](#)

Enables the use of local type inference in declaring variables.

Syntax

```
Option Infer { On | Off }
```

Parts

TERM	DEFINITION
On	Optional. Enables local type inference.
Off	Optional. Disables local type inference.

Remarks

To set `Option Infer` in a file, type `Option Infer On` or `Option Infer Off` at the top of the file, before any other source code. If the value set for `Option Infer` in a file conflicts with the value set in the IDE or on the command line, the value in the file has precedence.

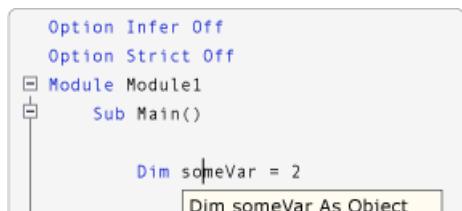

When you set `Option Infer` to `On`, you can declare local variables without explicitly stating a data type. The compiler infers the data type of a variable from the type of its initialization expression.

In the following illustration, `Option Infer` is turned on. The variable in the declaration `Dim someVar = 2` is declared as an integer by type inference.

IntelliSense when Option Infer is on

In the following illustration, `Option Infer` is turned off. The variable in the declaration `Dim someVar = 2` is declared as an `Object` by type inference. In this example, the **Option Strict** setting is set to **Off** on the [Compile Page, Project Designer \(Visual Basic\)](#).

IntelliSense when Option Infer is off

NOTE

When a variable is declared as an `Object`, the run-time type can change while the program is running. Visual Basic performs operations called *boxing* and *unboxing* to convert between an `Object` and a value type, which makes execution slower. For information about boxing and unboxing, see the [Visual Basic Language Specification](#).

Type inference applies at the procedure level, and does not apply outside a procedure in a class, structure, module, or interface.

For additional information, see [Local Type Inference](#).

When an Option Infer Statement Is Not Present

If the source code does not contain an `Option Infer` statement, the **Option Infer** setting on the [Compile Page](#), [Project Designer \(Visual Basic\)](#) is used. If the command-line compiler is used, the `/optioninfer` compiler option is used.

To set Option Infer in the IDE

1. In **Solution Explorer**, select a project. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Set the value in the **Option infer** box.

When you create a new project, the **Option Infer** setting on the **Compile** tab is set to the **Option Infer** setting in the **VB Defaults** dialog box. To access the **VB Defaults** dialog box, on the **Tools** menu, click **Options**. In the **Options** dialog box, expand **Projects and Solutions**, and then click **VB Defaults**. The initial default setting in **VB Defaults** is `On`.

To set Option Infer on the command line

- Include the `/optioninfer` compiler option in the `vbc` command.

Default Data Types and Values

The following table describes the results of various combinations of specifying the data type and initializer in a `Dim` statement.

DATA TYPE SPECIFIED?	INITIALIZER SPECIFIED?	EXAMPLE	RESULT
No	No	<code>Dim qty</code>	If <code>Option Strict</code> is off (the default), the variable is set to <code>Nothing</code> . If <code>Option Strict</code> is on, a compile-time error occurs.

DATA TYPE SPECIFIED?	INITIALIZER SPECIFIED?	EXAMPLE	RESULT
No	Yes	<code>Dim qty = 5</code>	<p>If <code>Option Infer</code> is on (the default), the variable takes the data type of the initializer. See Local Type Inference.</p> <p>If <code>Option Infer</code> is off and <code>Option Strict</code> is off, the variable takes the data type of <code>Object</code>.</p> <p>If <code>Option Infer</code> is off and <code>Option Strict</code> is on, a compile-time error occurs.</p>
Yes	No	<code>Dim qty As Integer</code>	The variable is initialized to the default value for the data type. For more information, see Dim Statement .
Yes	Yes	<code>Dim qty As Integer = 5</code>	If the data type of the initializer is not convertible to the specified data type, a compile-time error occurs.

Example

The following examples demonstrate how the `Option Infer` statement enables local type inference.

```

' Enable Option Infer before trying these examples.

' Variable num is an Integer.
Dim num = 5

' Variable dbl is a Double.
Dim dbl = 4.113

' Variable str is a String.
Dim str = "abc"

' Variable pList is an array of Process objects.
Dim pList = Process.GetProcesses()

' Variable i is an Integer.
For i = 1 To 10
    Console.WriteLine(i)
Next

' Variable item is a string.
Dim lst As New List(Of String) From {"abc", "def", "ghi"}

For Each item In lst
    Console.WriteLine(item)
Next

' Variable namedCust is an instance of the Customer class.
Dim namedCust = New Customer With {.Name = "Blue Yonder Airlines",
                                    .City = "Snoqualmie"}

' Variable product is an instance of an anonymous type.
Dim product = New With {Key .Name = "paperclips", .Price = 1.29}

' If customers is a collection of Customer objects in the following
' query, the inferred type of cust is Customer, and the inferred type
' of custs is IEnumerable(Of Customer).
Dim custs = From cust In customers
            Where cust.City = "Seattle"
            Select cust.Name, cust.ID

```

Example

The following example demonstrates that the run-time type can differ when a variable is identified as an `Object`.

```

' Disable Option Infer when trying this example.

Dim someVar = 5
Console.WriteLine(someVar.GetType.ToString())

' If Option Infer is instead enabled, the following
' statement causes a run-time error. This is because
' someVar was implicitly defined as an integer.
someVar = "abc"
Console.WriteLine(someVar.GetType.ToString())

' Output:
' System.Int32
' System.String

```

Option Strict Statement

3/5/2019 • 9 minutes to read • [Edit Online](#)

Restricts implicit data type conversions to only widening conversions, disallows late binding, and disallows implicit typing that results in an `Object` type.

Syntax

```
Option Strict { On | Off }
```

Parts

TERM	DEFINITION
<code>On</code>	Optional. Enables <code>Option Strict</code> checking.
<code>Off</code>	Optional. Disables <code>Option Strict</code> checking.

Remarks

When `Option Strict On` or `Option Strict` appears in a file, the following conditions cause a compile-time error:

- Implicit narrowing conversions
- Late binding
- Implicit typing that results in an `Object` type

NOTE

In the warning configurations that you can set on the [Compile Page](#), [Project Designer \(Visual Basic\)](#), there are three settings that correspond to the three conditions that cause a compile-time error. For information about how to use these settings, see [To set warning configurations in the IDE](#) later in this topic.

The `Option Strict Off` statement turns off error and warning checking for all three conditions, even if the associated IDE settings specify to turn on these errors or warnings. The `Option Strict On` statement turns on error and warning checking for all three conditions, even if the associated IDE settings specify to turn off these errors or warnings.

If used, the `Option Strict` statement must appear before any other code statements in a file.

When you set `Option Strict` to `On`, Visual Basic checks that data types are specified for all programming elements. Data types can be specified explicitly, or specified by using local type inference. Specifying data types for all your programming elements is recommended, for the following reasons:

- It enables IntelliSense support for your variables and parameters. This enables you to see their properties and other members as you type code.
- It enables the compiler to perform type checking. Type checking helps you find statements that can

fail at run time because of type conversion errors. It also identifies calls to methods on objects that do not support those methods.

- It speeds up the execution of code. One reason for this is that if you do not specify a data type for a programming element, the Visual Basic compiler assigns it the `Object` type. Compiled code might have to convert back and forth between `Object` and other data types, which reduces performance.

Implicit Narrowing Conversion Errors

Implicit narrowing conversion errors occur when there is an implicit data type conversion that is a narrowing conversion.

Visual Basic can convert many data types to other data types. Data loss can occur when the value of one data type is converted to a data type that has less precision or a smaller capacity. A run-time error occurs if such a narrowing conversion fails. `Option Strict` ensures compile-time notification of these narrowing conversions so that you can avoid them. For more information, see [Implicit and Explicit Conversions](#) and [Widening and Narrowing Conversions](#).

Conversions that can cause errors include implicit conversions that occur in expressions. For more information, see the following topics:

- [+ Operator](#)
- [+= Operator](#)
- [\ Operator \(Visual Basic\)](#)
- [/= Operator \(Visual Basic\)](#)
- [Char Data Type](#)

When you concatenate strings by using the [& Operator](#), all conversions to the strings are considered to be widening. So these conversions do not generate an implicit narrowing conversion error, even if `Option Strict` is on.

When you call a method that has an argument that has a data type different from the corresponding parameter, a narrowing conversion causes a compile-time error if `Option Strict` is on. You can avoid the compile-time error by using a widening conversion or an explicit conversion.

Implicit narrowing conversion errors are suppressed at compile-time for conversions from the elements in a `For Each...Next` collection to the loop control variable. This occurs even if `Option Strict` is on. For more information, see the "Narrowing Conversions" section in [For Each...Next Statement](#).

Late Binding Errors

An object is late bound when it is assigned to a property or method of a variable that is declared to be of type `Object`. For more information, see [Early and Late Binding](#).

Implicit Object Type Errors

Implicit object type errors occur when an appropriate type cannot be inferred for a declared variable, so a type of `Object` is inferred. This primarily occurs when you use a `Dim` statement to declare a variable without using an `As` clause, and `Option Infer` is off. For more information, see [Option Infer Statement](#) and the [Visual Basic Language Specification](#).

For method parameters, the `As` clause is optional if `Option Strict` is off. However, if any one parameter uses an `As` clause, they all must use it. If `Option Strict` is on, the `As` clause is required for every

parameter definition.

If you declare a variable without using an `As` clause and set it to `Nothing`, the variable has a type of `Object`. No compile-time error occurs in this case when `Option Strict` is on and `Option Infer` is on. An example of this is `Dim something = Nothing`.

Default Data Types and Values

The following table describes the results of various combinations of specifying the data type and initializer in a [Dim Statement](#).

DATA TYPE SPECIFIED?	INITIALIZER SPECIFIED?	EXAMPLE	RESULT
No	No	<code>Dim qty</code>	If <code>Option Strict</code> is off (the default), the variable is set to <code>Nothing</code> . If <code>Option Strict</code> is on, a compile-time error occurs.
No	Yes	<code>Dim qty = 5</code>	If <code>Option Infer</code> is on (the default), the variable takes the data type of the initializer. See Local Type Inference . If <code>Option Infer</code> is off and <code>Option Strict</code> is off, the variable takes the data type of <code>Object</code> . If <code>Option Infer</code> is off and <code>Option Strict</code> is on, a compile-time error occurs.
Yes	No	<code>Dim qty As Integer</code>	The variable is initialized to the default value for the data type. For more information, see Dim Statement .
Yes	Yes	<code>Dim qty As Integer = 5</code>	If the data type of the initializer is not convertible to the specified data type, a compile-time error occurs.

When an Option Strict Statement Is Not Present

If the source code does not contain an `Option Strict` statement, the **Option strict** setting on the [Compile Page](#), [Project Designer \(Visual Basic\)](#) is used. The **Compile Page** has settings that provide additional control over the conditions that generate an error.

If you are using the command-line compiler, you can use the `/optionstrict` compiler option to specify a setting for `Option Strict`.

To set Option Strict in the IDE

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

1. In **Solution Explorer**, select a project. On the **Project** menu, click **Properties**.
2. On the **Compile** tab, set the value in the **Option Strict** box.

To set warning configurations in the IDE

When you use the [Compile Page](#), [Project Designer \(Visual Basic\)](#) instead of an `Option Strict` statement, you have additional control over the conditions that generate errors. The **Warning configurations** section of the **Compile Page** has settings that correspond to the three conditions that cause a compile-time error when `Option Strict` is on. Following are these settings:

- **Implicit conversion**
- **Late binding; call could fail at run time**
- **Implicit type; object assumed**

When you set **Option Strict** to **On**, all three of these warning configuration settings are set to **Error**. When you set **Option Strict** to **Off**, all three settings are set to **None**.

You can individually change each warning configuration setting to **None**, **Warning**, or **Error**. If all three warning configuration settings are set to **Error**, `On` appears in the `Option Strict` box. If all three are set to **None**, `Off` appears in this box. For any other combination of these settings, **(custom)** appears.

To set the Option Strict default setting for new projects

When you create a project, the **Option Strict** setting on the **Compile** tab is set to the **Option Strict** setting in the **Options** dialog box.

To set `Option Strict` in this dialog box, on the **Tools** menu, click **Options**. In the **Options** dialog box, expand **Projects and Solutions**, and then click **VB Defaults**. The initial default setting in **VB Defaults** is `Off`.

To set Option Strict on the command line

Include the `/optionstrict` compiler option in the **vbc** command.

Example

The following examples demonstrate compile-time errors caused by implicit type conversions that are narrowing conversions. This category of errors corresponds to the **Implicit conversion** condition on the **Compile Page**.

```

' If Option Strict is on, this implicit narrowing
' conversion causes a compile-time error.
' The commented statements below use explicit
' conversions to avoid a compile-time error.
Dim cyclists As Long = 5
Dim bicycles As Integer = cyclists
'Dim bicycles As Integer = CType(cyclists, Integer)
'Dim bicycles As Integer = CInt(cyclists)
'Dim bicycles As Integer = Convert.ToInt32(cyclists)

' If Option Strict is on, this implicit narrowing
' conversion causes a compile-time error.
' The commented statements below use explicit
' conversions to avoid a compile-time error.
Dim charVal As Char = "a"
'Dim charVal As Char = "a"c
'Dim charVal As Char = CType("a", Char)

' If Option Strict is on, a compile-time error occurs.
' If Option Strict is off, the string is implicitly converted
' to a Double, and then is added to the other number.
Dim myAge As Integer = "34" + 6

' If Option Strict is on, a compile-time error occurs.
' If Option Strict is off, the floating-point number
' is implicitly converted to a Long.
Dim num = 123.45 \ 10

```

Example

The following example demonstrates a compile-time error caused by late binding. This category of errors corresponds to the **Late binding; call could fail at run time** condition on the **Compile Page**.

```

' If Option Strict is on, this late binding
' causes a compile-time error. If Option Strict
' is off, the late binding instead causes a
' run-time error.
Dim punchCard As New Object
punchCard.Column = 5

```

Example

The following examples demonstrate errors caused by variables that are declared with an implicit type of **Object**. This category of errors corresponds to the **Implicit type; object assumed** condition on the **Compile Page**.

```

' If Option Strict is on and Option Infer is off,
' this Dim statement without an As clause
' causes a compile-time error.
Dim cardReaders = 5

' If Option Strict is on, a compile-time error occurs.
' If Option Strict is off, the variable is set to Nothing.
Dim dryWall

```

```
' If Option Strict is on, this parameter without an
' As clause causes a compile-time error.
Private Sub DetectIntergalacticRange(ByVal photonAttenuation)

End Sub
```

Property Statement

2/28/2019 • 5 minutes to read • [Edit Online](#)

Declares the name of a property, and the property procedures used to store and retrieve the value of the property.

Syntax

```
[ <attributelist> ] [ Default ] [ accessmodifier ]
[ propertymodifiers ] [ Shared ] [ Shadows ] [ ReadOnly | WriteOnly ] [ Iterator ]
Property name ( [ parameterlist ] ) [ As returntype ] [ Implements implementslist ]
    [ <attributelist> ] [ accessmodifier ] Get
        [ statements ]
    End Get
    [ <attributelist> ] [ accessmodifier ] Set ( ByVal value As returntype [, parameterlist ] )
        [ statements ]
    End Set
End Property
- or -
[ <attributelist> ] [ Default ] [ accessmodifier ]
[ propertymodifiers ] [ Shared ] [ Shadows ] [ ReadOnly | WriteOnly ]
Property name ( [ parameterlist ] ) [ As returntype ] [ Implements implementslist ]
```

Parts

- **attributelist**

Optional. List of attributes that apply to this property or **Get** or **Set** procedure. See [Attribute List](#).

- **Default**

Optional. Specifies that this property is the default property for the class or structure on which it is defined. Default properties must accept parameters and can be set and retrieved without specifying the property name. If you declare the property as **Default**, you cannot use **Private** on the property or on either of its property procedures.

- **accessmodifier**

Optional on the **Property** statement and on at most one of the **Get** and **Set** statements. Can be one of the following:

- **Public**
- **Protected**
- **Friend**
- **Private**
- **Protected Friend**
- **Private Protected**

See [Access levels in Visual Basic](#).

- `propertymodifiers`

Optional. Can be one of the following:

- [Overloads](#)
- [Overrides](#)
- [Overridable](#)
- [NotOverridable](#)
- [MustOverride](#)
- `MustOverride Overrides`
- `NotOverridable Overrides`

- `Shared`

Optional. See [Shared](#).

- `Shadows`

Optional. See [Shadows](#).

- `ReadOnly`

Optional. See [ReadOnly](#).

- `WriteOnly`

Optional. See [WriteOnly](#).

- `Iterator`

Optional. See [Iterator](#).

- `name`

Required. Name of the property. See [Declared Element Names](#).

- `parameterlist`

Optional. List of local variable names representing the parameters of this property, and possible additional parameters of the `Set` procedure. See [Parameter List](#).

- `returntype`

Required if `option Strict` is `On`. Data type of the value returned by this property.

- `Implements`

Optional. Indicates that this property implements one or more properties, each one defined in an interface implemented by this property's containing class or structure. See [Implements Statement](#).

- `implementslist`

Required if `Implements` is supplied. List of properties being implemented.

`implementedproperty [, implementedproperty ...]`

Each `implementedproperty` has the following syntax and parts:

`interface.definedname`

PART	DESCRIPTION
<code>interface</code>	Required. Name of an interface implemented by this property's containing class or structure.
<code>definedname</code>	Required. Name by which the property is defined in <code>interface</code> .

- `Get`

Optional. Required if the property is marked `WriteOnly`. Starts a `Get` property procedure that is used to return the value of the property.

- `statements`

Optional. Block of statements to run within the `Get` or `Set` procedure.

- `End Get`

Terminates the `Get` property procedure.

- `Set`

Optional. Required if the property is marked `ReadOnly`. Starts a `Set` property procedure that is used to store the value of the property.

- `End Set`

Terminates the `Set` property procedure.

- `End Property`

Terminates the definition of this property.

Remarks

The `Property` statement introduces the declaration of a property. A property can have a `Get` procedure (read only), a `Set` procedure (write only), or both (read-write). You can omit the `Get` and `Set` procedure when using an auto-implemented property. For more information, see [Auto-Implemented Properties](#).

You can use `Property` only at class level. This means the *declaration context* for a property must be a class, structure, module, or interface, and cannot be a source file, namespace, procedure, or block. For more information, see [Declaration Contexts and Default Access Levels](#).

By default, properties use public access. You can adjust a property's access level with an access modifier on the `Property` statement, and you can optionally adjust one of its property procedures to a more restrictive access level.

Visual Basic passes a parameter to the `Set` procedure during property assignments. If you do not supply a parameter for `Set`, the integrated development environment (IDE) uses an implicit parameter named `value`. This parameter holds the value to be assigned to the property. You typically store this value in a private local variable and return it whenever the `Get` procedure is called.

Rules

- **Mixed Access Levels.** If you are defining a read-write property, you can optionally specify a different access level for either the `Get` or the `Set` procedure, but not both. If you do this, the procedure access level must be more restrictive than the property's access level. For example, if the property is declared `Friend`, you can declare the `Set` procedure `Private`, but not `Public`.

If you are defining a `ReadOnly` or `WriteOnly` property, the single property procedure (`Get` or `Set`, respectively) represents all of the property. You cannot declare a different access level for such a procedure, because that would set two access levels for the property.

- **Return Type.** The `Property` statement can declare the data type of the value it returns. You can specify any data type or the name of an enumeration, structure, class, or interface.

If you do not specify `returntype`, the property returns `Object`.

- **Implementation.** If this property uses the `Implements` keyword, the containing class or structure must have an `Implements` statement immediately following its `Class` or `Structure` statement. The `Implements` statement must include each interface specified in `implementslist`. However, the name by which an interface defines the `Property` (in `definedname`) does not have to be the same as the name of this property (in `name`).

Behavior

- **Returning from a Property Procedure.** When the `Get` or `Set` procedure returns to the calling code, execution continues with the statement following the statement that invoked it.

The `Exit Property` and `Return` statements cause an immediate exit from a property procedure. Any number of `Exit Property` and `Return` statements can appear anywhere in the procedure, and you can mix `Exit Property` and `Return` statements.

- **Return Value.** To return a value from a `Get` procedure, you can either assign the value to the property name or include it in a `Return` statement. The following example assigns the return value to the property name `quoteForTheDay` and then uses the `Exit Property` statement to return.

```
Private quoteValue As String = "No quote assigned yet."
```

```
ReadOnly Property quoteForTheDay() As String
    Get
        quoteForTheDay = quoteValue
        Exit Property
    End Get
End Property
```

If you use `Exit Property` without assigning a value to `name`, the `Get` procedure returns the default value for the property's data type.

The `Return` statement at the same time assigns the `Get` procedure return value and exits the procedure. The following example shows this.

```
Private quoteValue As String = "No quote assigned yet."
```

```
ReadOnly Property quoteForTheDay() As String
    Get
        Return quoteValue
    End Get
End Property
```

Example

The following example declares a property in a class.

```
Class Class1
    ' Define a local variable to store the property value.
    Private propertyValue As String
    ' Define the property.
    Public Property prop1() As String
        Get
            ' The Get property procedure is called when the value
            ' of a property is retrieved.
            Return propertyValue
        End Get
        Set(ByVal value As String)
            ' The Set property procedure is called when the value
            ' of a property is modified. The value to be assigned
            ' is passed in the argument to Set.
            propertyValue = value
        End Set
    End Property
End Class
```

Q-Z Statements

Resume	Return	Select...Case	Set
Stop	Structure	Sub	SyncLock
Then	Throw	Try...Catch...Finally	Using
While...End While	With...End With	Yield

RaiseEvent Statement

2/28/2019 • 3 minutes to read • [Edit Online](#)

Triggers an event declared at module level within a class, form, or document.

Syntax

```
RaiseEvent eventname[( argumentlist )]
```

Parts

`eventname`

Required. Name of the event to trigger.

`argumentlist`

Optional. Comma-delimited list of variables, arrays, or expressions. The `argumentlist` argument must be enclosed by parentheses. If there are no arguments, the parentheses must be omitted.

Remarks

The required `eventname` is the name of an event declared within the module. It follows Visual Basic variable naming conventions.

If the event has not been declared within the module in which it is raised, an error occurs. The following code fragment illustrates an event declaration and a procedure in which the event is raised.

```
' Declare an event at module level.  
Event LogonCompleted(ByVal UserName As String)  
  
Sub Logon(ByVal UserName As String)  
    ' Raise the event.  
    RaiseEvent LogonCompleted(UserName)  
End Sub
```

You cannot use `RaiseEvent` to raise events that are not explicitly declared in the module. For example, all forms inherit a `Click` event from `System.Windows.Forms.Form`, it cannot be raised using `RaiseEvent` in a derived form. If you declare a `Click` event in the form module, it shadows the form's own `Click` event. You can still invoke the form's `Click` event by calling the `OnClick` method.

By default, an event defined in Visual Basic raises its event handlers in the order that the connections are established. Because events can have `ByRef` parameters, a process that connects late may receive parameters that have been changed by an earlier event handler. After the event handlers execute, control is returned to the subroutine that raised the event.

NOTE

Non-shared events should not be raised within the constructor of the class in which they are declared. Although such events do not cause run-time errors, they may fail to be caught by associated event handlers. Use the `Shared` modifier to create a shared event if you need to raise an event from a constructor.

NOTE

You can change the default behavior of events by defining a custom event. For custom events, the `RaiseEvent` statement invokes the event's `RaiseEvent` accessor. For more information on custom events, see [Event Statement](#).

Example

The following example uses events to count down seconds from 10 to 0. The code illustrates several of the event-related methods, properties, and statements, including the `RaiseEvent` statement.

The class that raises an event is the event source, and the methods that process the event are the event handlers. An event source can have multiple handlers for the events it generates. When the class raises the event, that event is raised on every class that has elected to handle events for that instance of the object.

The example also uses a form (`Form1`) with a button (`Button1`) and a text box (`TextBox1`). When you click the button, the first text box displays a countdown from 10 to 0 seconds. When the full time (10 seconds) has elapsed, the first text box displays "Done".

The code for `Form1` specifies the initial and terminal states of the form. It also contains the code executed when events are raised.

To use this example, open a new Windows Application project, add a button named `Button1` and a text box named `TextBox1` to the main form, named `Form1`. Then right-click the form and click **View Code** to open the Code Editor.

Add a `WithEvents` variable to the declarations section of the `Form1` class.

```
Private WithEvents mText As TimerState
```

Example

Add the following code to the code for `Form1`. Replace any duplicate procedures that may exist, such as `Form_Load`, or `Button_Click`.

```

Private Sub Form1_Load() Handles MyBase.Load
    Button1.Text = "Start"
    mText = New TimerState
End Sub

Private Sub Button1_Click() Handles Button1.Click
    mText.StartCountdown(10.0, 0.1)
End Sub

Private Sub mText_ChangeText() Handles mText.Finished
    TextBox1.Text = "Done"
End Sub

Private Sub mTextUpdateTime(ByVal Countdown As Double
) Handles mText.UpdateTime

    TextBox1.Text = Format(Countdown, "##0.0")
    ' Use DoEvents to allow the display to refresh.
    My.Application.DoEvents()
End Sub

Class TimerState
    Public Event UpdateTime(ByVal Countdown As Double)
    Public Event Finished()
    Public Sub StartCountdown(ByVal Duration As Double,
        ByVal Increment As Double)
        Dim Start As Double = DateAndTime.Timer
        Dim ElapsedTime As Double = 0

        Dim SoFar As Double = 0
        Do While ElapsedTime < Duration
            If ElapsedTime > SoFar + Increment Then
                SoFar += Increment
                RaiseEvent UpdateTime(Duration - SoFar)
            End If
            ElapsedTime = DateAndTime.Timer - Start
        Loop
        RaiseEvent Finished()
    End Sub
End Class

```

Press F5 to run the preceding example, and click the button labeled **Start**. The first text box starts to count down the seconds. When the full time (10 seconds) has elapsed, the first text box displays "Done".

NOTE

The `My.Application.DoEvents` method does not process events in exactly the same way as the form does. To allow the form to handle the events directly, you can use multithreading. For more information, see [Managed Threading](#).

ReDim Statement (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Reallocates storage space for an array variable.

Syntax

```
ReDim [ Preserve ] name(boundlist) [ , name(boundlist) [, ...] ]
```

Parts

TERM	DEFINITION
<code>Preserve</code>	Optional. Modifier used to preserve the data in the existing array when you change the size of only the last dimension.
<code>name</code>	Required. Name of the array variable. See Declared Element Names .
<code>boundlist</code>	Required. List of bounds of each dimension of the redefined array.

Remarks

You can use the `ReDim` statement to change the size of one or more dimensions of an array that has already been declared. If you have a large array and you no longer need some of its elements, `ReDim` can free up memory by reducing the array size. On the other hand, if your array needs more elements, `ReDim` can add them.

The `ReDim` statement is intended only for arrays. It's not valid on scalars (variables that contain only a single value), collections, or structures. Note that if you declare a variable to be of type `Array`, the `ReDim` statement doesn't have sufficient type information to create the new array.

You can use `ReDim` only at procedure level. Therefore, the declaration context for the variable must be a procedure; it can't be a source file, a namespace, an interface, a class, a structure, a module, or a block. For more information, see [Declaration Contexts and Default Access Levels](#).

Rules

- **Multiple Variables.** You can resize several array variables in the same declaration statement and specify the `name` and `boundlist` parts for each variable. Multiple variables are separated by commas.
- **Array Bounds.** Each entry in `boundlist` can specify the lower and upper bounds of that dimension. The lower bound is always 0 (zero). The upper bound is the highest possible index value for that dimension, not the length of the dimension (which is the upper bound plus one). The index for each dimension can vary from 0 through its upper bound value.

The number of dimensions in `boundlist` must match the original number of dimensions (rank) of the array.

- **Data Types.** The `ReDim` statement cannot change the data type of an array variable or its elements.
- **Initialization.** The `ReDim` statement cannot provide new initialization values for the array elements.
- **Rank.** The `ReDim` statement cannot change the rank (the number of dimensions) of the array.
- **Resizing with Preserve.** If you use `Preserve`, you can resize only the last dimension of the array. For every other dimension, you must specify the bound of the existing array.

For example, if your array has only one dimension, you can resize that dimension and still preserve all the contents of the array, because you are changing the last and only dimension. However, if your array has two or more dimensions, you can change the size of only the last dimension if you use `Preserve`.

- **Properties.** You can use `ReDim` on a property that holds an array of values.

Behavior

- **Array Replacement.** `ReDim` releases the existing array and creates a new array with the same rank. The new array replaces the released array in the array variable.
- **Initialization without Preserve.** If you do not specify `Preserve`, `ReDim` initializes the elements of the new array by using the default value for their data type.
- **Initialization with Preserve.** If you specify `Preserve`, Visual Basic copies the elements from the existing array to the new array.

Example

The following example increases the size of the last dimension of a dynamic array without losing any existing data in the array, and then decreases the size with partial data loss. Finally, it decreases the size back to its original value and reinitializes all the array elements.

```
Dim intArray(10, 10, 10) As Integer
ReDim Preserve intArray(10, 10, 20)
ReDim Preserve intArray(10, 10, 15)
ReDim intArray(10, 10, 10)
```

The `Dim` statement creates a new array with three dimensions. Each dimension is declared with a bound of 10, so the array index for each dimension can range from 0 through 10. In the following discussion, the three dimensions are referred to as layer, row, and column.

The first `ReDim` creates a new array which replaces the existing array in variable `intArray`. `ReDim` copies all the elements from the existing array into the new array. It also adds 10 more columns to the end of every row in every layer and initializes the elements in these new columns to 0 (the default value of `Integer`, which is the element type of the array).

The second `ReDim` creates another new array and copies all the elements that fit. However, five columns are lost from the end of every row in every layer. This is not a problem if you have finished using these columns. Reducing the size of a large array can free up memory that you no longer need.

The third `ReDim` creates another new array and removes another five columns from the end of every row in every layer. This time it does not copy any existing elements. This statement reverts the array to its original size. Because the statement doesn't include the `Preserve` modifier, it sets all array elements to their original default values.

For additional examples, see [Arrays](#).

REM Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Used to include explanatory remarks in the source code of a program.

Syntax

```
REM comment  
' comment
```

Parts

comment

Optional. The text of any comment you want to include. A space is required between the REM keyword and comment .

Remarks

You can put a REM statement alone on a line, or you can put it on a line following another statement. The REM statement must be the last statement on the line. If it follows another statement, the REM must be separated from that statement by a space.

You can use a single quotation mark (') instead of REM . This is true whether your comment follows another statement on the same line or sits alone on a line.

NOTE

You cannot continue a REM statement by using a line-continuation sequence (\_). Once a comment begins, the compiler does not examine the characters for special meaning. For a multiple-line comment, use another REM statement or a comment symbol (') on each line.

Example

The following example illustrates the REM statement, which is used to include explanatory remarks in a program. It also shows the alternative of using the single quotation-mark character (') instead of REM .

```
Dim demoStr1, demoStr2 As String  
demoStr1 = "Hello" REM Comment after a statement using REM.  
demoStr2 = "Goodbye" ' Comment after a statement using the ' character.  
REM This entire line is a comment.  
' This entire line is also a comment.
```

RemoveHandler Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Removes the association between an event and an event handler.

Syntax

```
RemoveHandler event, AddressOf evenhandler
```

Parts

TERM	DEFINITION
event	The name of the event being handled.
evenhandler	The name of the procedure currently handling the event.

Remarks

The `AddHandler` and `RemoveHandler` statements allow you to start and stop event handling for a specific event at any time during program execution.

NOTE

For custom events, the `RemoveHandler` statement invokes the event's `RemoveHandler` accessor. For more information on custom events, see [Event Statement](#).

Example

```
Sub TestEvents()
    Dim Obj As New Class1
    ' Associate an event handler with an event.
    AddHandler Obj.Ev_Event, AddressOf EventHandler
    ' Call the method to raise the event.
    Obj.CauseSomeEvent()
    ' Stop handling events.
    RemoveHandler Obj.Ev_Event, AddressOf EventHandler
    ' This event will not be handled.
    Obj.CauseSomeEvent()
End Sub

Sub EventHandler()
    ' Handle the event.
    MsgBox("EventHandler caught event.")
End Sub

Public Class Class1
    ' Declare an event.
    Public Event Ev_Event()
    Sub CauseSomeEvent()
        ' Raise an event.
        RaiseEvent Ev_Event()
    End Sub
End Class

Resume Statement

2/28/2019 • 2 minutes to read • [Edit Online](#)

Resumes execution after an error-handling routine is finished.

We suggest that you use structured exception handling in your code whenever possible, rather than using unstructured exception handling and the `On Error` and `Resume` statements. For more information, see [Try...Catch...Finally Statement](#).

Syntax

```
Resume [ Next | line ]
```

Parts

`Resume`

Required. If the error occurred in the same procedure as the error handler, execution resumes with the statement that caused the error. If the error occurred in a called procedure, execution resumes at the statement that last called out of the procedure containing the error-handling routine.

`Next`

Optional. If the error occurred in the same procedure as the error handler, execution resumes with the statement immediately following the statement that caused the error. If the error occurred in a called procedure, execution resumes with the statement immediately following the statement that last called out of the procedure containing the error-handling routine (or `On Error Resume Next` statement).

`line`

Optional. Execution resumes at the line specified in the required `line` argument. The `line` argument is a line label or line number and must be in the same procedure as the error handler.

Remarks

NOTE

We recommend that you use structured exception handling in your code whenever possible, rather than using unstructured exception handling and the `On Error` and `Resume` statements. For more information, see [Try...Catch...Finally Statement](#).

If you use a `Resume` statement anywhere other than in an error-handling routine, an error occurs.

The `Resume` statement cannot be used in any procedure that contains a `Try...Catch...Finally` statement.

Example

This example uses the `Resume` statement to end error handling in a procedure and then resume execution with the statement that caused the error. Error number 55 is generated to illustrate use of the `Resume` statement.

```
Sub ResumeStatementDemo()
    On Error GoTo ErrorHandler    ' Enable error-handling routine.
    Dim x As Integer = 32
    Dim y As Integer = 0
    Dim z As Integer
    z = x / y      ' Creates a divide by zero error
    Exit Sub      ' Exit Sub to avoid error handler.
ErrorHandler:      ' Error-handling routine.
    Select Case Err.Number      ' Evaluate error number.
        Case 6      "Divide by zero" error.
            y = 1 ' Sets the value of y to 1 and tries the calculation again.
        Case Else
            ' Handle other situations here....
    End Select
    Resume      ' Resume execution at same line
    ' that caused the error.
End Sub
```

Return Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Returns control to the code that called a `Function`, `Sub`, `Get`, `Set`, or `Operator` procedure.

Syntax

```
Return  
-or-  
Return expression
```

Part

`expression`

Required in a `Function`, `Get`, or `Operator` procedure. Expression that represents the value to be returned to the calling code.

Remarks

In a `Sub` or `Set` procedure, the `Return` statement is equivalent to an `Exit Sub` or `Exit Property` statement, and `expression` must not be supplied.

In a `Function`, `Get`, or `Operator` procedure, the `Return` statement must include `expression`, and `expression` must evaluate to a data type that is convertible to the return type of the procedure. In a `Function` or `Get` procedure, you also have the alternative of assigning an expression to the procedure name to serve as the return value, and then executing an `Exit Function` or `Exit Property` statement. In an `Operator` procedure, you must use `Return expression`.

You can include as many `Return` statements as appropriate in the same procedure.

NOTE

The code in a `Finally` block runs after a `Return` statement in a `Try` or `Catch` block is encountered, but before that `Return` statement executes. A `Return` statement cannot be included in a `Finally` block.

Example

The following example uses the `Return` statement several times to return to the calling code when the procedure does not have to do anything else.

```
Public Function getAgePhrase(ByVal age As Integer) As String  
    If age > 60 Then Return "Senior"  
    If age > 40 Then Return "Middle-aged"  
    If age > 20 Then Return "Adult"  
    If age > 12 Then Return "Teen-aged"  
    If age > 4 Then Return "School-aged"  
    If age > 1 Then Return "Toddler"  
    Return "Infant"  
End Function
```

Select...Case Statement (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Runs one of several groups of statements, depending on the value of an expression.

Syntax

```
Select [ Case ] testexpression
    [ Case expressionlist
        [ statements ] ]
    [ Case Else
        [ elsestatements ] ]
End Select
```

Parts

TERM	DEFINITION
<code>testexpression</code>	Required. Expression. Must evaluate to one of the elementary data types (<code>Boolean</code> , <code>Byte</code> , <code>Char</code> , <code>Date</code> , <code>Double</code> , <code>Decimal</code> , <code>Integer</code> , <code>Long</code> , <code>Object</code> , <code>SByte</code> , <code>Short</code> , <code>Single</code> , <code>String</code> , <code>UInteger</code> , <code>ULong</code> , and <code>UShort</code>).

TERM	DEFINITION
<code>expressionlist</code>	<p>Required in a <code>Case</code> statement. List of expression clauses representing match values for <code>testexpression</code>. Multiple expression clauses are separated by commas. Each clause can take one of the following forms:</p> <ul style="list-style-type: none"> - <code>expression1 To expression2</code> - [<code>Is</code>] <code>comparisonoperator expression</code> - <code>expression</code> <p>Use the <code>To</code> keyword to specify the boundaries of a range of match values for <code>testexpression</code>. The value of <code>expression1</code> must be less than or equal to the value of <code>expression2</code>.</p> <p>Use the <code>Is</code> keyword with a comparison operator (<code>=</code>, <code><></code>, <code><</code>, <code><=</code>, <code>></code>, or <code>>=</code>) to specify a restriction on the match values for <code>testexpression</code>. If the <code>Is</code> keyword is not supplied, it is automatically inserted before <code>comparisonoperator</code>.</p> <p>The form specifying only <code>expression</code> is treated as a special case of the <code>Is</code> form where <code>comparisonoperator</code> is the equal sign (<code>=</code>). This form is evaluated as <code>testexpression = expression</code>.</p> <p>The expressions in <code>expressionlist</code> can be of any data type, provided they are implicitly convertible to the type of <code>testexpression</code> and the appropriate <code>comparisonoperator</code> is valid for the two types it is being used with.</p>
<code>statements</code>	Optional. One or more statements following <code>Case</code> that run if <code>testexpression</code> matches any clause in <code>expressionlist</code> .
<code>elsestatements</code>	Optional. One or more statements following <code>Case Else</code> that run if <code>testexpression</code> does not match any clause in the <code>expressionlist</code> of any of the <code>Case</code> statements.
<code>End Select</code>	Terminates the definition of the <code>Select ... Case</code> construction.

Remarks

If `testexpression` matches any `Case expressionlist` clause, the statements following that `Case` statement run up to the next `Case`, `Case Else`, or `End Select` statement. Control then passes to the statement following `End Select`. If `testexpression` matches an `expressionlist` clause in more than one `Case` clause, only the statements following the first match run.

The `Case Else` statement is used to introduce the `elsestatements` to run if no match is found between the `testexpression` and an `expressionlist` clause in any of the other `Case` statements. Although not required, it is a good idea to have a `Case Else` statement in your `Select Case` construction to handle unforeseen `testexpression` values. If no `Case expressionlist` clause matches `testexpression` and there is no `Case Else` statement, control passes to the statement following `End Select`.

You can use multiple expressions or ranges in each `Case` clause. For example, the following line is valid.

```
Case 1 To 4, 7 To 9, 11, 13, Is > maxNumber
```

NOTE

The `Is` keyword used in the `Case` and `Case Else` statements is not the same as the [Is Operator](#), which is used for object reference comparison.

You can specify ranges and multiple expressions for character strings. In the following example, `Case` matches any string that is exactly equal to "apples", has a value between "nuts" and "soup" in alphabetical order, or contains the exact same value as the current value of `testItem`.

```
Case "apples", "nuts" To "soup", testItem
```

The setting of `Option Compare` can affect string comparisons. Under `Option Compare Text`, the strings "Apples" and "apples" compare as equal, but under `Option Compare Binary`, they do not.

NOTE

A `Case` statement with multiple clauses can exhibit behavior known as *short-circuiting*. Visual Basic evaluates the clauses from left to right, and if one produces a match with `testexpression`, the remaining clauses are not evaluated. Short-circuiting can improve performance, but it can produce unexpected results if you are expecting every expression in `expressionlist` to be evaluated. For more information on short-circuiting, see [Boolean Expressions](#).

If the code within a `Case` or `Case Else` statement block does not need to run any more of the statements in the block, it can exit the block by using the `Exit Select` statement. This transfers control immediately to the statement following `End Select`.

`Select Case` constructions can be nested. Each nested `Select Case` construction must have a matching `End Select` statement and must be completely contained within a single `case` or `Case Else` statement block of the outer `Select Case` construction within which it is nested.

Example

The following example uses a `Select Case` construction to write a line corresponding to the value of the variable `number`. The second `Case` statement contains the value that matches the current value of `number`, so the statement that writes "Between 6 and 8, inclusive" runs.

```
Dim number As Integer = 8
Select Case number
    Case 1 To 5
        Debug.WriteLine("Between 1 and 5, inclusive")
        ' The following is the only Case clause that evaluates to True.
    Case 6, 7, 8
        Debug.WriteLine("Between 6 and 8, inclusive")
    Case 9 To 10
        Debug.WriteLine("Equal to 9 or 10")
    Case Else
        Debug.WriteLine("Not between 1 and 10, inclusive")
End Select
```

Set Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Declares a `Set` property procedure used to assign a value to a property.

Syntax

```
[ <attributelist> ] [ accessmodifier ] Set (ByVal value [ As datatype ])
    [ statements ]
End Set
```

Parts

`attributelist`

Optional. See [Attribute List](#).

`accessmodifier`

Optional on at most one of the `Get` and `Set` statements in this property. Can be one of the following:

- [Protected](#)
- [Friend](#)
- [Private](#)
- `Protected Friend`

See [Access levels in Visual Basic](#).

`value`

Required. Parameter containing the new value for the property.

`datatype`

Required if `Option Strict` is `On`. Data type of the `value` parameter. The data type specified must be the same as the data type of the property where this `Set` statement is declared.

`statements`

Optional. One or more statements that run when the `Set` property procedure is called.

`End Set`

Required. Terminates the definition of the `Set` property procedure.

Remarks

Every property must have a `Set` property procedure unless the property is marked `ReadOnly`. The `Set` procedure is used to set the value of the property.

Visual Basic automatically calls a property's `Set` procedure when an assignment statement provides a value to be stored in the property.

Visual Basic passes a parameter to the `Set` procedure during property assignments. If you do not supply a parameter for `Set`, the integrated development environment (IDE) uses an implicit parameter named `value`. The parameter holds the value to be assigned to the property. You typically store this value in a private local

variable and return it whenever the `Get` procedure is called.

The body of the property declaration can contain only the property's `Get` and `Set` procedures between the [Property Statement](#) and the `End Property` statement. It cannot store anything other than those procedures. In particular, it cannot store the property's current value. You must store this value outside the property, because if you store it inside either of the property procedures, the other property procedure cannot access it. The usual approach is to store the value in a [Private](#) variable declared at the same level as the property. You must define a `Set` procedure inside the property to which it applies.

The `Set` procedure defaults to the access level of its containing property unless you use `accessmodifier` in the `Set` statement.

Rules

- **Mixed Access Levels.** If you are defining a read-write property, you can optionally specify a different access level for either the `Get` or the `Set` procedure, but not both. If you do this, the procedure access level must be more restrictive than the property's access level. For example, if the property is declared `Friend`, you can declare the `Set` procedure `Private`, but not `Public`.

If you are defining a `WriteOnly` property, the `Set` procedure represents the entire property. You cannot declare a different access level for `Set`, because that would set two access levels for the property.

Behavior

- **Returning from a Property Procedure.** When the `Set` procedure returns to the calling code, execution continues following the statement that provided the value to be stored.

`Set` property procedures can return using either the [Return Statement](#) or the [Exit Statement](#).

The `Exit Property` and `Return` statements cause an immediate exit from a property procedure. Any number of `Exit Property` and `Return` statements can appear anywhere in the procedure, and you can mix `Exit Property` and `Return` statements.

Example

The following example uses the `Set` statement to set the value of a property.

```
Class propClass
    Private propVal As Integer
    Property prop1() As Integer
        Get
            Return propVal
        End Get
        Set(ByVal value As Integer)
            propVal = value
        End Set
    End Property
End Class
```

Stop Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Suspends execution.

Syntax

```
Stop
```

Remarks

You can place `stop` statements anywhere in procedures to suspend execution. Using the `Stop` statement is similar to setting a breakpoint in the code.

The `stop` statement suspends execution, but unlike `End`, it does not close any files or clear any variables, unless it is encountered in a compiled executable (.exe) file.

NOTE

If the `Stop` statement is encountered in code that is running outside of the integrated development environment (IDE), the debugger is invoked. This is true regardless of whether the code was compiled in debug or retail mode.

Example

This example uses the `Stop` statement to suspend execution for each iteration through the `For...Next` loop.

```
Dim i As Integer
For i = 1 To 10
    Debug.WriteLine(i)
    ' Stop during each iteration and wait for user to resume.
    Stop
Next i
```

Structure Statement

2/28/2019 • 5 minutes to read • [Edit Online](#)

Declares the name of a structure and introduces the definition of the variables, properties, events, and procedures that the structure comprises.

Syntax

```
[ <attributelist> ] [ accessmodifier ] [ Shadows ] [ Partial ] _  
Structure name [ ( Of typelist ) ]  
    [ Implements interfacenames ]  
    [ datamemberdeclarations ]  
    [ methodmemberdeclarations ]  
End Structure
```

Parts

TERM	DEFINITION
<code>attributelist</code>	Optional. See Attribute List .
<code>accessmodifier</code>	Optional. Can be one of the following: <ul style="list-style-type: none">- Public- Protected- Friend- Private- Protected Friend- Private Protected See Access levels in Visual Basic .
<code>Shadows</code>	Optional. See Shadows .
<code>Partial</code>	Optional. Indicates a partial definition of the structure. See Partial .
<code>name</code>	Required. Name of this structure. See Declared Element Names .
<code>of</code>	Optional. Specifies that this is a generic structure.
<code>typelist</code>	Required if you use the <code>Of</code> keyword. List of type parameters for this structure. See Type List .
<code>Implements</code>	Optional. Indicates that this structure implements the members of one or more interfaces. See Implements Statement .
<code>interfacenames</code>	Required if you use the <code>Implements</code> statement. The names of the interfaces this structure implements.

TERM	DEFINITION
<code>datamemberdeclarations</code>	Required. Zero or more <code>Const</code> , <code>Dim</code> , <code>Enum</code> , or <code>Event</code> statements declaring <i>data members</i> of the structure.
<code>methodmemberdeclarations</code>	Optional. Zero or more declarations of <code>Function</code> , <code>Operator</code> , <code>Property</code> , or <code>Sub</code> procedures, which serve as <i>method members</i> of the structure.
<code>End Structure</code>	Required. Terminates the <code>Structure</code> definition.

Remarks

The `Structure` statement defines a composite value type that you can customize. A *structure* is a generalization of the user-defined type (UDT) of previous versions of Visual Basic. For more information, see [Structures](#).

Structures support many of the same features as classes. For example, structures can have properties and procedures, they can implement interfaces, and they can have parameterized constructors. However, there are significant differences between structures and classes in areas such as inheritance, declarations, and usage. Also, classes are reference types and structures are value types. For more information, see [Structures and Classes](#).

You can use `Structure` only at namespace or module level. This means the *declaration context* for a structure must be a source file, namespace, class, structure, module, or interface, and cannot be a procedure or block. For more information, see [Declaration Contexts and Default Access Levels](#).

Structures default to `Friend` access. You can adjust their access levels with the access modifiers. For more information, see [Access levels in Visual Basic](#).

Rules

- **Nesting.** You can define one structure within another. The outer structure is called the *containing structure*, and the inner structure is called a *nested structure*. However, you cannot access a nested structure's members through the containing structure. Instead, you must declare a variable of the nested structure's data type.
- **Member Declaration.** You must declare every member of a structure. A structure member cannot be `Protected` or `Protected Friend` because nothing can inherit from a structure. The structure itself, however, can be `Protected` or `Protected Friend`.

You can declare zero or more nonshared variables or nonshared, noncustom events in a structure. You cannot have only constants, properties, and procedures, even if some of them are nonshared.

- **Initialization.** You cannot initialize the value of any nonshared data member of a structure as part of its declaration. You must either initialize such a data member by means of a parameterized constructor on the structure, or assign a value to the member after you have created an instance of the structure.
 - **Inheritance.** A structure cannot inherit from any type other than `ValueType`, from which all structures inherit. In particular, one structure cannot inherit from another.
- You cannot use the [Inherits Statement](#) in a structure definition, even to specify `ValueType`.
- **Implementation.** If the structure uses the [Implements Statement](#), you must implement every member defined by every interface you specify in `interfacenames`.

- **Default Property.** A structure can specify at most one property as its *default property*, using the [Default](#) modifier. For more information, see [Default](#).

Behavior

- **Access Level.** Within a structure, you can declare each member with its own access level. All structure members default to [Public](#) access. Note that if the structure itself has a more restricted access level, this automatically restricts access to its members, even if you adjust their access levels with the access modifiers.

- **Scope.** A structure is in scope throughout its containing namespace, class, structure, or module.

The scope of every structure member is the entire structure.

- **Lifetime.** A structure does not itself have a lifetime. Rather, each instance of that structure has a lifetime independent of all other instances.

The lifetime of an instance begins when it is created by a [New Operator](#) clause. It ends when the lifetime of the variable that holds it ends.

You cannot extend the lifetime of a structure instance. An approximation to static structure functionality is provided by a module. For more information, see [Module Statement](#).

Structure members have lifetimes depending on how and where they are declared. For more information, see "Lifetime" in [Class Statement](#).

- **Qualification.** Code outside a structure must qualify a member's name with the name of that structure.

If code inside a nested structure makes an unqualified reference to a programming element, Visual Basic searches for the element first in the nested structure, then in its containing structure, and so on out to the outermost containing element. For more information, see [References to Declared Elements](#).

- **Memory Consumption.** As with all composite data types, you cannot safely calculate the total memory consumption of a structure by adding together the nominal storage allocations of its members. Furthermore, you cannot safely assume that the order of storage in memory is the same as your order of declaration. If you need to control the storage layout of a structure, you can apply the [StructLayoutAttribute](#) attribute to the [Structure](#) statement.

Example

The following example uses the [Structure](#) statement to define a set of related data for an employee. It shows the use of [Public](#), [Friend](#), and [Private](#) members to reflect the sensitivity of the data items. It also shows procedure, property, and event members.

```
Public Structure employee
    ' Public members, accessible from throughout declaration region.
    Public firstName As String
    Public middleName As String
    Public lastName As String
    ' Friend members, accessible from anywhere within the same assembly.
    Friend employeeNumber As Integer
    Friend workPhone As Long
    ' Private members, accessible only from within the structure itself.
    Private homePhone As Long
    Private level As Integer
    Private salary As Double
    Private bonus As Double
    ' Procedure member, which can access structure's private members.
    Friend Sub calculateBonus(ByVal rate As Single)
        bonus = salary * CDbl(rate)
    End Sub
    ' Property member to return employee's eligibility.
    Friend ReadOnly Property eligible() As Boolean
        Get
            Return level >= 25
        End Get
    End Property
    ' Event member, raised when business phone number has changed.
    Public Event changedWorkPhone(ByVal newPhone As Long)
End Structure
```

Sub Statement (Visual Basic)

2/28/2019 • 6 minutes to read • [Edit Online](#)

Declares the name, parameters, and code that define a `Sub` procedure.

Syntax

```
[ <attributelist> ] [ Partial ] [ accessmodifier ] [ proceduremodifiers ] [ Shared ] [ Shadows ] [  
    Async ]  
Sub name [ (Of typeparamlist) ] [ (parameterlist) ] [ Implements implementslist | Handles eventlist  
    ]  
    [ statements ]  
    [ Exit Sub ]  
    [ statements ]  
End Sub
```

Parts

- `attributelist`

Optional. See [Attribute List](#).

- `Partial`

Optional. Indicates definition of a partial method. See [Partial Methods](#).

- `accessmodifier`

Optional. Can be one of the following:

- [Public](#)
- [Protected](#)
- [Friend](#)
- [Private](#)
- [Protected Friend](#)
- [Private Protected](#)

See [Access levels in Visual Basic](#).

- `proceduremodifiers`

Optional. Can be one of the following:

- [Overloads](#)
- [Overrides](#)
- [Overridable](#)
- [NotOverridable](#)
- [MustOverride](#)

- `MustOverride` Overrides
- `NotOverridable` Overrides
- `Shared`

Optional. See [Shared](#).

- `Shadows`

Optional. See [Shadows](#).

- `Async`

Optional. See [Async](#).

- `name`

Required. Name of the procedure. See [Declared Element Names](#). To create a constructor procedure for a class, set the name of a `Sub` procedure to the `New` keyword. For more information, see [Object Lifetime: How Objects Are Created and Destroyed](#).

- `typeparamlist`

Optional. List of type parameters for a generic procedure. See [Type List](#).

- `parameterlist`

Optional. List of local variable names representing the parameters of this procedure. See [Parameter List](#).

- `Implements`

Optional. Indicates that this procedure implements one or more `Sub` procedures, each one defined in an interface implemented by this procedure's containing class or structure. See [Implements Statement](#).

- `implementslist`

Required if `Implements` is supplied. List of `Sub` procedures being implemented.

```
implementedprocedure [ , implementedprocedure ... ]
```

Each `implementedprocedure` has the following syntax and parts:

`interface.definedname`

PART	DESCRIPTION
<code>interface</code>	Required. Name of an interface implemented by this procedure's containing class or structure.
<code>definedname</code>	Required. Name by which the procedure is defined in <code>interface</code> .

- `Handles`

Optional. Indicates that this procedure can handle one or more specific events. See [Handles](#).

- `eventlist`

Required if `Handles` is supplied. List of events this procedure handles.

```
eventspecifier [ , eventspecifier ... ]
```

Each `eventspecifier` has the following syntax and parts:

```
eventvariable.event
```

PART	DESCRIPTION
<code>eventvariable</code>	Required. Object variable declared with the data type of the class or structure that raises the event.
<code>event</code>	Required. Name of the event this procedure handles.

- `statements`

Optional. Block of statements to run within this procedure.

- `End Sub`

Terminates the definition of this procedure.

Remarks

All executable code must be inside a procedure. Use a `Sub` procedure when you don't want to return a value to the calling code. Use a `Function` procedure when you want to return a value.

Defining a Sub Procedure

You can define a `Sub` procedure only at the module level. The declaration context for a sub procedure must, therefore, be a class, a structure, a module, or an interface and can't be a source file, a namespace, a procedure, or a block. For more information, see [Declaration Contexts and Default Access Levels](#).

`Sub` procedures default to public access. You can adjust their access levels by using the access modifiers.

If the procedure uses the `Implements` keyword, the containing class or structure must have an `Implements` statement that immediately follows its `Class` or `Structure` statement. The `Implements` statement must include each interface that's specified in `implementslist`. However, the name by which an interface defines the `Sub` (in `definedname`) doesn't have to match the name of this procedure (in `name`).

Returning from a Sub Procedure

When a `Sub` procedure returns to the calling code, execution continues with the statement after the statement that called it.

The following example shows a return from a `Sub` procedure.

```
Sub mySub(ByVal q As String)
    Return
End Sub
```

The `Exit Sub` and `Return` statements cause an immediate exit from a `Sub` procedure. Any number of `Exit Sub` and `Return` statements can appear anywhere in the procedure, and you can mix `Exit Sub` and `Return` statements.

Calling a Sub Procedure

You call a `Sub` procedure by using the procedure name in a statement and then following that name with its argument list in parentheses. You can omit the parentheses only if you don't supply any arguments. However, your code is more readable if you always include the parentheses.

A `Sub` procedure and a `Function` procedure can have parameters and perform a series of statements. However, a `Function` procedure returns a value, and a `Sub` procedure doesn't. Therefore, you can't use a `Sub` procedure in an expression.

You can use the `Call` keyword when you call a `Sub` procedure, but that keyword isn't recommended for most uses. For more information, see [Call Statement](#).

Visual Basic sometimes rearranges arithmetic expressions to increase internal efficiency. For that reason, if your argument list includes expressions that call other procedures, you shouldn't assume that those expressions will be called in a particular order.

Async Sub Procedures

By using the `Async` feature, you can invoke asynchronous functions without using explicit callbacks or manually splitting your code across multiple functions or lambda expressions.

If you mark a procedure with the `Async` modifier, you can use the `Await` operator in the procedure. When control reaches an `Await` expression in the `Async` procedure, control returns to the caller, and progress in the procedure is suspended until the awaited task completes. When the task is complete, execution can resume in the procedure.

NOTE

An `Async` procedure returns to the caller when either the first awaited object that's not yet complete is encountered or the end of the `Async` procedure is reached, whichever occurs first.

You can also mark a [Function Statement](#) with the `Async` modifier. An `Async` function can have a return type of `Task<TResult>` or `Task`. An example later in this topic shows an `Async` function that has a return type of `Task<TResult>`.

`Async Sub` procedures are primarily used for event handlers, where a value can't be returned. An `Async Sub` procedure can't be awaited, and the caller of an `Async Sub` procedure can't catch exceptions that the `Sub` procedure throws.

An `Async` procedure can't declare any `ByRef` parameters.

For more information about `Async` procedures, see [Asynchronous Programming with Async and Await](#), [Control Flow in Async Programs](#), and [Async Return Types](#).

Example

The following example uses the `Sub` statement to define the name, parameters, and code that form the body of a `Sub` procedure.

```

Sub computeArea(ByVal length As Double, ByVal width As Double)
    ' Declare local variable.
    Dim area As Double
    If length = 0 Or width = 0 Then
        ' If either argument = 0 then exit Sub immediately.
        Exit Sub
    End If
    ' Calculate area of rectangle.
    area = length * width
    ' Print area to Immediate window.
    Debug.WriteLine(area)
End Sub

```

Example

In the following example, `DelayAsync` is an `Async Function` that has a return type of `Task<TResult>`. `DelayAsync` has a `Return` statement that returns an integer. Therefore, the function declaration of `DelayAsync` must have a return type of `Task(Of Integer)`. Because the return type is `Task(Of Integer)`, the evaluation of the `Await` expression in `DoSomethingAsync` produces an integer, as the following statement shows: `Dim result As Integer = Await delayTask`.

The `startButton_Click` procedure is an example of an `Async Sub` procedure. Because `DoSomethingAsync` is an `Async` function, the task for the call to `DoSomethingAsync` must be awaited, as the following statement shows: `Await DoSomethingAsync()`. The `startButton_Click` `Sub` procedure must be defined with the `Async` modifier because it has an `Await` expression.

```

' Imports System.Diagnostics
' Imports System.Threading.Tasks

' This Click event is marked with the Async modifier.
Private Async Sub startButton_Click(sender As Object, e As RoutedEventArgs) Handles
    startButton.Click
    Await DoSomethingAsync()
End Sub

Private Async Function DoSomethingAsync() As Task
    Dim delayTask As Task(Of Integer) = DelayAsync()
    Dim result As Integer = Await delayTask

    ' The previous two statements may be combined into
    ' the following statement.
    ' Dim result As Integer = Await DelayAsync()

    Debug.WriteLine("Result: " & result)
End Function

Private Async Function DelayAsync() As Task(Of Integer)
    Await Task.Delay(100)
    Return 5
End Function

' Output:
' Result: 5

SyncLock Statement

2/28/2019 • 5 minutes to read • [Edit Online](#)

Acquires an exclusive lock for a statement block before executing the block.

Syntax

```
SyncLock lockobject  
  [ block ]  
End SyncLock
```

Parts

`lockobject`

Required. Expression that evaluates to an object reference.

`block`

Optional. Block of statements that are to execute when the lock is acquired.

`End SyncLock`

Terminates a `SyncLock` block.

Remarks

The `SyncLock` statement ensures that multiple threads do not execute the statement block at the same time.

`SyncLock` prevents each thread from entering the block until no other thread is executing it.

The most common use of `SyncLock` is to protect data from being updated by more than one thread simultaneously. If the statements that manipulate the data must go to completion without interruption, put them inside a `SyncLock` block.

A statement block protected by an exclusive lock is sometimes called a *critical section*.

Rules

- Branching. You cannot branch into a `SyncLock` block from outside the block.
- Lock Object Value. The value of `lockobject` cannot be `Nothing`. You must create the lock object before you use it in a `SyncLock` statement.

You cannot change the value of `lockobject` while executing a `SyncLock` block. The mechanism requires that the lock object remain unchanged.

- You can't use the `Await` operator in a `SyncLock` block.

Behavior

- Mechanism. When a thread reaches the `SyncLock` statement, it evaluates the `lockobject` expression and suspends execution until it acquires an exclusive lock on the object returned by the expression. When another thread reaches the `SyncLock` statement, it does not acquire a lock until the first thread executes the `End SyncLock` statement.

- Protected Data. If `lockobject` is a `Shared` variable, the exclusive lock prevents a thread in any instance of the class from executing the `SyncLock` block while any other thread is executing it. This protects data that is shared among all the instances.

If `lockobject` is an instance variable (not `shared`), the lock prevents a thread running in the current instance from executing the `SyncLock` block at the same time as another thread in the same instance. This protects data maintained by the individual instance.
- Acquisition and Release. A `SyncLock` block behaves like a `Try...Finally` construction in which the `Try` block acquires an exclusive lock on `lockobject` and the `Finally` block releases it. Because of this, the `SyncLock` block guarantees release of the lock, no matter how you exit the block. This is true even in the case of an unhandled exception.
- Framework Calls. The `SyncLock` block acquires and releases the exclusive lock by calling the `Enter` and `Exit` methods of the `Monitor` class in the `System.Threading` namespace.

Programming Practices

The `lockobject` expression should always evaluate to an object that belongs exclusively to your class. You should declare a `Private` object variable to protect data belonging to the current instance, or a `Private Shared` object variable to protect data common to all instances.

You should not use the `Me` keyword to provide a lock object for instance data. If code external to your class has a reference to an instance of your class, it could use that reference as a lock object for a `SyncLock` block completely different from yours, protecting different data. In this way, your class and the other class could block each other from executing their unrelated `SyncLock` blocks. Similarly locking on a string can be problematic since any other code in the process using the same string will share the same lock.

You should also not use the `Me.GetType` method to provide a lock object for shared data. This is because `GetType` always returns the same `Type` object for a given class name. External code could call `GetType` on your class and obtain the same lock object you are using. This would result in the two classes blocking each other from their `SyncLock` blocks.

Examples

Description

The following example shows a class that maintains a simple list of messages. It holds the messages in an array and the last used element of that array in a variable. The `addAnotherMessage` procedure increments the last element and stores the new message. Those two operations are protected by the `SyncLock` and `End SyncLock` statements, because once the last element has been incremented, the new message must be stored before any other thread can increment the last element again.

If the `simpleMessageList` class shared one list of messages among all its instances, the variables `messagesList` and `messagesLast` would be declared as `Shared`. In this case, the variable `messagesLock` should also be `Shared`, so that there would be a single lock object used by every instance.

Code

```
Class simpleMessageList
    Public messagesList() As String = New String(50) {}
    Public messagesLast As Integer = -1
    Private messagesLock As New Object
    Public Sub addAnotherMessage(ByVal newMessage As String)
        SyncLock messagesLock
            messagesLast += 1
            If messagesLast < messagesList.Length Then
                messagesList(messagesLast) = newMessage
            End If
        End SyncLock
    End Sub
End Class
```

Description

The following example uses threads and `SyncLock`. As long as the `SyncLock` statement is present, the statement block is a critical section and `balance` never becomes a negative number. You can comment out the `SyncLock` and `End SyncLock` statements to see the effect of leaving out the `SyncLock` keyword.

Code

```

Imports System.Threading

Module Module1

    Class Account
        Dim thisLock As New Object
        Dim balance As Integer

        Dim r As New Random()

        Public Sub New(ByVal initial As Integer)
            balance = initial
        End Sub

        Public Function Withdraw(ByVal amount As Integer) As Integer
            ' This condition will never be true unless the SyncLock statement
            ' is commented out:
            If balance < 0 Then
                Throw New Exception("Negative Balance")
            End If

            ' Comment out the SyncLock and End SyncLock lines to see
            ' the effect of leaving out the SyncLock keyword.
            SyncLock thisLock
                If balance >= amount Then
                    Console.WriteLine("Balance before Withdrawal : " & balance)
                    Console.WriteLine("Amount to Withdraw : -" & amount)
                    balance = balance - amount
                    Console.WriteLine("Balance after Withdrawal : " & balance)
                    Return amount
                Else
                    ' Transaction rejected.
                    Return 0
                End If
            End SyncLock
        End Function

        Public Sub DoTransactions()
            For i As Integer = 0 To 99
                Withdraw(r.Next(1, 100))
            Next
        End Sub
    End Class

    Sub Main()
        Dim threads(10) As Thread
        Dim acc As New Account(1000)

        For i As Integer = 0 To 9
            Dim t As New Thread(New ThreadStart(AddressOf acc.DoTransactions))
            threads(i) = t
        Next

        For i As Integer = 0 To 9
            threads(i).Start()
        Next
    End Sub

End Module

```

Throw Statement (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Throws an exception within a procedure.

Syntax

```
Throw [ expression ]
```

Part

`expression`

Provides information about the exception to be thrown. Optional when residing in a `Catch` statement, otherwise required.

Remarks

The `Throw` statement throws an exception that you can handle with structured exception-handling code (`Try ... Catch ... Finally`) or unstructured exception-handling code (`On Error GoTo`). You can use the `Throw` statement to trap errors within your code because Visual Basic moves up the call stack until it finds the appropriate exception-handling code.

A `Throw` statement with no expression can only be used in a `Catch` statement, in which case the statement rethrows the exception currently being handled by the `Catch` statement.

The `Throw` statement resets the call stack for the `expression` exception. If `expression` is not provided, the call stack is left unchanged. You can access the call stack for the exception through the `StackTrace` property.

Example

The following code uses the `Throw` statement to throw an exception:

```
' Throws a new exception.  
Throw New System.Exception("An exception has occurred.")
```

Try...Catch...Finally Statement (Visual Basic)

1/11/2019 • 13 minutes to read • [Edit Online](#)

Provides a way to handle some or all possible errors that may occur in a given block of code, while still running code.

Syntax

```
Try
    [ tryStatements ]
    [ Exit Try ]
    [ Catch [ exception [ As type ] ] [ When expression ]
        [ catchStatements ]
        [ Exit Try ] ]
    [ Catch ... ]
    [ Finally
        [ finallyStatements ] ]
End Try
```

Parts

TERM	DEFINITION
<code>tryStatements</code>	Optional. Statement(s) where an error can occur. Can be a compound statement.
<code>Catch</code>	Optional. Multiple <code>Catch</code> blocks permitted. If an exception occurs when processing the <code>Try</code> block, each <code>Catch</code> statement is examined in textual order to determine whether it handles the exception, with <code>exception</code> representing the exception that has been thrown.
<code>exception</code>	Optional. Any variable name. The initial value of <code>exception</code> is the value of the thrown error. Used with <code>Catch</code> to specify the error caught. If omitted, the <code>Catch</code> statement catches any exception.
<code>type</code>	Optional. Specifies the type of class filter. If the value of <code>exception</code> is of the type specified by <code>type</code> or of a derived type, the identifier becomes bound to the exception object.
<code>When</code>	Optional. A <code>Catch</code> statement with a <code>When</code> clause catches exceptions only when <code>expression</code> evaluates to <code>True</code> . A <code>When</code> clause is applied only after checking the type of the exception, and <code>expression</code> may refer to the identifier representing the exception.

TERM	DEFINITION
<code>expression</code>	Optional. Must be implicitly convertible to <code>Boolean</code> . Any expression that describes a generic filter. Typically used to filter by error number. Used with <code>When</code> keyword to specify circumstances under which the error is caught.
<code>catchStatements</code>	Optional. Statement(s) to handle errors that occur in the associated <code>Try</code> block. Can be a compound statement.
<code>Exit Try</code>	Optional. Keyword that breaks out of the <code>Try...Catch...Finally</code> structure. Execution resumes with the code immediately following the <code>End Try</code> statement. The <code>Finally</code> statement will still be executed. Not allowed in <code>Finally</code> blocks.
<code>Finally</code>	Optional. A <code>Finally</code> block is always executed when execution leaves any part of the <code>Try...Catch</code> statement.
<code>finallyStatements</code>	Optional. Statement(s) that are executed after all other error processing has occurred.
<code>End Try</code>	Terminates the <code>Try...Catch...Finally</code> structure.

Remarks

If you expect that a particular exception might occur during a particular section of code, put the code in a `Try` block and use a `Catch` block to retain control and handle the exception if it occurs.

A `Try...Catch` statement consists of a `Try` block followed by one or more `Catch` clauses, which specify handlers for various exceptions. When an exception is thrown in a `Try` block, Visual Basic looks for the `Catch` statement that handles the exception. If a matching `Catch` statement is not found, Visual Basic examines the method that called the current method, and so on up the call stack. If no `Catch` block is found, Visual Basic displays an unhandled exception message to the user and stops execution of the program.

You can use more than one `Catch` statement in a `Try...Catch` statement. If you do this, the order of the `Catch` clauses is significant because they are examined in order. Catch the more specific exceptions before the less specific ones.

The following `Catch` statement conditions are the least specific, and will catch all exceptions that derive from the `Exception` class. You should ordinarily use one of these variations as the last `Catch` block in the `Try...Catch...Finally` structure, after catching all the specific exceptions you expect. Control flow can never reach a `Catch` block that follows either of these variations.

- The `type` is `Exception`, for example: `Catch ex As Exception`
- The statement has no `exception` variable, for example: `Catch`

When a `Try...Catch...Finally` statement is nested in another `Try` block, Visual Basic first examines each `Catch` statement in the innermost `Try` block. If no matching `Catch` statement is found, the search proceeds to the `Catch` statements of the outer `Try...Catch...Finally` block.

Local variables from a `Try` block are not available in a `Catch` block because they are separate blocks. If you want to use a variable in more than one block, declare the variable outside the `Try...Catch...Finally` structure.

TIP

The `Try...Catch...Finally` statement is available as an IntelliSense code snippet. In the Code Snippets Manager, expand **Code Patterns - If, For Each, Try Catch, Property, etc**, and then **Error Handling (Exceptions)**. For more information, see [Code Snippets](#).

Finally block

If you have one or more statements that must run before you exit the `Try` structure, use a `Finally` block. Control passes to the `Finally` block just before it passes out of the `Try...Catch` structure. This is true even if an exception occurs anywhere inside the `Try` structure.

A `Finally` block is useful for running any code that must execute even if there is an exception. Control is passed to the `Finally` block regardless of how the `Try...Catch` block exits.

The code in a `Finally` block runs even if your code encounters a `Return` statement in a `Try` or `Catch` block. Control does not pass from a `Try` or `Catch` block to the corresponding `Finally` block in the following cases:

- An [End Statement](#) is encountered in the `Try` or `Catch` block.
- A [StackOverflowException](#) is thrown in the `Try` or `Catch` block.

It is not valid to explicitly transfer execution into a `Finally` block. Transferring execution out of a `Finally` block is not valid, except through an exception.

If a `Try` statement does not contain at least one `Catch` block, it must contain a `Finally` block.

TIP

If you do not have to catch specific exceptions, the `Using` statement behaves like a `Try...Finally` block, and guarantees disposal of the resources, regardless of how you exit the block. This is true even with an unhandled exception. For more information, see [Using Statement](#).

Exception argument

The `Catch` block `exception` argument is an instance of the [Exception](#) class or a class that derives from the `Exception` class. The `Exception` class instance corresponds to the error that occurred in the `Try` block.

The properties of the `Exception` object help to identify the cause and location of an exception. For example, the `StackTrace` property lists the called methods that led to the exception, helping you find where the error occurred in the code. `Message` returns a message that describes the exception. `HelpLink` returns a link to an associated Help file. `InnerException` returns the `Exception` object that caused the current exception, or it returns `Nothing` if there is no original `Exception`.

Considerations when using a Try...Catch statement

Use a `Try...Catch` statement only to signal the occurrence of unusual or unanticipated program events.

Reasons for this include the following:

- Catching exceptions at runtime creates additional overhead, and is likely to be slower than pre-checking to avoid exceptions.
- If a `Catch` block is not handled correctly, the exception might not be reported correctly to users.

- Exception handling makes a program more complex.

You do not always need a `Try...Catch` statement to check for a condition that is likely to occur. The following example checks whether a file exists before trying to open it. This reduces the need for catching an exception thrown by the `OpenText` method.

```
Private Sub TextFileExample(ByVal filePath As String)

    ' Verify that the file exists.
    If System.IO.File.Exists(filePath) = False Then
        Console.WriteLine("File Not Found: " & filePath)
    Else
        ' Open the text file and display its contents.
        Dim sr As System.IO.StreamReader =
            System.IO.File.OpenText(filePath)

        Console.WriteLine(sr.ReadToEnd)

        sr.Close()
    End If
End Sub
```

Ensure that code in `Catch` blocks can properly report exceptions to users, whether through thread-safe logging or appropriate messages. Otherwise, exceptions might remain unknown.

Async methods

If you mark a method with the `Async` modifier, you can use the `Await` operator in the method. A statement with the `Await` operator suspends execution of the method until the awaited task completes. The task represents ongoing work. When the task that's associated with the `Await` operator finishes, execution resumes in the same method. For more information, see [Control Flow in Async Programs](#).

A task returned by an `Async` method may end in a faulted state, indicating that it completed due to an unhandled exception. A task may also end in a canceled state, which results in an `OperationCanceledException` being thrown out of the `Await` expression. To catch either type of exception, place the `Await` expression that's associated with the task in a `Try` block, and catch the exception in the `Catch` block. An example is provided later in this topic.

A task can be in a faulted state because multiple exceptions were responsible for its faulting. For example, the task might be the result of a call to `Task.WhenAll`. When you await such a task, the caught exception is only one of the exceptions, and you can't predict which exception will be caught. An example is provided later in this topic.

An `Await` expression can't be inside a `Catch` block or `Finally` block.

Iterators

An iterator function or `Get` accessor performs a custom iteration over a collection. An iterator uses a `Yield` statement to return each element of the collection one at a time. You call an iterator function by using a [For Each...Next Statement](#).

A `Yield` statement can be inside a `Try` block. A `Try` block that contains a `Yield` statement can have `Catch` blocks, and can have a `Finally` block. See the "Try Blocks in Visual Basic" section of [Iterators](#) for an example.

A `Yield` statement cannot be inside a `Catch` block or a `Finally` block.

If the `For Each` body (outside of the iterator function) throws an exception, a `Catch` block in the iterator

function is not executed, but a `Finally` block in the iterator function is executed. A `Catch` block inside an iterator function catches only exceptions that occur inside the iterator function.

Partial-trust situations

In partial-trust situations, such as an application hosted on a network share, `Try...Catch...Finally` does not catch security exceptions that occur before the method that contains the call is invoked. The following example, when you put it on a server share and run from there, produces the error "System.Security.SecurityException: Request Failed." For more information about security exceptions, see the [SecurityException](#) class.

```
Try
    Process.Start("http://www.microsoft.com")
Catch ex As Exception
    MsgBox("Can't load Web page" & vbCrLf & ex.Message)
End Try
```

In such a partial-trust situation, you have to put the `Process.Start` statement in a separate `Sub`. The initial call to the `Sub` will fail. This enables `Try...Catch` to catch it before the `Sub` that contains `Process.Start` is started and the security exception produced.

Examples

The structure of Try...Catch...Finally

The following example illustrates the structure of the `Try...Catch...Finally` statement.

```
Public Sub TryExample()
    ' Declare variables.
    Dim x As Integer = 5
    Dim y As Integer = 0

    ' Set up structured error handling.
    Try
        ' Cause a "Divide by Zero" exception.
        x = x \ y

        ' This statement does not execute because program
        ' control passes to the Catch block when the
        ' exception occurs.
        MessageBox.Show("end of Try block")
    Catch ex As Exception
        ' Show the exception's message.
        MessageBox.Show(ex.Message)

        ' Show the stack trace, which is a list of methods
        ' that are currently executing.
        MessageBox.Show("Stack Trace: " & vbCrLf & ex.StackTrace)
    Finally
        ' This line executes whether or not the exception occurs.
        MessageBox.Show("in Finally block")
    End Try
End Sub
```

Exception in a method called from a Try block

In the following example, the `CreateException` method throws a `NullReferenceException`. The code that generates the exception is not in a `Try` block. Therefore, the `CreateException` method does not handle the exception. The `RunSample` method does handle the exception because the call to the `CreateException` method is in a `Try` block.

The example includes `Catch` statements for several types of exceptions, ordered from the most specific to the most general.

```
Public Sub RunSample()
    Try
        CreateException()
    Catch ex As System.IO.IOException
        ' Code that reacts to IOException.
    Catch ex As NullReferenceException
        MessageBox.Show("NullReferenceException: " & ex.Message)
        MessageBox.Show("Stack Trace: " & vbCrLf & ex.StackTrace)
    Catch ex As Exception
        ' Code that reacts to any other exception.
    End Try
End Sub

Private Sub CreateException()
    ' This code throws a NullReferenceException.
    Dim obj = Nothing
    Dim prop = obj.Name

    ' This code also throws a NullReferenceException.
    Throw New NullReferenceException("Something happened.")
End Sub
```

The Catch When statement

The following example shows how to use a `Catch When` statement to filter on a conditional expression. If the conditional expression evaluates to `True`, the code in the `catch` block runs.

```
Private Sub WhenExample()
    Dim i As Integer = 5

    Try
        Throw New ArgumentException()
    Catch e As OverflowException When i = 5
        Console.WriteLine("First handler")
    Catch e As ArgumentException When i = 4
        Console.WriteLine("Second handler")
    Catch When i = 5
        Console.WriteLine("Third handler")
    End Try
End Sub
' Output: Third handler
```

Nested Try statements

The following example has a `Try...Catch` statement that is contained in a `Try` block. The inner `Catch` block throws an exception that has its `InnerException` property set to the original exception. The outer `Catch` block reports its own exception and the inner exception.

```

Private Sub InnerExceptionExample()
    Try
        Try
            ' Set a reference to a StringBuilder.
            ' The exception below does not occur if the commented
            ' out statement is used instead.
            Dim sb As System.Text.StringBuilder
            'Dim sb As New System.Text.StringBuilder

            ' Cause a NullReferenceException.
            sb.Append("text")
        Catch ex As Exception
            ' Throw a new exception that has the inner exception
            ' set to the original exception.
            Throw New ApplicationException("Something happened :(", ex)
        End Try
    Catch ex2 As Exception
        ' Show the exception.
        Console.WriteLine("Exception: " & ex2.Message)
        Console.WriteLine(ex2.StackTrace)

        ' Show the inner exception, if one is present.
        If ex2.InnerException IsNot Nothing Then
            Console.WriteLine("Inner Exception: " & ex2.InnerException.Message)
            Console.WriteLine(ex2.StackTrace)
        End If
    End Try
End Sub

```

Exception handling for async methods

The following example illustrates exception handling for async methods. To catch an exception that applies to an async task, the `Await` expression is in a `Try` block of the caller, and the exception is caught in the `Catch` block.

Uncomment the `Throw New Exception` line in the example to demonstrate exception handling. The exception is caught in the `Catch` block, the task's `IsFaulted` property is set to `True`, and the task's `Exception.InnerException` property is set to the exception.

Uncomment the `Throw New OperationCancelledException` line to demonstrate what happens when you cancel an asynchronous process. The exception is caught in the `Catch` block, and the task's `IsCanceled` property is set to `True`. However, under some conditions that don't apply to this example, `IsFaulted` is set to `True` and `IsCanceled` is set to `False`.

```

Public Async Function DoSomethingAsync() As Task
    Dim theTask As Task(Of String) = DelayAsync()

    Try
        Dim result As String = Await theTask
        Debug.WriteLine("Result: " & result)
    Catch ex As Exception
        Debug.WriteLine("Exception Message: " & ex.Message)
    End Try

    Debug.WriteLine("Task IsCanceled: " & theTask.IsCanceled)
    Debug.WriteLine("Task IsFaulted: " & theTask.IsFaulted)
    If theTask.Exception IsNot Nothing Then
        Debug.WriteLine("Task Exception Message: " &
            theTask.Exception.Message)
        Debug.WriteLine("Task Inner Exception Message: " &
            theTask.Exception.InnerException.Message)
    End If
End Function

Private Async Function DelayAsync() As Task(Of String)
    Await Task.Delay(100)

    ' Uncomment each of the following lines to
    ' demonstrate exception handling.

    ' Throw New OperationCanceledException("canceled")
    ' Throw New Exception("Something happened.")
    Return "Done"
End Function

' Output when no exception is thrown in the awaited method:
'   Result: Done
'   Task IsCanceled: False
'   Task IsFaulted:  False

' Output when an Exception is thrown in the awaited method:
'   Exception Message: Something happened.
'   Task IsCanceled: False
'   Task IsFaulted:  True
'   Task Exception Message: One or more errors occurred.
'   Task Inner Exception Message: Something happened.

' Output when an OperationCanceledException or TaskCanceledException
' is thrown in the awaited method:
'   Exception Message: canceled
'   Task IsCanceled: True
'   Task IsFaulted:  False

```

Handling multiple exceptions in async methods

The following example illustrates exception handling where multiple tasks can result in multiple exceptions. The `Try` block has the `Await` expression for the task that `Task.WhenAll` returned. The task is complete when the three tasks to which `Task.WhenAll` is applied are complete.

Each of the three tasks causes an exception. The `catch` block iterates through the exceptions, which are found in the `Exception.InnerExceptions` property of the task that `Task.WhenAll` returned.

```

Public Async Function DoMultipleAsync() As Task
    Dim theTask1 As Task = ExcAsync(info:="First Task")
    Dim theTask2 As Task = ExcAsync(info:="Second Task")
    Dim theTask3 As Task = ExcAsync(info:="Third Task")

    Dim allTasks As Task = Task.WhenAll(theTask1, theTask2, theTask3)

    Try
        Await allTasks
    Catch ex As Exception
        Debug.WriteLine("Exception: " & ex.Message)
        Debug.WriteLine("Task IsFaulted: " & allTasks.IsFaulted)
        For Each inEx In allTasks.Exception.InnerExceptions
            Debug.WriteLine("Task Inner Exception: " + inEx.Message)
        Next
    End Try
End Function

Private Async Function ExcAsync(info As String) As Task
    Await Task.Delay(100)

    Throw New Exception("Error-" & info)
End Function

' Output:
'   Exception: Error-First Task
'   Task IsFaulted: True
'   Task Inner Exception: Error-First Task
'   Task Inner Exception: Error-Second Task
'   Task Inner Exception: Error-Third Task

Using Statement (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

Declares the beginning of a `Using` block and optionally acquires the system resources that the block controls.

Syntax

```
Using { resourcelist | resourceexpression }
    [ statements ]
End Using
```

Parts

TERM	DEFINITION
<code>resourcelist</code>	Required if you do not supply <code>resourceexpression</code> . List of one or more system resources that this <code>Using</code> block controls, separated by commas.
<code>resourceexpression</code>	Required if you do not supply <code>resourcelist</code> . Reference variable or expression referring to a system resource to be controlled by this <code>Using</code> block.
<code>statements</code>	Optional. Block of statements that the <code>using</code> block runs.
<code>End Using</code>	Required. Terminates the definition of the <code>Using</code> block and disposes of all the resources that it controls.

Each resource in the `resourcelist` part has the following syntax and parts:

```
resourcename As New resourcetype [ ( [ arglist ] ) ]
```

-or-

```
resourcename As resourcetype = resourceexpression
```

resourcelist Parts

TERM	DEFINITION
<code>resourcename</code>	Required. Reference variable that refers to a system resource that the <code>Using</code> block controls.
<code>New</code>	Required if the <code>Using</code> statement acquires the resource. If you have already acquired the resource, use the second syntax alternative.
<code>resourcetype</code>	Required. The class of the resource. The class must implement the <code>IDisposable</code> interface.

TERM	DEFINITION
<code>arglist</code>	Optional. List of arguments you are passing to the constructor to create an instance of <code>resourcetype</code> . See Parameter List .
<code>resourceexpression</code>	Required. Variable or expression referring to a system resource satisfying the requirements of <code>resourcetype</code> . If you use the second syntax alternative, you must acquire the resource before passing control to the <code>using</code> statement.

Remarks

Sometimes your code requires an unmanaged resource, such as a file handle, a COM wrapper, or a SQL connection. A `using` block guarantees the disposal of one or more such resources when your code is finished with them. This makes them available for other code to use.

Managed resources are disposed of by the .NET Framework garbage collector (GC) without any extra coding on your part. You do not need a `Using` block for managed resources. However, you can still use a `Using` block to force the disposal of a managed resource instead of waiting for the garbage collector.

A `using` block has three parts: acquisition, usage, and disposal.

- *Acquisition* means creating a variable and initializing it to refer to the system resource. The `Using` statement can acquire one or more resources, or you can acquire exactly one resource before entering the block and supply it to the `Using` statement. If you supply `resourceexpression`, you must acquire the resource before passing control to the `Using` statement.
- *Usage* means accessing the resources and performing actions with them. The statements between `Using` and `End Using` represent the usage of the resources.
- *Disposal* means calling the `Dispose` method on the object in `resourcename`. This allows the object to cleanly terminate its resources. The `End Using` statement disposes of the resources under the `Using` block's control.

Behavior

A `using` block behaves like a `Try ... Finally` construction in which the `Try` block uses the resources and the `Finally` block disposes of them. Because of this, the `using` block guarantees disposal of the resources, no matter how you exit the block. This is true even in the case of an unhandled exception, except for a [StackOverflowException](#).

The scope of every resource variable acquired by the `Using` statement is limited to the `Using` block.

If you specify more than one system resource in the `Using` statement, the effect is the same as if you nested `Using` blocks one within another.

If `resourcename` is `Nothing`, no call to `Dispose` is made, and no exception is thrown.

Structured Exception Handling Within a Using Block

If you need to handle an exception that might occur within the `Using` block, you can add a complete `Try ... Finally` construction to it. If you need to handle the case where the `Using` statement is not successful in acquiring a resource, you can test to see if `resourcename` is `Nothing`.

Structured Exception Handling Instead of a Using Block

If you need finer control over the acquisition of the resources, or you need additional code in the `Finally` block, you can rewrite the `Using` block as a `Try ... Finally` construction. The following example shows skeleton `Try` and `Using` constructions that are equivalent in the acquisition and disposal of `resource`.

```
Using resource As New resourceType
    ' Insert code to work with resource.
End Using

' For the acquisition and disposal of resource, the following
' Try construction is equivalent to the Using block.
Dim resource As New resourceType
Try
    ' Insert code to work with resource.
Finally
    If resource IsNot Nothing Then
        resource.Dispose()
    End If
End Try
```

NOTE

The code inside the `Using` block should not assign the object in `resourcename` to another variable. When you exit the `Using` block, the resource is disposed, and the other variable cannot access the resource to which it points.

Example

The following example creates a file that is named log.txt and writes two lines of text to the file. The example also reads that same file and displays the lines of text.

Because the `TextWriter` and `TextReader` classes implement the `IDisposable` interface, the code can use `Using` statements to ensure that the file is correctly closed after the write and read operations.

```
Private Sub WriteFile()
    Using writer As System.IO.TextWriter = System.IO.File.CreateText("log.txt")
        writer.WriteLine("This is line one.")
        writer.WriteLine("This is line two.")
    End Using
End Sub

Private Sub ReadFile()
    Using reader As System.IO.TextReader = System.IO.File.OpenText("log.txt")
        Dim line As String

        line = reader.ReadLine()
        Do Until line Is Nothing
            Console.WriteLine(line)
            line = reader.ReadLine()
        Loop
    End Using
End Sub
```

While...End While Statement (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Runs a series of statements as long as a given condition is `True`.

Syntax

```
While condition
    [ statements ]
    [ Continue While ]
    [ statements ]
    [ Exit While ]
    [ statements ]
End While
```

Parts

TERM	DEFINITION
<code>condition</code>	Required. <code>Boolean</code> expression. If <code>condition</code> is <code>Nothing</code> , Visual Basic treats it as <code>False</code> .
<code>statements</code>	Optional. One or more statements following <code>While</code> , which run every time <code>condition</code> is <code>True</code> .
<code>Continue While</code>	Optional. Transfers control to the next iteration of the <code>While</code> block.
<code>Exit While</code>	Optional. Transfers control out of the <code>While</code> block.
<code>End While</code>	Required. Terminates the definition of the <code>While</code> block.

Remarks

Use a `While...End While` structure when you want to repeat a set of statements an indefinite number of times, as long as a condition remains `True`. If you want more flexibility with where you test the condition or what result you test it for, you might prefer the [Do...Loop Statement](#). If you want to repeat the statements a set number of times, the [For...Next Statement](#) is usually a better choice.

NOTE

The `While` keyword is also used in the [Do...Loop Statement](#), the [Skip While Clause](#) and the [Take While Clause](#).

If `condition` is `True`, all of the `statements` run until the `End While` statement is encountered. Control then returns to the `While` statement, and `condition` is again checked. If `condition` is still `True`, the process is repeated. If it's `False`, control passes to the statement that follows the `End While` statement.

The `While` statement always checks the condition before it starts the loop. Looping continues while the

condition remains `True`. If `condition` is `False` when you first enter the loop, it doesn't run even once.

The `condition` usually results from a comparison of two values, but it can be any expression that evaluates to a [Boolean Data Type](#) value (`True` or `False`). This expression can include a value of another data type, such as a numeric type, that has been converted to `Boolean`.

You can nest `While` loops by placing one loop within another. You can also nest different kinds of control structures within one another. For more information, see [Nested Control Structures](#).

Exit While

The [Exit While](#) statement can provide another way to exit a `While` loop. `Exit While` immediately transfers control to the statement that follows the `End While` statement.

You typically use `Exit While` after some condition is evaluated (for example, in an `If...Then...Else` structure). You might want to exit a loop if you detect a condition that makes it unnecessary or impossible to continue iterating, such as an erroneous value or a termination request. You can use `Exit While` when you test for a condition that could cause an *endless loop*, which is a loop that could run an extremely large or even infinite number of times. You can then use `Exit While` to escape the loop.

You can place any number of `Exit While` statements anywhere in the `While` loop.

When used within nested `While` loops, `Exit While` transfers control out of the innermost loop and into the next higher level of nesting.

The `Continue While` statement immediately transfers control to the next iteration of the loop. For more information, see [Continue Statement](#).

Example

In the following example, the statements in the loop continue to run until the `index` variable is greater than 10.

```
Dim index As Integer = 0
While index <= 10
    Debug.WriteLine(index.ToString & " ")
    index += 1
End While

Debug.WriteLine("")
' Output: 0 1 2 3 4 5 6 7 8 9 10
```

Example

The following example illustrates the use of the `Continue While` and `Exit While` statements.

```

Dim index As Integer = 0
While index < 100000
    index += 1

    ' If index is between 5 and 7, continue
    ' with the next iteration.
    If index >= 5 And index <= 8 Then
        Continue While
    End If

    ' Display the index.
    Debug.WriteLine(index.ToString & " ")

    ' If index is 10, exit the loop.
    If index = 10 Then
        Exit While
    End If
End While

Debug.WriteLine("")
' Output: 1 2 3 4 9 10

```

Example

The following example reads all lines in a text file. The [OpenText](#) method opens the file and returns a [StreamReader](#) that reads the characters. In the `While` condition, the [Peek](#) method of the [StreamReader](#) determines whether the file contains additional characters.

```

Private Sub ShowText(ByVal textFilePath As String)
    If System.IO.File.Exists(textFilePath) = False Then
        Debug.WriteLine("File Not Found: " & textFilePath)
    Else
        Dim sr As System.IO.StreamReader = System.IO.File.OpenText(textFilePath)

        While sr.Peek() >= 0
            Debug.WriteLine(sr.ReadLine())
        End While

        sr.Close()
    End If
End Sub

```

With...End With Statement (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Executes a series of statements that repeatedly refer to a single object or structure so that the statements can use a simplified syntax when accessing members of the object or structure. When using a structure, you can only read the values of members or invoke methods, and you get an error if you try to assign values to members of a structure used in a `With...End With` statement.

Syntax

```
With objectExpression  
    [ statements ]  
End With
```

Parts

TERM	DEFINITION
<code>objectExpression</code>	Required. An expression that evaluates to an object. The expression may be arbitrarily complex and is evaluated only once. The expression can evaluate to any data type, including elementary types.
<code>statements</code>	Optional. One or more statements between <code>With</code> and <code>End With</code> that may refer to members of an object that's produced by the evaluation of <code>objectExpression</code> .
<code>End With</code>	Required. Terminates the definition of the <code>With</code> block.

Remarks

By using `With...End With`, you can perform a series of statements on a specified object without specifying the name of the object multiple times. Within a `With` statement block, you can specify a member of the object starting with a period, as if the `With` statement object preceded it.

For example, to change multiple properties on a single object, place the property assignment statements inside the `With...End With` block, referring to the object only once instead of once for each property assignment.

If your code accesses the same object in multiple statements, you gain the following benefits by using the `With` statement:

- You don't need to evaluate a complex expression multiple times or assign the result to a temporary variable to refer to its members multiple times.
- You make your code more readable by eliminating repetitive qualifying expressions.

The data type of `objectExpression` can be any class or structure type or even a Visual Basic elementary type such as `Integer`. If `objectExpression` results in anything other than an object, you can only read the values of its members or invoke methods, and you get an error if you try to assign values to members of a structure used in a `With...End With` statement. This is the same error you would get if you invoked a method that returned a

structure and immediately accessed and assigned a value to a member of the function's result, such as `GetAPoint().x = 1`. The problem in both cases is that the structure exists only on the call stack, and there is no way a modified structure member in these situations can write to a location such that any other code in the program can observe the change.

The `objectExpression` is evaluated once, upon entry into the block. You can't reassign the `objectExpression` from within the `With` block.

Within a `With` block, you can access the methods and properties of only the specified object without qualifying them. You can use methods and properties of other objects, but you must qualify them with their object names.

You can place one `With...End With` statement within another. Nested `With...End With` statements may be confusing if the objects that are being referred to aren't clear from context. You must provide a fully qualified reference to an object that's in an outer `With` block when the object is referenced from within an inner `With` block.

You can't branch into a `With` statement block from outside the block.

Unless the block contains a loop, the statements run only once. You can nest different kinds of control structures. For more information, see [Nested Control Structures](#).

NOTE

You can use the `With` keyword in object initializers also. For more information and examples, see [Object Initializers: Named and Anonymous Types](#) and [Anonymous Types](#).

If you're using a `With` block only to initialize the properties or fields of an object that you've just instantiated, consider using an object initializer instead.

Example

In the following example, each `With` block executes a series of statements on a single object.

```
Private Sub AddCustomer()
    Dim theCustomer As New Customer

    With theCustomer
        .Name = "Coho Vineyard"
        .URL = "http://www.cohovineyard.com/"
        .City = "Redmond"
    End With

    With theCustomer.Comments
        .Add("First comment.")
        .Add("Second comment.")
    End With
End Sub

Public Class Customer
    Public Property Name As String
    Public Property City As String
    Public Property URL As String

    Public Property Comments As New List(Of String)
End Class
```

Example

The following example nests `With...End With` statements. Within the nested `With` statement, the syntax refers to the inner object.

```
Dim theWindow As New EntryWindow

With theWindow
    With .InfoLabel
        .Content = "This is a message."
        .Foreground = Brushes.DarkSeaGreen
        .Background = Brushes.LightYellow
    End With

    .Title = "The Form Title"
    .Show()
End With

Yield Statement (Visual Basic)

3/6/2019 • 4 minutes to read • [Edit Online](#)

Sends the next element of a collection to a `For Each...Next` statement.

Syntax

```
Yield expression
```

Parameters

TERM	DEFINITION
<code>expression</code>	Required. An expression that is implicitly convertible to the type of the iterator function or <code>Get</code> accessor that contains the <code>Yield</code> statement.

Remarks

The `Yield` statement returns one element of a collection at a time. The `Yield` statement is included in an iterator function or `Get` accessor, which perform custom iterations over a collection.

You consume an iterator function by using a [For Each...Next Statement](#) or a LINQ query. Each iteration of the `For Each` loop calls the iterator function. When a `Yield` statement is reached in the iterator function, `expression` is returned, and the current location in code is retained. Execution is restarted from that location the next time that the iterator function is called.

An implicit conversion must exist from the type of `expression` in the `Yield` statement to the return type of the iterator.

You can use an `Exit Function` or `Return` statement to end the iteration.

"Yield" is not a reserved word and has special meaning only when it is used in an `Iterator` function or `Get` accessor.

For more information about iterator functions and `Get` accessors, see [Iterators](#).

Iterator Functions and Get Accessors

The declaration of an iterator function or `Get` accessor must meet the following requirements:

- It must include an `Iterator` modifier.
- The return type must be `IEnumerable`, `IEnumerable<T>`, `IEnumerator`, or `IEnumerator<T>`.
- It cannot have any `ByRef` parameters.

An iterator function cannot occur in an event, instance constructor, static constructor, or static destructor.

An iterator function can be an anonymous function. For more information, see [Iterators](#).

Exception Handling

A `Yield` statement can be inside a `Try` block of a [Try...Catch...Finally Statement](#). A `Try` block that has a `Yield` statement can have `Catch` blocks, and can have a `Finally` block.

A `Yield` statement cannot be inside a `Catch` block or a `Finally` block.

If the `For Each` body (outside of the iterator function) throws an exception, a `Catch` block in the iterator function is not executed, but a `Finally` block in the iterator function is executed. A `catch` block inside an iterator function catches only exceptions that occur inside the iterator function.

Technical Implementation

The following code returns an `IEnumerable (Of String)` from an iterator function and then iterates through the elements of the `IEnumerable (Of String)`.

```
Dim elements As IEnumerable(Of String) = MyIteratorFunction()
...
For Each element As String In elements
Next
```

The call to `MyIteratorFunction` doesn't execute the body of the function. Instead the call returns an `IEnumerable(Of String)` into the `elements` variable.

On an iteration of the `For Each` loop, the `MoveNext` method is called for `elements`. This call executes the body of `MyIteratorFunction` until the next `Yield` statement is reached. The `Yield` statement returns an expression that determines not only the value of the `element` variable for consumption by the loop body but also the `Current` property of `elements`, which is an `IEnumerable (Of String)`.

On each subsequent iteration of the `For Each` loop, the execution of the iterator body continues from where it left off, again stopping when it reaches a `Yield` statement. The `For Each` loop completes when the end of the iterator function or a `Return` or `Exit Function` statement is reached.

Example

The following example has a `Yield` statement that is inside a `For...Next` loop. Each iteration of the `For Each` statement body in `Main` creates a call to the `Power` iterator function. Each call to the iterator function proceeds to the next execution of the `Yield` statement, which occurs during the next iteration of the `For...Next` loop.

The return type of the iterator method is `IEnumerable<T>`, an iterator interface type. When the iterator method is called, it returns an enumerable object that contains the powers of a number.

```

Sub Main()
    For Each number In Power(2, 8)
        Console.WriteLine(number & " ")
    Next
    ' Output: 2 4 8 16 32 64 128 256
    Console.ReadKey()
End Sub

Private Iterator Function Power(
    ByVal base As Integer, ByVal highExponent As Integer) _
As System.Collections.Generic.IEnumerable(Of Integer)

    Dim result = 1

    For counter = 1 To highExponent
        result = result * base
        Yield result
    Next
End Function

```

Example

The following example demonstrates a `Get` accessor that is an iterator. The property declaration includes an `Iterator` modifier.

```

Sub Main()
    Dim theGalaxies As New Galaxies
    For Each theGalaxy In theGalaxies.NextGalaxy
        With theGalaxy
            Console.WriteLine(.Name & " " & .MegaLightYears)
        End With
    Next
    Console.ReadKey()
End Sub

Public Class Galaxies
    Public ReadOnly Iterator Property NextGalaxy _ 
    As System.Collections.Generic.IEnumerable(Of Galaxy)
        Get
            Yield New Galaxy With {.Name = "Tadpole", .MegaLightYears = 400}
            Yield New Galaxy With {.Name = "Pinwheel", .MegaLightYears = 25}
            Yield New Galaxy With {.Name = "Milky Way", .MegaLightYears = 0}
            Yield New Galaxy With {.Name = "Andromeda", .MegaLightYears = 3}
        End Get
    End Property
End Class

Public Class Galaxy
    Public Property Name As String
    Public Property MegaLightYears As Integer
End Class

```

Indicates that an external procedure has another name in its DLL.

Remarks

The `Alias` keyword can be used in this context:

Declare Statement

In the following example, the `Alias` keyword is used to provide the name of the function in advapi32.dll, `GetUserNameA`, that `getUserName` is used in place of in this example. Function `getUserName` is called in sub `getUser`, which displays the name of the current user.

```
Declare Function getUserName Lib "advapi32.dll" Alias "GetUserNameA" (  
    ByVal lpBuffer As String, ByRef nSize As Integer) As Integer  
Sub getUser()  
    Dim buffer As String = New String(CChar(" "), 25)  
    Dim retVal As Integer = getUserName(buffer, 25)  
    Dim userName As String = Strings.Left(buffer, InStr(buffer, Chr(0)) - 1)

Parts

`proceduredeclaration`

The `Sub` procedure declaration for the procedure that will handle the event.

`eventlist`

List of the events for `proceduredeclaration` to handle, separated by commas. The events must be raised by either the base class for the current class, or by an object declared using the `WithEvents` keyword.

Remarks

Use the `Handles` keyword at the end of a procedure declaration to cause it to handle events raised by an object variable declared using the `WithEvents` keyword. The `Handles` keyword can also be used in a derived class to handle events from a base class.

The `Handles` keyword and the `AddHandler` statement both allow you to specify that particular procedures handle particular events, but there are differences. Use the `Handles` keyword when defining a procedure to specify that it handles a particular event. The `AddHandler` statement connects procedures to events at run time. For more information, see [AddHandler Statement](#).

For custom events, the application invokes the event's `AddHandler` accessor when it adds the procedure as an event handler. For more information on custom events, see [Event Statement](#).

Example

```

Public Class ContainerClass
    ' Module or class level declaration.
    WithEvents Obj As New Class1

    Public Class Class1
        ' Declare an event.
        Public Event Ev_Event()
        Sub CauseSomeEvent()
            ' Raise an event.
            RaiseEvent Ev_Event()
        End Sub
    End Class

    Sub EventHandler() Handles Obj.Ev_Event
        ' Handle the event.
        MsgBox("EventHandler caught event.")
    End Sub

    ' Call the TestEvents procedure from an instance of the ContainerClass
    ' class to test the Ev_Event event and the event handler.
    Public Sub TestEvents()
        Obj.CauseSomeEvent()
    End Sub
End Class

```

The following example demonstrates how a derived class can use the `Handles` statement to handle an event from a base class.

```

Public Class BaseClass
    ' Declare an event.
    Event Ev1()
End Class
Class DerivedClass
    Inherits BaseClass
    Sub TestEvents() Handles MyBase.Ev1
        ' Add code to handle this event.
    End Sub
End Class

```

Example

The following example contains two button event handlers for a **WPF Application** project.

```

Private Sub Button1_Click(sender As System.Object, e As System.Windows.RoutedEventArgs) Handles
    Button1.Click
    MessageBox.Show(sender.Name & " clicked")
End Sub

Private Sub Button2_Click(sender As System.Object, e As System.Windows.RoutedEventArgs) Handles
    Button2.Click
    MessageBox.Show(sender.Name & " clicked")
End Sub

```

Example

The following example is equivalent to the previous example. The `eventlist` in the `Handles` clause contains the events for both buttons.

```
Private Sub Button_Click(sender As System.Object, e As System.Windows.RoutedEventArgs) Handles  
Button1.Click, Button2.Click  
    MessageBox.Show(sender.Name & " clicked")  
End Sub
```

Implements Clause (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Indicates that a class or structure member is providing the implementation for a member defined in an interface.

Remarks

The `Implements` keyword is not the same as the [Implements Statement](#). You use the `Implements` statement to specify that a class or structure implements one or more interfaces, and then for each member you use the `Implements` keyword to specify which interface and which member it implements.

If a class or structure implements an interface, it must include the `Implements` statement immediately after the [Class Statement](#) or [Structure Statement](#), and it must implement all the members defined by the interface.

Reimplementation

In a derived class, you can reimplement an interface member that the base class has already implemented. This is different from overriding the base class member in the following respects:

- The base class member does not need to be [Overridable](#) to be reimplemented.
- You can reimplement the member with a different name.

The `Implements` keyword can be used in the following contexts:

- [Event Statement](#)
- [Function Statement](#)
- [Property Statement](#)
- [Sub Statement](#)

In Clause (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies the group that the loop variable is to traverse in a `For Each` loop, or specifies the collection to query in a `From`, `Join`, or `Group Join` clause.

Remarks

The `In` keyword can be used in the following contexts:

Into Clause (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Identifies aggregate functions or groupings to apply to a collection.

Remarks

The `Each` keyword is used in the following contexts:

Of Clause (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Introduces an `of` clause, which identifies a *type parameter* on a *generic class*, structure, interface, delegate, or procedure. For information on generic types, see [Generic Types in Visual Basic](#).

Using the Of Keyword

The following code example uses the `of` keyword to define the outline of a class that takes two type parameters. It *constraints* the `keyType` parameter by the [IComparable](#) interface, which means the consuming code must supply a type argument that implements [IComparable](#). This is necessary so that the `add` procedure can call the [IComparable.CompareTo](#) method. For more information on constraints, see [Type List](#).

```
Public Class Dictionary(Of entryType, keyType As IComparable)
    Public Sub add(ByVal e As entryType, ByVal k As keyType)
        Dim dk As keyType
        If k.CompareTo(dk) = 0 Then
            End If
        End Sub
    Public Function find(ByVal k As keyType) As entryType
    End Function
End Class
```

If you complete the preceding class definition, you can construct a variety of `dictionary` classes from it. The types you supply to `entryType` and `keyType` determine what type of entry the class holds and what type of key it associates with each entry. Because of the constraint, you must supply to `keyType` a type that implements [IComparable](#).

The following code example creates an object that holds `String` entries and associates an `Integer` key with each one. `Integer` implements [IComparable](#) and therefore satisfies the constraint on `keyType`.

```
Dim d As New dictionary(Of String, Integer)
```

The `of` keyword can be used in these contexts:

Declaration Contexts and Default Access Levels (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic describes which Visual Basic types can be declared within which other types, and what their access levels default to if not specified.

Declaration Context Levels

The *declaration context* of a programming element is the region of code in which it is declared. This is often another programming element, which is then called the *containing element*.

The levels for declaration contexts are the following:

- *Namespace level* — within a source file or namespace but not within a class, structure, module, or interface
- *Module level* — within a class, structure, module, or interface but not within a procedure or block
- *Procedure level* — within a procedure or block (such as `If` or `For`)

The following table shows the default access levels for various declared programming elements, depending on their declaration contexts.

DECLARED ELEMENT	NAMESPACE LEVEL	MODULE LEVEL	PROCEDURE LEVEL
Variable (Dim Statement)	Not allowed	<code>Private</code> (<code>Public</code> in <code>Structure</code> , not allowed in <code>Interface</code>)	<code>Public</code>
Constant (Const Statement)	Not allowed	<code>Private</code> (<code>Public</code> in <code>Structure</code> , not allowed in <code>Interface</code>)	<code>Public</code>
Enumeration (Enum Statement)	<code>Friend</code>	<code>Public</code>	Not allowed
Class (Class Statement)	<code>Friend</code>	<code>Public</code>	Not allowed
Structure (Structure Statement)	<code>Friend</code>	<code>Public</code>	Not allowed
Module (Module Statement)	<code>Friend</code>	Not allowed	Not allowed
Interface (Interface Statement)	<code>Friend</code>	<code>Public</code>	Not allowed
Procedure (Function Statement, Sub Statement)	Not allowed	<code>Public</code>	Not allowed

DECLARED ELEMENT	NAMESPACE LEVEL	MODULE LEVEL	PROCEDURE LEVEL
External reference (Declare Statement)	Not allowed	<code>Public</code> (not allowed in <code>Interface</code>)	Not allowed
Operator (Operator Statement)	Not allowed	<code>Public</code> (not allowed in <code>Interface</code> or <code>Module</code>)	Not allowed
Property (Property Statement)	Not allowed	<code>Public</code>	Not allowed
Default property (Default)	Not allowed	<code>Public</code> (not allowed in <code>Module</code>)	Not allowed
Event (Event Statement)	Not allowed	<code>Public</code>	Not allowed
Delegate (Delegate Statement)	<code>Friend</code>	<code>Public</code>	Not allowed

Attribute List (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies the attributes to be applied to a declared programming element. Multiple attributes are separated by commas. Following is the syntax for one attribute.

Syntax

```
[ attributemodifier ] attributename [ ( attributearguments | attributeinitializer ) ]
```

Parts

<code>attributemodifier</code>	Required for attributes applied at the beginning of a source file. Can be Assembly or Module .
<code>attributename</code>	Required. Name of the attribute.
<code>attributearguments</code>	Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
<code>attributeinitializer</code>	Optional. List of variable or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

You can apply one or more attributes to nearly any programming element (types, procedures, properties, and so forth). Attributes appear in your assembly's metadata, and they can help you annotate your code or specify how to use a particular programming element. You can apply attributes defined by Visual Basic and the .NET Framework, and you can define your own attributes.

For more information on when to use attributes, see [Attributes overview](#). For information on attribute names, see [Declared Element Names](#).

Rules

- **Placement.** You can apply attributes to most declared programming elements. To apply one or more attributes, you place an *attribute block* at the beginning of the element declaration. Each entry in the attribute list specifies an attribute you wish to apply, and the modifier and arguments you are using for this invocation of the attribute.
- **Angle Brackets.** If you supply an attribute list, you must enclose it in angle brackets ("<" and ">").
- **Part of the Declaration.** The attribute must be part of the element declaration, not a separate statement. You can use the line-continuation sequence ("`_`") to extend the declaration statement onto multiple source-code lines.
- **Modifiers.** An attribute modifier (`Assembly` or `Module`) is required on every attribute applied to a programming element at the beginning of a source file. Attribute modifiers are not allowed on

attributes applied to elements that are not at the beginning of a source file.

- **Arguments.** All positional arguments for an attribute must precede any variable or property initializers.

Example

The following example applies the [DllImportAttribute](#) attribute to a skeleton definition of a [Function](#) procedure.

```
<DllImportAttribute("kernel32.dll", EntryPoint:="MoveFileW",
    SetLastError:=True, CharSet:=CharSet.Unicode,
    ExactSpelling:=True,
    CallingConvention:=CallingConvention.StdCall)>
Public Shared Function moveFile(ByVal src As String,
    ByVal dst As String) As Boolean
    ' This function copies a file from the path src to the path dst.
    ' Leave this function empty. The DllImport attribute forces calls
    ' to moveFile to be forwarded to MoveFileW in KERNEL32.DLL.
End Function
```

[DllImportAttribute](#) indicates that the attributed procedure represents an entry point in an unmanaged dynamic-link library (DLL). The attribute supplies the DLL name as a positional argument and the other information as variable initializers.

Parameter List (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Specifies the parameters a procedure expects when it is called. Multiple parameters are separated by commas. The following is the syntax for one parameter.

Syntax

```
[ <attributelist> ] [ Optional ] [{ ByVal | ByRef }] [ ParamArray ]  
parametername[( )] [ As parametertype ] [ = defaultvalue ]
```

Parts

`attributelist`

Optional. List of attributes that apply to this parameter. You must enclose the [Attribute List](#) in angle brackets ("<" and ">").

`Optional`

Optional. Specifies that this parameter is not required when the procedure is called.

`ByVal`

Optional. Specifies that the procedure cannot replace or reassign the variable element underlying the corresponding argument in the calling code.

`ByRef`

Optional. Specifies that the procedure can modify the underlying variable element in the calling code the same way the calling code itself can.

`ParamArray`

Optional. Specifies that the last parameter in the parameter list is an optional array of elements of the specified data type. This lets the calling code pass an arbitrary number of arguments to the procedure.

`parametername`

Required. Name of the local variable representing the parameter.

`parametertype`

Required if `Option Strict` is `On`. Data type of the local variable representing the parameter.

`defaultvalue`

Required for `Optional` parameters. Any constant or constant expression that evaluates to the data type of the parameter. If the type is `Object`, or a class, interface, array, or structure, the default value can only be `Nothing`.

Remarks

Parameters are surrounded by parentheses and separated by commas. A parameter can be declared with any data type. If you do not specify `parametertype`, it defaults to `Object`.

When the calling code calls the procedure, it passes an *argument* to each required parameter. For more information, see [Differences Between Parameters and Arguments](#).

The argument the calling code passes to each parameter is a pointer to an underlying element in the calling

code. If this element is *nonvariable* (a constant, literal, enumeration, or expression), it is impossible for any code to change it. If it is a *variable* element (a declared variable, field, property, array element, or structure element), the calling code can change it. For more information, see [Differences Between Modifiable and Nonmodifiable Arguments](#).

If a variable element is passed `ByRef`, the procedure can change it as well. For more information, see [Differences Between Passing an Argument By Value and By Reference](#).

Rules

- **Parentheses.** If you specify a parameter list, you must enclose it in parentheses. If there are no parameters, you can still use parentheses enclosing an empty list. This improves the readability of your code by clarifying that the element is a procedure.
- **Optional Parameters.** If you use the `optional` modifier on a parameter, all subsequent parameters in the list must also be optional and be declared by using the `optional` modifier.

Every optional parameter declaration must supply the `defaultvalue` clause.

For more information, see [Optional Parameters](#).

- **Parameter Arrays.** You must specify `ByVal` for a `ParamArray` parameter.

You cannot use both `Optional` and `ParamArray` in the same parameter list.

For more information, see [Parameter Arrays](#).

- **Passing Mechanism.** The default mechanism for every argument is `ByVal`, which means the procedure cannot change the underlying variable element. However, if the element is a reference type, the procedure can modify the contents or members of the underlying object, even though it cannot replace or reassign the object itself.
- **Parameter Names.** If the parameter's data type is an array, follow `parametername` immediately by parentheses. For more information on parameter names, see [Declared Element Names](#).

Example

The following example shows a `Function` procedure that defines two parameters.

```
Public Function howMany(ByVal ch As Char, ByVal st As String) As Integer
End Function
Dim howManyA As Integer = howMany("a"c, "How many a's in this string?")
```

Type List (Visual Basic)

2/28/2019 • 3 minutes to read • [Edit Online](#)

Specifies the *type parameters* for a *generic* programming element. Multiple parameters are separated by commas. Following is the syntax for one type parameter.

Syntax

```
[genericmodifier] typename [ As constraintlist ]
```

Parts

TERM	DEFINITION
<code>genericmodifier</code>	Optional. Can be used only in generic interfaces and delegates. You can declare a type covariant by using the <code>Out</code> keyword or contravariant by using the <code>In</code> keyword. See Covariance and Contravariance .
<code>typename</code>	Required. Name of the type parameter. This is a placeholder, to be replaced by a defined type supplied by the corresponding type argument.
<code>constraintlist</code>	Optional. List of requirements that constrain the data type that can be supplied for <code>typename</code> . If you have multiple constraints, enclose them in curly braces (<code>{ }</code>) and separate them with commas. You must introduce the constraint list with the <code>As</code> keyword. You use <code>As</code> only once, at the beginning of the list.

Remarks

Every generic programming element must take at least one type parameter. A type parameter is a placeholder for a specific type (a *constructed element*) that client code specifies when it creates an instance of the generic type. You can define a generic class, structure, interface, procedure, or delegate.

For more information on when to define a generic type, see [Generic Types in Visual Basic](#). For more information on type parameter names, see [Declared Element Names](#).

Rules

- **Parentheses.** If you supply a type parameter list, you must enclose it in parentheses, and you must introduce the list with the `Of` keyword. You use `Of` only once, at the beginning of the list.
- **Constraints.** A list of *constraints* on a type parameter can include the following items in any combination:
 - Any number of interfaces. The supplied type must implement every interface in this list.
 - At most one class. The supplied type must inherit from that class.

- The `New` keyword. The supplied type must expose a parameterless constructor that your generic type can access. This is useful if you constrain a type parameter by one or more interfaces. A type that implements interfaces does not necessarily expose a constructor, and depending on the access level of a constructor, the code within the generic type might not be able to access it.
- Either the `Class` keyword or the `Structure` keyword. The `Class` keyword constrains a generic type parameter to require that any type argument passed to it be a reference type, for example a string, array, or delegate, or an object created from a class. The `Structure` keyword constrains a generic type parameter to require that any type argument passed to it be a value type, for example a structure, enumeration, or elementary data type. You cannot include both `Class` and `Structure` in the same `constraintlist`.

The supplied type must satisfy every requirement you include in `constraintlist`.

Constraints on each type parameter are independent of constraints on other type parameters.

Behavior

- **Compile-Time Substitution.** When you create a constructed type from a generic programming element, you supply a defined type for each type parameter. The Visual Basic compiler substitutes that supplied type for every occurrence of `typename` within the generic element.
- **Absence of Constraints.** If you do not specify any constraints on a type parameter, your code is limited to the operations and members supported by the [Object Data Type](#) for that type parameter.

Example

The following example shows a skeleton definition of a generic dictionary class, including a skeleton function to add a new entry to the dictionary.

```
Public Class dictionary(Of entryType, keyType As {IComparable, IFormattable, New})
    Public Sub add(ByVal et As entryType, ByVal kt As keyType)
        Dim dk As keyType
        If kt.CompareTo(dk) = 0 Then
            End If
        End Sub
    End Class
```

Example

Because `dictionary` is generic, the code that uses it can create a variety of objects from it, each having the same functionality but acting on a different data type. The following example shows a line of code that creates a `dictionary` object with `String` entries and `Integer` keys.

```
Dim dictInt As New dictionary(Of String, Integer)
```

Example

The following example shows the equivalent skeleton definition generated by the preceding example.

```
Public Class dictionary
    Public Sub add(ByVal et As String, ByVal kt As Integer)
        Dim dk As Integer
        If kt.CompareTo(dk) = 0 Then
            End If
    End Sub
End Class
```

Recommended XML Tags for Documentation Comments (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The Visual Basic compiler can process documentation comments in your code to an XML file. You can use additional tools to process the XML file into documentation.

XML comments are allowed on code constructs such as types and type members. For partial types, only one part of the type can have XML comments, although there is no restriction on commenting its members.

NOTE

Documentation comments cannot be applied to namespaces. The reason is that one namespace can span several assemblies, and not all assemblies have to be loaded at the same time.

The compiler processes any tag that is valid XML. The following tags provide commonly used functionality in user documentation.

<c>	<code>	<example>
<exception> <sup>1</sup>	<include> <sup>1</sup>	<list>
<para>	<param> <sup>1</sup>	<paramref>
<permission> <sup>1</sup>	<remarks>	<returns>
<see> <sup>1</sup>	<seealso> <sup>1</sup>	<summary>
<typeparam> <sup>1</sup>	<value>	

(<sup>1</sup> The compiler verifies syntax.)

NOTE

If you want angle brackets to appear in the text of a documentation comment, use < and >. For example, the string "<text in angle brackets>" will appear as <text in angle brackets>.

<c> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Indicates that text within a description is code.

Syntax

```
<c>text</c>
```

Parameters

PARAMETER	DESCRIPTION
text	The text you would like to indicate as code.

Remarks

The `<c>` tag gives you a way to indicate that text within a description should be marked as code. Use [<code>](#) to indicate multiple lines as code.

Compile with [/doc](#) to process documentation comments to a file.

Example

This example uses the `<c>` tag in the summary section to indicate that `Counter` is code.

```
''' <summary>
''' Resets the value the <c>Counter</c> field.
''' </summary>
Public Sub ResetCounter()
    counterValue = 0
End Sub
Private counterValue As Integer = 0
''' <summary>
''' Returns the number of times Counter was called.
''' </summary>
''' <value>Number of times Counter was called.</value>
Public ReadOnly Property Counter() As Integer
    Get
        counterValue += 1
        Return counterValue
    End Get
End Property
```

<code> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Indicates that the text is multiple lines of code.

Syntax

```
<code>content</code>
```

Parameters

content

The text to mark as code.

Remarks

Use the `<code>` tag to indicate multiple lines as code. Use `<c>` to indicate that text within a description should be marked as code.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<code>` tag to include example code for using the `ID` field.

```
Public Class Employee
    ''' <remarks>
    ''' <example> This sample shows how to set the <c>ID</c> field.
    ''' <code>
    ''' Dim alice As New Employee
    ''' alice.ID = 1234
    ''' </code>
    ''' </example>
    ''' </remarks>
    Public ID As Integer
End Class
```

<example> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies an example for the member.

Syntax

```
<example>description</example>
```

Parameters

`description`

A description of the code sample.

Remarks

The `<example>` tag lets you specify an example of how to use a method or other library member. This commonly involves using the `<code>` tag.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<example>` tag to include an example for using the `ID` field.

```
Public Class Employee
    ''' <remarks>
    ''' <example> This sample shows how to set the <c>ID</c> field.
    ''' <code>
    ''' Dim alice As New Employee
    ''' alice.ID = 1234
    ''' </code>
    ''' </example>
    ''' </remarks>
    Public ID As Integer
End Class
```

<exception> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies which exceptions can be thrown.

Syntax

```
<exception cref="member">description</exception>
```

Parameters

`member`

A reference to an exception that is available from the current compilation environment. The compiler checks that the given exception exists and translates `member` to the canonical element name in the output XML. `member` must appear within double quotation marks ("").

`description`

A description.

Remarks

Use the `<exception>` tag to specify which exceptions can be thrown. This tag is applied to a method definition.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<exception>` tag to describe an exception that the `IntDivide` function can throw.

```
''' <exception cref="System.OverflowException">
''' Thrown when <paramref name="denominator"/><c> = 0</c>.
''' </exception>
Public Function IntDivide(
    ByVal numerator As Integer,
    ByVal denominator As Integer
) As Integer
    Return numerator \ denominator
End Function
```

<include> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Refers to another file that describes the types and members in your source code.

Syntax

```
<include file="filename" path="tagpath[@name='id']" />
```

Parameters

`filename`

Required. The name of the file containing the documentation. The file name can be qualified with a path. Enclose `filename` in double quotation marks ("").

`tagpath`

Required. The path of the tags in `filename` that leads to the tag `name`. Enclose the path in double quotation marks ("").

`name`

Required. The name specifier in the tag that precedes the comments. `Name` will have an `id`.

`id`

Required. The ID for the tag that precedes the comments. Enclose the ID in single quotation marks ('').

Remarks

Use the `<include>` tag to refer to comments in another file that describe the types and members in your source code. This is an alternative to placing documentation comments directly in your source code file.

The `<include>` tag uses the W3C XML Path Language (XPath) Version 1.0 Recommendation. For more information about ways to customize your `<include>` use, see <https://www.w3.org/TR/xpath>.

Example

This example uses the `<include>` tag to import member documentation comments from a file called `commentFile.xml`.

```
''' <include file="commentFile.xml"
''' path="Docs/Members[@name='Open']/*" />
Public Sub Open(ByVal filename As String)
    ' Code goes here.
End Sub
''' <include file="commentFile.xml"
''' path="Docs/Members[@name='Close']/*" />
Public Sub Close(ByVal filename As String)
    ' Code goes here.
End Sub
```

The format of the `commentFile.xml` is as follows.

```
<Docs>
<Members name="Open">
<summary>Opens a file.</summary>
<param name="filename">File name to open.</param>
</Members>
<Members name="Close">
<summary>Closes a file.</summary>
<param name="filename">File name to close.</param>
</Members>
</Docs>
```

<list> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Defines a list or table.

Syntax

```
<list type="type">
  <listheader>
    <term>term</term>
    <description>description</description>
  </listheader>
  <item>
    <term>term</term>
    <description>description</description>
  </item>
</list>
```

Parameters

`type`

The type of the list. Must be a "bullet" for a bulleted list, "number" for a numbered list, or "table" for a two-column table.

`term`

Only used when `type` is "table." A term to define, which is defined in the description tag.

`description`

When `type` is "bullet" or "number," `description` is an item in the list. When `type` is "table," `description` is the definition of `term`.

Remarks

The `<listheader>` block defines the heading of either a table or definition list. When defining a table, you only have to supply an entry for `term` in the heading.

Each item in the list is specified with an `<item>` block. When creating a definition list, you must specify both `term` and `description`. However, for a table, bulleted list, or numbered list, you only have to supply an entry for `description`.

A list or table can have as many `<item>` blocks as needed.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<list>` tag to define a bulleted list in the remarks section.

```
''' <remarks>Before calling the <c>Reset</c> method, be sure to:  
''' <list type="bullet">  
''' <item><description>Close all connections.</description></item>  
''' <item><description>Save the object state.</description></item>  
''' </list>  
''' </remarks>  
Public Sub Reset()  
    ' Code goes here.  
End Sub
```

<para> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies that the content is formatted as a paragraph.

Syntax

```
<para>content</para>
```

Parameters

content

The text of the paragraph.

Remarks

The `<para>` tag is for use inside a tag, such as `<summary>`, `<remarks>`, or `<returns>`, and lets you add structure to the text.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<para>` tag to split the remarks section for the `UpdateRecord` method into two paragraphs.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that
''' the record exists before calling this method.</para>
''' </remarks>
Public Sub UpdateRecord(ByVal id As Integer)
    ' Code goes here.
End Sub
''' <param name="id">The ID of the record to check.</param>
''' <returns><c>True</c> if <paramref name="id"/> exists,
''' <c>False</c> otherwise.</returns>
''' <remarks><seealso cref="UpdateRecord"/></remarks>
Public Function DoesRecordExist(ByVal id As Integer) As Boolean
    ' Code goes here.
End Function
```

<param> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Defines a parameter name and description.

Syntax

```
<param name="name">description</param>
```

Parameters

name

The name of a method parameter. Enclose the name in double quotation marks ("").

description

A description for the parameter.

Remarks

The `<param>` tag should be used in the comment for a method declaration to describe one of the parameters for the method.

The text for the `<param>` tag will appear in the following locations:

- Parameter Info of IntelliSense. For more information, see [Using IntelliSense](#).
- Object Browser. For more information, see [Viewing the Structure of Code](#).

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<param>` tag to describe the `id` parameter.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that
''' the record exists before calling this method.</para>
''' </remarks>
Public Sub UpdateRecord(ByVal id As Integer)
    ' Code goes here.
End Sub
''' <param name="id">The ID of the record to check.</param>
''' <returns><c>True</c> if <paramref name="id"/> exists,
''' <c>False</c> otherwise.</returns>
''' <remarks><seealso cref="UpdateRecord"/></remarks>

<paramref> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Formats a word as a parameter.

Syntax

```
<paramref name="name"/>
```

Parameters

name

The name of the parameter to refer to. Enclose the name in double quotation marks ("").

Remarks

The `<paramref>` tag gives you a way to indicate that a word is a parameter. The XML file can be processed to format this parameter in some distinct way.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<paramref>` tag to refer to the `id` parameter.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that
''' the record exists before calling this method.</para>
''' </remarks>
Public Sub UpdateRecord(ByVal id As Integer)
    ' Code goes here.

<permission> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies a required permission for the member.

Syntax

```
<permission cref="member">description</permission>
```

Parameters

`member`

A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and translates `member` to the canonical element name in the output XML. Enclose `member` in quotation marks ("").

`description`

A description of the access to the member.

Remarks

Use the `<permission>` tag to document the access of a member. Use the [PermissionSet](#) class to specify access to a member.

Compile with [/doc](#) to process documentation comments to a file.

Example

This example uses the `<permission>` tag to describe that the [FileIOPermission](#) is required by the `ReadFile` method.

```
''' <permission cref="System.Security.Permissions.FileIOPermission">
''' Needs full access to the specified file.
''' </permission>
Public Sub ReadFile(ByVal filename As String)
    ' Code goes here.
End Sub

<remarks> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies a remarks section for the member.

Syntax

```
<remarks>description</remarks>
```

Parameters

`description`

A description of the member.

Remarks

Use the `<remarks>` tag to add information about a type, supplementing the information specified with [`<summary>`](#).

This information appears in the Object Browser. For information about the Object Browser, see [Viewing the Structure of Code](#).

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<remarks>` tag to explain what the `UpdateRecord` method does.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that

<returns> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies the return value of the property or function.

Syntax

```
<returns>description</returns>
```

Parameters

`description`

A description of the return value.

Remarks

Use the `<returns>` tag in the comment for a method declaration to describe the return value.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<returns>` tag to explain what the `DoesRecordExist` function returns.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that

<see> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies a link to another member.

Syntax

```
<see cref="member"/>
```

Parameters

member

A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and passes member to the element name in the output XML. member must appear within double quotation marks (" ").

Remarks

Use the <see> tag to specify a link from within text. Use <seealso> to indicate text that you might want to appear in a "See Also" section.

Compile with /doc to process documentation comments to a file.

Example

This example uses the <see> tag in the UpdateRecord remarks section to refer to the DoesRecordExist method.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that

<seealso> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies a link that appears in the See Also section.

Syntax

```
<seealso cref="member"/>
```

Parameters

member

A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and passes member to the element name in the output XML. member must appear within double quotation marks (" ").

Remarks

Use the <seealso> tag to specify the text that you want to appear in a See Also section. Use <see> to specify a link from within text.

Compile with /doc to process documentation comments to a file.

Example

This example uses the <seealso> tag in the DoesRecordExist remarks section to refer to the UpdateRecord method.

```
''' <param name="id">The ID of the record to update.</param>
''' <remarks>Updates the record <paramref name="id"/>.
''' <para>Use <see cref="DoesRecordExist"/> to verify that

<summary> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies the summary of the member.

Syntax

```
<summary>description</summary>
```

Parameters

`description`

A summary of the object.

Remarks

Use the `<summary>` tag to describe a type or a type member. Use [`<remarks>`](#) to add supplemental information to a type description.

The text for the `<summary>` tag is the only source of information about the type in IntelliSense, and is also displayed in the Object Browser. For information about the Object Browser, see [Viewing the Structure of Code](#).

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<summary>` tag to describe the `ResetCounter` method and `Counter` property.

```
''' <summary>
''' Resets the value the <c>Counter</c> field.
''' </summary>
Public Sub ResetCounter()
    counterValue = 0
End Sub
Private counterValue As Integer = 0
''' <summary>
''' Returns the number of times Counter was called.
''' </summary>
''' <value>Number of times Counter was called.</value>

<typeparam> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Defines a type parameter name and description.

Syntax

```
<typeparam name="name">description</typeparam>
```

Parameters

`name`

The name of the type parameter. Enclose the name in double quotation marks ("").

`description`

A description of the type parameter.

Remarks

Use the `<typeparam>` tag in the comment for a generic type or generic member declaration to describe one of the type parameters.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<typeparam>` tag to describe the `id` parameter.

```
''' <typeparam name="T">
''' The base item type. Must implement IComparable.
''' </typeparam>
Public Class itemManager(Of T As IComparable)
    ' Insert code that defines class members.
End Class
```

<value> (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies the description of a property.

Syntax

```
<value>property-description</value>
```

Parameters

property-description

A description for the property.

Remarks

Use the `<value>` tag to describe a property. Note that when you add a property using the code wizard in the Visual Studio development environment, it will add a `<summary>` tag for the new property. You should then manually add a `<value>` tag to describe the value that the property represents.

Compile with `/doc` to process documentation comments to a file.

Example

This example uses the `<value>` tag to describe what value the `Counter` property holds.

```
''' <summary>
''' Resets the value the <c>Counter</c> field.
''' </summary>
Public Sub ResetCounter()
    counterValue = 0
End Sub
Private counterValue As Integer = 0
''' <summary>
''' Returns the number of times Counter was called.
''' </summary>
''' <value>Number of times Counter was called.</value>
Public ReadOnly Property Counter() As Integer
    Get
        counterValue += 1
        Return counterValue
    End Get
End Property

XML Axis Properties (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The topics in this section document the syntax of XML axis properties in Visual Basic. The XML axis properties make it easy to access XML directly in your code.

In This Section

TOPIC	DESCRIPTION
XML Attribute Axis Property	Describes how to access the attributes of an <code>XElement</code> object.
XML Child Axis Property	Describes how to access the children of an <code>XElement</code> object.
XML Descendant Axis Property	Describes how to access the descendants of an <code>XElement</code> object.
Extension Indexer Property	Describes how to access individual elements in a collection of <code>XElement</code> or <code>XAttribute</code> objects.
XML Value Property	Describes how to access the value of the first element of a collection of <code>XElement</code> or <code>XAttribute</code> objects.

XML Attribute Axis Property (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides access to the value of an attribute for an [XElement](#) object or to the first element in a collection of [XElement](#) objects.

Syntax

```
object.@attribute  
-or-  
object.ATTRIBUTE>
```

Parts

`object`

Required. An [XElement](#) object or a collection of [XElement](#) objects.

`.@`

Required. Denotes the start of an attribute axis property.

`<`

Optional. Denotes the beginning of the name of the attribute when `attribute` is not a valid identifier in Visual Basic.

`attribute`

Required. Name of the attribute to access, of the form `[prefix:]name`.

PART	DESCRIPTION
<code>prefix</code>	Optional. XML namespace prefix for the attribute. Must be a global XML namespace defined with an Imports statement.
<code>name</code>	Required. Local attribute name. See Names of Declared XML Elements and Attributes .

`>`

Optional. Denotes the end of the name of the attribute when `attribute` is not a valid identifier in Visual Basic.

Return Value

A string that contains the value of `attribute`. If the attribute name does not exist, `Nothing` is returned.

Remarks

You can use an XML attribute axis property to access the value of an attribute by name from an [XElement](#) object or from the first element in a collection of [XElement](#) objects. You can retrieve an attribute value by name, or add a new attribute to an element by specifying a new name preceded by the @ identifier.

When you refer to an XML attribute using the @ identifier, the attribute value is returned as a string and you do not need to explicitly specify the [Value](#) property.

The naming rules for XML attributes differ from the naming rules for Visual Basic identifiers. To access an XML attribute that has a name that is not a valid Visual Basic identifier, enclose the name in angle brackets (< and >).

XML Namespaces

The name in an attribute axis property can use only XML namespace prefixes declared globally by using the `Imports` statement. It cannot use XML namespace prefixes declared locally within XML element literals. For more information, see [Imports Statement \(XML Namespace\)](#).

Example

The following example shows how to get the values of the XML attributes named `type` from a collection of XML elements that are named `phone`.

```
' Topic: XML Attribute Axis Property
Dim phones As XElement =
    <phones>
        <phone type="home">206-555-0144</phone>
        <phone type="work">425-555-0145</phone>
    </phones>

Dim phoneTypes As XElement =
    <phoneTypes>
        <%= From phone In phones.<phone>
            Select <type><%= phone.@type %></type>
        %>
    </phoneTypes>

Console.WriteLine(phoneTypes)
```

This code displays the following text:

```
<phoneTypes>
    <type>home</type>
    <type>work</type>
</phoneTypes>
```

Example

The following example shows how to create attributes for an XML element both declaratively, as part of the XML, and dynamically by adding an attribute to an instance of an `XElement` object. The `type` attribute is created declaratively and the `owner` attribute is created dynamically.

```
Dim phone2 As XElement = <phone type="home">206-555-0144</phone>
phone2.@owner = "Harris, Phyllis"

Console.WriteLine(phone2)
```

This code displays the following text:

```
<phone type="home" owner="Harris, Phyllis">206-555-0144</phone>
```

Example

The following example uses the angle bracket syntax to get the value of the XML attribute named `number-type`, which is not a valid identifier in Visual Basic.

```
Dim phone As XElement =
    <phone number-type=" work">425-555-0145</phone>

Console.WriteLine("Phone type: " & phone.@<number-type>)
```

This code displays the following text:

```
Phone type: work
```

Example

The following example declares `ns` as an XML namespace prefix. It then uses the prefix of the namespace to create an XML literal and access the first child node with the qualified name "`ns:name`".

```
Imports <xmllns:ns = "http://SomeNamespace">

Class TestClass3

    Shared Sub TestPrefix()
        Dim phone =
            <ns:phone ns:type="home">206-555-0144</ns:phone>

        Console.WriteLine("Phone type: " & phone.@ns:type)
    End Sub

End Class
```

This code displays the following text:

```
Phone type: home
```

XML Child Axis Property (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides access to the children of one of the following: an [XElement](#) object, an [XDocument](#) object, a collection of [XElement](#) objects, or a collection of [XDocument](#) objects.

Syntax

```
object.<child>
```

Parts

TERM	DEFINITION
<code>object</code>	Required. An XElement object, an XDocument object, a collection of XElement objects, or a collection of XDocument objects.
<code>.<</code>	Required. Denotes the start of a child axis property.
<code>child</code>	Required. Name of the child nodes to access, of the form [<code>prefix:]name</code>]. - <code>Prefix</code> - Optional. XML namespace prefix for the child node. Must be a global XML namespace defined with an Imports statement. - <code>Name</code> - Required. Local child node name. See Names of Declared XML Elements and Attributes .
<code>></code>	Required. Denotes the end of a child axis property.

Return Value

A collection of [XElement](#) objects.

Remarks

You can use an XML child axis property to access child nodes by name from an [XElement](#) or [XDocument](#) object, or from a collection of [XElement](#) or [XDocument](#) objects. Use the XML [Value](#) property to access the value of the first child node in the returned collection. For more information, see [XML Value Property](#).

The Visual Basic compiler converts child axis properties to calls to the [Elements](#) method.

XML Namespaces

The name in a child axis property can use only XML namespace prefixes declared globally with the [Imports](#) statement. It cannot use XML namespace prefixes declared locally within XML element literals. For more information, see [Imports Statement \(XML Namespace\)](#).

Example

The following example shows how to access the child nodes named `phone` from the `contact` object.

```
Dim contact As XElement =
<contact>
    <name>Patrick Hines</name>
    <phone type="home">206-555-0144</phone>
    <phone type="work">425-555-0145</phone>
</contact>

Dim homePhone = From hp In contact.<phone>
                  Where contact.<phone>.@type = "home"
                  Select hp

Console.WriteLine("Home Phone = {0}", homePhone(0).Value)
```

This code displays the following text:

```
Home Phone = 206-555-0144
```

Example

The following example shows how to access the child nodes named `phone` from the collection returned by the `contact` child axis property of the `contacts` object.

```
Dim contacts As XElement =
<contacts>
    <contact>
        <name>Patrick Hines</name>
        <phone type="home">206-555-0144</phone>
    </contact>
    <contact>
        <name>Lance Tucker</name>
        <phone type="work">425-555-0145</phone>
    </contact>
</contacts>

Dim homePhone = From contact In contacts.<contact>
                  Where contact.<phone>.@type = "home"
                  Select contact.<phone>

Console.WriteLine("Home Phone = {0}", homePhone(0).Value)
```

This code displays the following text:

```
Home Phone = 206-555-0144
```

Example

The following example declares `ns` as an XML namespace prefix. It then uses the prefix of the namespace to create an XML literal and access the first child node with the qualified name `ns:name`.

```
Imports <xmllns:ns = "http://SomeNamespace">

Class TestClass4

    Shared Sub TestPrefix()
        Dim contact = <ns:contact>
            <ns:name>Patrick Hines</ns:name>
        </ns:contact>
        Console.WriteLine(contact.<ns:name>.Value)
    End Sub

End Class
```

This code displays the following text:

XML Descendant Axis Property (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

Provides access to the descendants of the following: an [XElement](#) object, an [XDocument](#) object, a collection of [XElement](#) objects, or a collection of [XDocument](#) objects.

Syntax

```
object...<descendant>
```

Parts

object Required. An [XElement](#) object, an [XDocument](#) object, a collection of [XElement](#) objects, or a collection of [XDocument](#) objects.

...< Required. Denotes the start of a descendant axis property.

descendant Required. Name of the descendant nodes to access, of the form [**prefix:**][name](#).

PART	DESCRIPTION
prefix	Optional. XML namespace prefix for the descendant node. Must be a global XML namespace that is defined by using an Imports statement.
name	Required. Local name of the descendant node. See Names of Declared XML Elements and Attributes .

> Required. Denotes the end of a descendant axis property.

Return Value

A collection of [XElement](#) objects.

Remarks

You can use an XML descendant axis property to access descendant nodes by name from an [XElement](#) or [XDocument](#) object, or from a collection of [XElement](#) or [XDocument](#) objects. Use the XML **Value** property to access the value of the first descendant node in the returned collection. For more information, see [XML Value Property](#).

The Visual Basic compiler converts descendant axis properties into calls to the [Descendants](#) method.

XML Namespaces

The name in a descendant axis property can use only XML namespaces declared globally with the [Imports](#) statement. It cannot use XML namespaces declared locally within XML element literals. For more information, see [Imports Statement \(XML Namespace\)](#).

Example

The following example shows how to access the value of the first descendant node named `name` and the values of all descendant nodes named `phone` from the `contacts` object.

```
Dim contacts As XElement =
    <contacts>
        <contact>
            <name>Patrick Hines</name>
            <phone type="home">206-555-0144</phone>
            <phone type="work">425-555-0145</phone>
        </contact>
    </contacts>

Console.WriteLine("Name: " & contacts...<name>.Value)

Dim homePhone = From phone In contacts...<phone>
                  Select phone.Value

Console.WriteLine("Home Phone = {0}", homePhone(0))
```

This code displays the following text:

Name: Patrick Hines

Home Phone = 206-555-0144

Example

The following example declares `ns` as an XML namespace prefix. It then uses the prefix of the namespace to create an XML literal and access the value of the first child node with the qualified name `ns:name`.

```
Imports <xmldns:ns = "http://SomeNamespace">

Class TestClass2

    Shared Sub TestPrefix()
        Dim contacts =
            <ns:contacts>
                <ns:contact>
                    <ns:name>Patrick Hines</ns:name>
                </ns:contact>
            </ns:contacts>

        Console.WriteLine("Name: " & contacts...<ns:name>.Value)
    End Sub

End Class
```

This code displays the following text:

Name: Patrick Hines

Extension Indexer Property (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides access to individual elements in a collection.

Syntax

```
object(index)
```

Parts

TERM	DEFINITION
object	Required. A queryable collection. That is, a collection that implements IEnumerable<T> or IQueryable<T> .
(Required. Denotes the start of the indexer property.
index	Required. An integer expression that specifies the zero-based position of an element of the collection.
)	Required. Denotes the end of the indexer property.

Return Value

The object from the specified location in the collection, or `Nothing` if the index is out of range.

Remarks

You can use the extension indexer property to access individual elements in a collection. This indexer property is typically used on the output of XML axis properties. The XML child and XML descendant axis properties return collections of [XElement](#) objects or an attribute value.

The Visual Basic compiler converts extension indexer properties to calls to the `ElementAtOrDefault` method. Unlike an array indexer, the `ElementAtOrDefault` method returns `Nothing` if the index is out of range. This behavior is useful when you cannot easily determine the number of elements in a collection.

This indexer property is like an extension property for collections that implement [IEnumerable<T>](#) or [IQueryable<T>](#): it is used only if the collection does not have an indexer or a default property.

To access the value of the first element in a collection of [XElement](#) or [XAttribute](#) objects, you can use the XML `Value` property. For more information, see [XML Value Property](#).

Example

The following example shows how to use the extension indexer to access the second child node in a collection of [XElement](#) objects. The collection is accessed by using the child axis property, which gets all child elements named `phone` in the `contact` object.

```
Dim contact As XElement =
<contact>
  <name>Patrick Hines</name>
  <phone type="home">206-555-0144</phone>
  <phone type="work">425-555-0145</phone>
</contact>

Console.WriteLine("Second phone number: " & contact.<phone>(1).Value)
```

This code displays the following text:

```
Second phone number: 425-555-0145
```

XML Value Property (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

Provides access to the value of the first element of a collection of [XElement](#) objects.

Syntax

```
object.Value
```

Parts

TERM	DEFINITION
<code>object</code>	Required. Collection of XElement objects.

Return Value

A `String` that contains the value of the first element of the collection, or `Nothing` if the collection is empty.

Remarks

The [Value](#) property makes it easy to access the value of the first element in a collection of [XElement](#) objects. This property first checks whether the collection contains at least one object. If the collection is empty, this property returns `Nothing`. Otherwise, this property returns the value of the [Value](#) property of the first element in the collection.

NOTE

When you access the value of an XML attribute using the '@' identifier, the attribute value is returned as a `String` and you do not need to explicitly specify the [Value](#) property.

To access other elements in a collection, you can use the XML extension indexer property. For more information, see [Extension Indexer Property](#).

Inheritance

Most users will not have to implement `IEnumerable<T>`, and can therefore ignore this section.

The [Value](#) property is an extension property for types that implement `IEnumerable(Of XElement)`. The binding of this extension property is like the binding of extension methods: if a type implements one of the interfaces and defines a property that has the name "Value", that property has precedence over the extension property. In other words, this [Value](#) property can be overridden by defining a new property in a class that implements `IEnumerable(Of XElement)`.

Example

The following example shows how to use the [Value](#) property to access the first node in a collection of [XElement](#)

objects. The example uses the child axis property to get the collection of all child nodes named `phone` that are in the `contact` object.

```
Dim contact As XElement =
<contact>
    <name>Patrick Hines</name>
    <phone type="home">206-555-0144</phone>
    <phone type="work">425-555-0145</phone>
</contact>

Console.WriteLine("Phone number: " & contact.<phone>.Value)
```

This code displays the following text:

```
Phone number: 206-555-0144
```

Example

The following example shows how to get the value of an XML attribute from a collection of [XAttribute](#) objects. The example uses the attribute axis property to display the value of the `type` attribute for all of the `phone` elements.

```
Dim contact As XElement =
<contact>
    <name>Patrick Hines</name>
    <phone type="home">206-555-0144</phone>
    <phone type="work">425-555-0145</phone>
</contact>

Dim types = contact.<phone>.Attributes("type")

For Each attr In types
    Console.WriteLine(attr.Value)
Next
```

This code displays the following text:

```
home
```

```
work
```

XML Literals (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The topics in this section document the syntax of XML literals in Visual Basic. The XML literal syntax enables you to incorporate XML directly in your code.

In This Section

TOPIC	DESCRIPTION
XML Element Literal	Describes the syntax for literals that represent <code>XElement</code> objects.
XML Document Literal	Describes the syntax for literals that represent <code>XDocument</code> objects.
XML CDATA Literal	Describes the syntax for literals that represent <code>XCDATA</code> objects.
XML Comment Literal	Describes the syntax for literals that represent <code>XComment</code> objects.
XML Processing Instruction Literal	Describes the syntax for literals that represent <code>XProcessingInstruction</code> objects.

XML Element Literal (Visual Basic)

2/28/2019 • 4 minutes to read • [Edit Online](#)

A literal that represents an `XElement` object.

Syntax

```
<name [ attributeList ] />  
-or-  
<name [ attributeList ] > [ elementContents ] </[ name ]>
```

Parts

- `<`

Required. Opens the starting element tag.

- `name`

Required. Name of the element. The format is one of the following:

- Literal text for the element name, of the form `[ePrefix:]eName`, where:

PART	DESCRIPTION
<code>ePrefix</code>	Optional. XML namespace prefix for the element. Must be a global XML namespace that is defined with an <code>Imports</code> statement in the file or at the project level, or a local XML namespace that is defined in this element or a parent element.
<code>eName</code>	Required. Name of the element. The format is one of the following: <ul style="list-style-type: none">- Literal text. See Names of Declared XML Elements and Attributes.- Embedded expression of the form <code><%= eNameExp %></code>. The type of <code>eNameExp</code> must be <code>String</code> or a type that is implicitly convertible to <code>XName</code>.

- Embedded expression of the form `<%= nameExp %>`. The type of `nameExp` must be `String` or a type implicitly convertible to `XName`. An embedded expression is not allowed in a closing tag of an element.

- `attributeList`

Optional. List of attributes declared in the literal.

```
attribute [ attribute ... ]
```

Each `attribute` has one of the following syntaxes:

- Attribute assignment, of the form `[aPrefix:]aName=aValue`, where:

PART	DESCRIPTION
<code>aPrefix</code>	Optional. XML namespace prefix for the attribute. Must be a global XML namespace that is defined with an <code>Imports</code> statement, or a local XML namespace that is defined in this element or a parent element.
<code>aName</code>	Required. Name of the attribute. The format is one of the following: - Literal text. See Names of Declared XML Elements and Attributes . - Embedded expression of the form <code><%= aNameExp %></code> . The type of <code>aNameExp</code> must be <code>String</code> or a type that is implicitly convertible to <code>XName</code> .
<code>aValue</code>	Optional. Value of the attribute. The format is one of the following: - Literal text, enclosed in quotation marks. - Embedded expression of the form <code><%= aValueExp %></code> . Any type is allowed.

- Embedded expression of the form `<%= aExp %>`.

- `/>`

Optional. Indicates that the element is an empty element, without content.

- `>`

Required. Ends the beginning or empty element tag.

- `elementContents`

Optional. Content of the element.

`content [content ...]`

Each `content` can be one of the following:

- Literal text. All the white space in `elementContents` becomes significant if there is any literal text.
- Embedded expression of the form `<%= contentExp %>`.
- XML element literal.
- XML comment literal. See [XML Comment Literal](#).
- XML processing instruction literal. See [XML Processing Instruction Literal](#).
- XML CDATA literal. See [XML CDATA Literal](#).

- `</[name]>`

Optional. Represents the closing tag for the element. The optional `name` parameter is not allowed when it is the result of an embedded expression.

Return Value

An [XElement](#) object.

Remarks

You can use the XML element literal syntax to create [XElement](#) objects in your code.

NOTE

An XML literal can span multiple lines without using line continuation characters. This feature enables you to copy content from an XML document and paste it directly into a Visual Basic program.

Embedded expressions of the form `<%= exp %>` enable you to add dynamic information to an XML element literal. For more information, see [Embedded Expressions in XML](#).

The Visual Basic compiler converts the XML element literal into calls to the [XElement](#) constructor and, if it is required, the [XmlAttribute](#) constructor.

XML Namespaces

XML namespace prefixes are useful when you have to create XML literals with elements from the same namespace many times in code. You can use global XML namespace prefixes, which you define by using the [Imports](#) statement, or local prefixes, which you define by using the `xmlns:xmlPrefix="xmlNamespace"` attribute syntax. For more information, see [Imports Statement \(XML Namespace\)](#).

In accordance with the scoping rules for XML namespaces, local prefixes take precedence over global prefixes. However, if an XML literal defines an XML namespace, that namespace is not available to expressions that appear in an embedded expression. The embedded expression can access only the global XML namespace.

The Visual Basic compiler converts each global XML namespace that is used by an XML literal into a one local namespace definition in the generated code. Global XML namespaces that are not used do not appear in the generated code.

Example

The following example shows how to create a simple XML element that has two nested empty elements.

```
Dim test1 As XElement =
<outer>
  <inner1></inner1>
  <inner2/>
</outer>

Console.WriteLine(test1)
```

The example displays the following text. Notice that the literal preserves the structure of the empty elements.

```
<outer>
  <inner1></inner1>
  <inner2 />
</outer>
```

Example

The following example shows how to use embedded expressions to name an element and create attributes.

```

Dim elementType = "book"
Dim authorName = "My Author"
Dim attributeName1 = "year"
Dim attributeValue1 = 1999
Dim attributeName2 = "title"
Dim attributeValue2 = "My Book"

Dim book As XElement =
<<%= elementType %>
    isbn="1234"
    author=<%= authorName %>
    <%= attributeName1 %>=<%= attributeValue1 %>
    <%= New XAttribute(attributeName2, attributeValue2) %>
/>

Console.WriteLine(book)

```

This code displays the following text:

```
<book isbn="1234" author="My Author" year="1999" title="My Book" />
```

Example

The following example declares `ns` as an XML namespace prefix. It then uses the prefix of the namespace to create an XML literal and displays the element's final form.

```

' Place Imports statements at the top of your program.
Imports <xmllns:ns="http://SomeNamespace">

Class TestClass1

    Shared Sub TestPrefix()
        ' Create test using a global XML namespace prefix.
        Dim inner2 = <ns:inner2/>

        Dim test =
<ns:outer>
    <ns:middle xmlns:ns="http://NewNamespace">
        <ns:inner1/>
        <%= inner2 %>
    </ns:middle>
</ns:outer>

        ' Display test to see its final form.
        Console.WriteLine(test)
    End Sub

End Class

```

This code displays the following text:

```
<ns:outer xmlns:ns="http://SomeNamespace">
    <ns:middle xmlns:ns="http://NewNamespace">
        <ns:inner1 />
        <inner2 xmlns="http://SomeNamespace" />
    </ns:middle>
</ns:outer>
```

Notice that the compiler converted the prefix of the global XML namespace into a prefix definition for the XML

namespace. The `<ns:middle>` element redefines the XML namespace prefix for the `<ns:inner1>` element. However, the `<ns:inner2>` element uses the namespace defined by the `Imports` statement.

XML Document Literal (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

A literal representing an [XDocument](#) object.

Syntax

```
<?xml version="1.0" [encoding="encoding"] [standalone="standalone"] ?>
[ piCommentList ]
rootElement
[ piCommentList ]
```

Parts

TERM	DEFINITION
<code>encoding</code>	Optional. Literal text declaring which encoding the document uses.
<code>standalone</code>	Optional. Literal text. Must be "yes" or "no".
<code>piCommentList</code>	Optional. List of XML processing instructions and XML comments. Takes the following format: <code>piComment [piComment ...]</code> Each <code>piComment</code> can be one of the following: - XML Processing Instruction Literal . - XML Comment Literal .
<code>rootElement</code>	Required. Root element of the document. The format is one of the following: <ul style="list-style-type: none">• XML Element Literal.• Embedded expression of the form <code><%= elementExp %></code>. The <code>elementExp</code> returns one of the following:<ul style="list-style-type: none">◦ An XElement object.◦ A collection that contains one XElement object and any number of XProcessingInstruction and XComment objects. For more information, see Embedded Expressions in XML .

Return Value

An [XDocument](#) object.

Remarks

An XML document literal is identified by the XML declaration at the start of the literal. Although each XML document literal must have exactly one root XML element, it can have any number of XML processing instructions and XML comments.

An XML document literal cannot appear in an XML element.

NOTE

An XML literal can span multiple lines without using line continuation characters. This enables you to copy content from an XML document and paste it directly into a Visual Basic program.

The Visual Basic compiler converts the XML document literal into calls to the [XDocument](#) and [XDeclaration](#) constructors.

Example

The following example creates an XML document that has an XML declaration, a processing instruction, a comment, and an element that contains another element.

```
Dim libraryRequest As XDocument =
    <?xml version="1.0" encoding="UTF-8" standalone="yes"?>
    <xm...-stylesheet type="text/xsl" href="show_book.xsl"?>
    <!-- Tests that the application works. -->
    <books>
        <book/>
    </books>
Console.WriteLine(libraryRequest)
```

XML CDATA Literal (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

A literal representing an [XCData](#) object.

Syntax

```
<![CDATA[content]]>
```

Parts

`<![CDATA[`

Required. Denotes the start of the XML CDATA section.

`content`

Required. Text content to appear in the XML CDATA section.

`]]>`

Required. Denotes the end of the section.

Return Value

An [XCData](#) object.

Remarks

XML CDATA sections contain raw text that should be included, but not parsed, with the XML that contains it. A XML CDATA section can contain any text. This includes reserved XML characters. The XML CDATA section ends with the sequence "]]>". This implies the following points:

- You cannot use an embedded expression in an XML CDATA literal because the embedded expression delimiters are valid XML CDATA content.
- XML CDATA sections cannot be nested, because `content` cannot contain the value "]]>".

You can assign an XML CDATA literal to a variable, or include it in an XML element literal.

NOTE

An XML literal can span multiple lines but does not use line continuation characters. This enables you to copy content from an XML document and paste it directly into a Visual Basic program.

The Visual Basic compiler converts the XML CDATA literal to a call to the [XCData](#) constructor.

Example

The following example creates a CDATA section that contains the text "Can contain literal <XML> tags".

```
Dim cdata As XCData = <![CDATA[Can contain literal <XML> tags]]>
```

XML Comment Literal (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

A literal representing an [XComment](#) object.

Syntax

```
<!-- content -->
```

Parts

TERM	DEFINITION
<!--	Required. Denotes the start of the XML comment.
content	Required. Text to appear in the XML comment. Cannot contain a series of two hyphens (--) or end with a hyphen adjacent to the closing tag.
-->	Required. Denotes the end of the XML comment.

Return Value

An [XComment](#) object.

Remarks

XML comment literals do not contain document content; they contain information about the document. The XML comment section ends with the sequence "-->". This implies the following points:

- You cannot use an embedded expression in an XML comment literal because the embedded expression delimiters are valid XML comment content.
- XML comment sections cannot be nested, because `content` cannot contain the value "-->".

You can assign an XML comment literal to a variable, or you can include it in an XML element literal.

NOTE

An XML literal can span multiple lines without using line continuation characters. This feature enables you to copy content from an XML document and paste it directly into a Visual Basic program.

The Visual Basic compiler converts the XML comment literal to a call to the [XComment](#) constructor.

Example

The following example creates an XML comment that contains the text "This is a comment".

```
Dim com As XComment = <!-- This is a comment -->
```

XML Processing Instruction Literal (Visual Basic)

2/28/2019 • 2 minutes to read • [Edit Online](#)

A literal representing an [XProcessingInstruction](#) object.

Syntax

```
<?piName [ = piData ] ?>
```

Parts

`<?`

Required. Denotes the start of the XML processing instruction literal.

`piName`

Required. Name indicating which application the processing instruction targets. Cannot begin with "xml" or "XML".

`piData`

Optional. String indicating how the application targeted by `piName` should process the XML document.

`?>`

Required. Denotes the end of the processing instruction.

Return Value

An [XProcessingInstruction](#) object.

Remarks

XML processing instruction literals indicate how applications should process an XML document. When an application loads an XML document, the application can check the XML processing instructions to determine how to process the document. The application interprets the meaning of `piName` and `piData`.

The XML document literal uses syntax that is similar to that of the XML processing instruction. For more information, see [XML Document Literal](#).

NOTE

The `piName` element cannot begin with the strings "xml" or "XML", because the XML 1.0 specification reserves those identifiers.

You can assign an XML processing instruction literal to a variable or include it in an XML document literal.

NOTE

An XML literal can span multiple lines without needing line continuation characters. This enables you to copy content from an XML document and paste it directly into a Visual Basic program.

The Visual Basic compiler converts the XML processing instruction literal to a call to the [XProcessingInstruction](#) constructor.

Example

The following example creates a processing instruction identifying a style-sheet for an XML document.

```
Dim pi As XProcessingInstruction =
    <?xml-stylesheet type="text/xsl" href="show_book.xsl"?>
```

Error Messages (Visual Basic)

5/4/2018 • 2 minutes to read • [Edit Online](#)

When you write, compile, or run a Visual Basic application, the following types of errors can occur:

1. Design-time errors, which occur when you write an application in Visual Studio.
2. Compile-time errors, which occur when you compile an application in Visual Studio or at a command prompt.
3. Run-time errors, which occur when you run an application in Visual Studio or as a stand-alone executable file.

For information about how to troubleshoot a specific error, see [Additional Resources for Visual Basic Programmers](#).

Run Time Errors

If a Visual Basic application tries to perform an action that the system can't execute, a run-time error occurs, and Visual Basic throws an `Exception` object. Visual Basic can generate custom errors of any data type, including `Exception` objects, by using the `Throw` statement. An application can identify the error by displaying the error number and message of a caught exception. If an error isn't caught, the application ends.

The code can trap and examine run-time errors. If you enclose the code that produces the error in a `Try` block, you can catch any thrown error within a matching `Catch` block. For information about how to trap errors at run time and respond to them in your code, see [Try...Catch...Finally Statement](#).

Compile Time Errors

If the Visual Basic compiler encounters a problem in the code, a compile-time error occurs. In the Code Editor, you can easily identify which line of code caused the error because a wavy line appears under that line of code. The error message appears if you either point to the wavy underline or open the **Error List**, which also shows other messages.

If an identifier has a wavy underline and a short underline appears under the rightmost character, you can generate a stub for the class, constructor, method, property, field or enum. For more information, see [Generate From Usage](#).

By resolving warnings from the Visual Basic compiler, you might be able to write code that runs faster and has fewer bugs. These warnings identify code that may cause errors when the application is run. For example, the compiler warns you if you try to invoke a member of an unassigned object variable, return from a function without setting the return value, or execute a `Try` block with errors in the logic to catch exceptions. For more information about warnings, including how to turn them on and off, see [Configuring Warnings in Visual Basic](#).

'#ElseIf' must be preceded by a matching '#If' or '#ElseIf'

1/30/2019 • 2 minutes to read • [Edit Online](#)

#ElseIf is a conditional compilation directive. An #ElseIf clause must be preceded by a matching #If or #ElseIf clause.

Error ID: BC30014

To correct this error

1. Check that a preceding #If or #ElseIf has not been separated from this #ElseIf by an intervening conditional compilation block or an incorrectly placed #End If .
2. If the #ElseIf is preceded by a #Else directive, either remove the #Else or change it to an #ElseIf .
3. If everything else is in order, add an #If directive to the beginning of the conditional compilation block.

See also

- [#If...Then...#Else Directives](#)

'#Region' and '#End Region' statements are not valid within method bodies/multiline lambdas

1/30/2019 • 2 minutes to read • [Edit Online](#)

The `#Region` block must be declared at a class, module, or namespace level. A collapsible region can include one or more procedures, but it cannot begin or end inside of a procedure.

Error ID: BC32025

To correct this error

1. Ensure that the preceding procedure is properly terminated with an `End Function` or `End Sub` statement.
2. Ensure that the `#Region` and `#End Region` directives are in the same code block.

See also

- [#Region Directive](#)

'<attribute>' cannot be applied because the format of the GUID '<number>' is not correct

1/30/2019 • 2 minutes to read • [Edit Online](#)

A `comclassAttribute` attribute block specifies a globally unique identifier (GUID) that does not conform to the proper format for a GUID. `COMClassAttribute` uses GUIDs to uniquely identify the class, the interface, and the creation event.

A GUID consists of 16 bytes, of which the first eight are numeric and the last eight are binary. It is generated by Microsoft utilities such as `uuidgen.exe` and is guaranteed to be unique in space and time.

Error ID: BC32500

To correct this error

1. Determine the correct GUID or GUIDs necessary to identify the COM object.
2. Ensure that the GUID strings presented to the `comclassAttribute` attribute block are copied correctly.

- [Guid](#)
- [Attributes overview](#)

'<classname>' is not CLS-compliant because the interface '<interfacename>' it implements is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

A class or interface is marked as `<CLSCompliant(True)>` when it derives from or implements a type that is marked as `<CLSCompliant(False)>` or is not marked.

For a class or interface to be compliant with the [Language Independence and Language-Independent Components](#) (CLS), its entire inheritance hierarchy must be compliant. That means every type from which it inherits, directly or indirectly, must be compliant. Similarly, if a class implements one or more interfaces, they must all be compliant throughout their inheritance hierarchies.

When you apply the [`CLSCompliantAttribute`](#) to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply the [`CLSCompliantAttribute`](#) to an element, it is considered to be noncompliant.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40029

To correct this error

- If you require CLS compliance, define this type within a different inheritance hierarchy or implementation scheme.
- If you require that this type remain within its current inheritance hierarchy or implementation scheme, remove the [`CLSCompliantAttribute`](#) from its definition or mark it as `<CLSCompliant(False)>`.

'<elementname>' is obsolete (Visual Basic Warning)

1/30/2019 • 2 minutes to read • [Edit Online](#)

A statement attempts to access a programming element which has been marked with the `ObsoleteAttribute` attribute and the directive to treat it as a warning.

You can mark any programming element as being no longer in use by applying `ObsoleteAttribute` to it. If you do this, you can set the attribute's `IsError` property to either `True` or `False`. If you set it to `True`, the compiler treats an attempt to use the element as an error. If you set it to `False`, or let it default to `False`, the compiler issues a warning if there is an attempt to use the element.

By default, this message is a warning, because the `IsError` property of `ObsoleteAttribute` is `False`. For more information about hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40008

To correct this error

- Ensure that the source-code reference is spelling the element name correctly.

- [Attributes overview](#)

'<eventname>' is an event, and cannot be called directly

1/30/2019 • 2 minutes to read • [Edit Online](#)

'<eventname>' is an event, and so cannot be called directly. Use a `RaiseEvent` statement to raise an event.

A procedure call specifies an event for the procedure name. An event handler is a procedure, but the event itself is a signaling device, which must be raised and handled.

Error ID: BC32022

To correct this error

1. Use a `RaiseEvent` statement to signal an event and invoke the procedure or procedures that handle it.

See also

- [RaiseEvent Statement](#)

'<expression>' cannot be used as a type constraint

1/30/2019 • 2 minutes to read • [Edit Online](#)

A constraint list includes an expression that does not represent a valid constraint on a type parameter.

A constraint list imposes requirements on the type argument passed to the type parameter. You can specify the following requirements in any combination:

- The type argument must implement one or more interfaces
- The type argument must inherit from at most one class
- The type argument must expose a parameterless constructor that the creating code can access (include the `New` constraint)

If you do not include any specific class or interface in the constraint list, you can impose a more general requirement by specifying one of the following:

- The type argument must be a value type (include the `Structure` constraint)
- The type argument must be a reference type (include the `Class` constraint)

You cannot specify both `Structure` and `Class` for the same type parameter, and you cannot specify either one more than once.

Error ID: BC32061

To correct this error

- Verify that the expression and its elements are spelled correctly.
- If the expression does not qualify for the preceding list of requirements, remove it from the constraint list.
- If the expression refers to an interface or class, verify that the compiler has access to that interface or class. '<functionname>' is not declared (Smart Device/Visual Basic Compiler Error)

1/30/2019 • 2 minutes to read • [Edit Online](#)

<`functionname`> is not declared. File I/O functionality is normally available in the `Microsoft.VisualBasic` namespace, but the targeted version of the .NET Compact Framework does not support it.

'<interfacename>.<membername>' is already implemented by the base class '<basedclassname>'. Re-implementation of <type> assumed

1/30/2019 • 2 minutes to read • [Edit Online](#)

A property, procedure, or event in a derived class uses an `Implements` clause specifying an interface member that is already implemented in the base class.

A derived class can reimplement an interface member that is implemented by its base class. This is not the same as overriding the base class implementation. For more information, see [Implements](#).

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42015

To correct this error

- If you intend to reimplement the interface member, you do not need to take any action. Code in your derived class accesses the reimplemented member unless you use the `MyBase` keyword to access the base class implementation.
- If you do not intend to reimplement the interface member, remove the `Implements` clause from the property, procedure, or event declaration.

'<membername>' cannot expose type '<typename>' outside the project through <containertype>'<containertypename>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A variable, procedure parameter, or function return is exposed outside its container, but it is declared as a type that must not be exposed outside the container.

The following skeleton code shows a situation that generates this error.

```
Private Class privateClass
End Class
Public Class mainClass
    Public exposedVar As New privateClass
End Class
```

A type that is declared `Protected`, `Friend`, `Protected Friend`, or `Private` is intended to have limited access outside its declaration context. Using it as the data type of a variable with less restricted access would defeat this purpose. In the preceding skeleton code, `exposedVar` is `Public` and would expose `privateClass` to code that should not have access to it.

Error ID: BC30909

To correct this error

- Change the access level of the variable, procedure parameter, or function return to be at least as restrictive as the access level of its data type.

1/30/2019 • 2 minutes to read • [Edit Online](#)

The interface inherits two or more members with the same name from multiple interfaces.

Error ID: BC30685

To correct this error

```
Interface Left
    Sub MySub()
End Interface

Interface Right
    Sub MySub()
End Interface

Interface LeftRight
    Inherits Left, Right
End Interface

Module test
    Sub Main()
        Dim x As LeftRight
        ' x.MySub() 'x is ambiguous.
        CType(x, Left).MySub() ' Cast to base type.
        CType(x, Right).MySub() ' Call the other base type.
    End Sub
End Module

<message> This error could also be due to mixing a file reference with a project reference to assembly '<assemblyname>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

<message> This error could also be due to mixing a file reference with a project reference to assembly '<assemblyname>'. In this case, try replacing the file reference to '<assemblyfilename>' in project '<projectname1>' with a project reference to '<projectname2>'.

Code in your project accesses a member of another project, but the configuration of your solution does not allow the Visual Basic compiler to resolve the reference.

To access a type defined in another assembly, the Visual Basic compiler must have a reference to that assembly. This must be a single, unambiguous reference that does not cause circular references among projects.

Error ID: BC30971

To correct this error

1. Determine which project produces the best assembly for your project to reference. For this decision, you might use criteria such as ease of file access and frequency of updates.
2. In your project properties, add a reference to the project that contains the assembly that defines the type you are using.

<proceduresignature1> is not CLS-compliant because it overloads <proceduresignature2> which differs from it only by array of array parameter types or by the rank of the array parameter types

1/30/2019 • 2 minutes to read • [Edit Online](#)

A procedure or property is marked as `<CLSCompliant(True)>` when it overrides another procedure or property and the only difference between their parameter lists is the nesting level of a jagged array or the rank of an array.

In the following declarations, the second and third declarations generate this error.

```
Overloads Sub processArray(ByVal arrayParam() As Integer)  
  
Overloads Sub processArray(ByVal arrayParam()() As Integer)  
  
Overloads Sub processArray(ByVal arrayParam(,) As Integer)
```

The second declaration changes the original one-dimensional parameter `arrayParam` to an array of arrays. The third declaration changes `arrayParam` to a two-dimensional array (rank 2). While Visual Basic allows overloads to differ only by one of these changes, such overloading is not compliant with the [Language Independence and Language-Independent Components \(CLS\)](#).

When you apply the [CLSCompliantAttribute](#) to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply the [CLSCompliantAttribute](#) to an element, it is considered to be noncompliant.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40035

To correct this error

- If you require CLS compliance, define your overloads to differ from each other in more ways than only the changes cited on this Help page.
- If you require that the overloads differ only by the changes cited on this Help page, remove the [CLSCompliantAttribute](#) from their definitions or mark them as `<CLSCompliant(False)>`.

<type1>'<typename>' must implement '<membername>' for interface '<interfacename>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

'<typename>' must implement '<membername>' for interface '<interfacename>'. Implementing property must have matching 'ReadOnly'/'WriteOnly' specifiers.

A class or structure claims to implement an interface but does not implement a procedure, property, or event defined by the interface. Every member of the interface must be implemented.

Error ID: BC30154

To correct this error

1. Declare a member with the same name and signature as defined in the interface. Be sure to include at least the `End Function`, `End Sub`, or `End Property` statement.
2. Add an `Implements` clause to the end of the `Function`, `Sub`, `Property`, or `Event` statement. For example:

```
Public Event ItHappened() Implements IBaseInterface.ItHappened
```
3. When implementing a property, make sure that `ReadOnly` or `WriteOnly` is used in the same way as in the interface definition.
4. When implementing a property, declare `Get` and `Set` procedures, as appropriate.

'<typename>' cannot inherit from <type>
'<basetypename>' because it expands the access of
the base <type> outside the assembly

1/30/2019 • 2 minutes to read • [Edit Online](#)

A class or interface inherits from a base class or interface but has a less restrictive access level.

For example, a `Public` interface inherits from a `Friend` interface, or a `Protected` class inherits from a `Private` class. This exposes the base class or interface to access beyond the intended level.

Error ID: BC30910

To correct this error

- Change the access level of the derived class or interface to be at least as restrictive as that of the base class or interface.
-or-

'<typename>' is a delegate type

1/30/2019 • 2 minutes to read • [Edit Online](#)

'<typename>' is a delegate type. Delegate construction permits only a single `AddressOf` expression as an argument list. Often an `AddressOf` expression can be used instead of a delegate construction.

A `New` clause creating an instance of a delegate class supplies an invalid argument list to the delegate constructor.

You can supply only a single `AddressOf` expression when creating a new delegate instance.

This error can result if you do not pass any arguments to the delegate constructor, if you pass more than one argument, or if you pass a single argument that is not a valid `AddressOf` expression.

Error ID: BC32008

A property or method call cannot include a reference to a private object, either as an argument or as a return value

1/23/2019 • 2 minutes to read • [Edit Online](#)

Among the possible causes of this error are:

- A client invoked a property or method of an out-of-process component and attempted to pass a reference to a private object as one of the arguments.
- An out-of-process component invoked a call-back method on its client and attempted to pass a reference to a private object.
- An out-of-process component attempted to pass a reference to a private object as an argument of an event it was raising.

To correct this error

1. Remove the reference.

A reference was created to embedded interop assembly '<assembly1>' because of an indirect reference to that assembly from assembly '<assembly2>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A reference was created to embedded interop assembly '<assembly1>' because of an indirect reference to that assembly from assembly '<assembly2>'. Consider changing the 'Embed Interop Types' property on either assembly.

You have added a reference to an assembly (assembly1) that has the `Embed Interop Types` property set to `True`. This instructs the compiler to embed interop type information from that assembly. However, the compiler cannot embed interop type information from that assembly because another assembly that you have referenced (assembly2) also references that assembly (assembly1) and has the `Embed Interop Types` property set to `False`.

NOTE

Setting the `Embed Interop Types` property on an assembly reference to `True` is equivalent to referencing the assembly by using the `/link` option for the command-line compiler.

Error ID: BC40059

To address this warning

- To embed interop type information for both assemblies, set the `Embed Interop Types` property on all references to assembly1 to `True`.
- To remove the warning, you can set the `Embed Interop Types` property of assembly1 to `False`. In this case, interop type information is provided by a primary interop assembly (PIA).

Access of shared member through an instance; qualifying expression will not be evaluated

1/23/2019 • 2 minutes to read • [Edit Online](#)

An instance variable of a class or structure is used to access a `Shared` variable, property, procedure, or event defined in that class or structure. This warning can also occur if an instance variable is used to access an implicitly shared member of a class or structure, such as a constant or enumeration, or a nested class or structure.

The purpose of sharing a member is to create only a single copy of that member and make that single copy available to every instance of the class or structure in which it is declared. It is consistent with this purpose to access a `Shared` member through the name of its class or structure, rather than through a variable that holds an individual instance of that class or structure.

Accessing a `Shared` member through an instance variable can make your code more difficult to understand by obscuring the fact that the member is `Shared`. Furthermore, if such access is part of an expression that performs other actions, such as a `Function` procedure that returns an instance of the shared member, Visual Basic bypasses the expression and any other actions it would otherwise perform.

For more information and an example, see [Shared](#).

By default, this message is a warning. For more information about hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42025

To correct this error

- Use the name of the class or structure that defines the `Shared` member to access it, as shown in the following example.

```
Public Class testClass
    Public Shared Sub sayHello()
        MsgBox("Hello")
    End Sub
End Class

Module testModule
    Public Sub Main()
        ' Access a shared method through an instance variable.
        ' This generates a warning.
        Dim tc As New testClass
        tc.sayHello()

        ' Access a shared method by using the class name.
        ' This does not generate a warning.
        testClass.sayHello()
    End Sub
End Module
```

NOTE

Be alert for the effects of scope when two programming elements have the same name. In the previous example, if you declare an instance by using `Dim testClass as testClass = Nothing`, the compiler treats a call to `testClass.sayHello()` as an access of the method through the class name, and no warning occurs.

An unexpected error has occurred because an operating system resource required for single instance startup cannot be acquired

1/23/2019 • 2 minutes to read • [Edit Online](#)

The application could not acquire a necessary operating system resource. Some of the possible causes for this problem are:

- The application does not have permissions to create named operating-system objects.
- The common language runtime does not have permissions to create memory-mapped files.
- The application needs to access an operating-system object, but another process is using it.

To correct this error

1. Check that the application has sufficient permissions to create named operating-system objects.
2. Check that the common language runtime has sufficient permissions to create memory-mapped files.
3. Restart the computer to clear any process that may be using the resource needed to connect to the original instance application.

'As Any' is not supported in 'Declare' statements

2/28/2019 • 2 minutes to read • [Edit Online](#)

The `Any` data type was used with `Declare` statements in Visual Basic 6.0 and earlier versions to permit the use of arguments that could contain any type of data. Visual Basic supports overloading, however, and so makes the `Any` data type obsolete.

To correct this error

1. Declare parameters of the specific type you want to use; for example.

```
Declare Function GetUserName Lib "advapi32.dll" Alias "GetUserNameA" (

Bad checksum value, non hex digits or odd number of hex digits

1/23/2019 • 2 minutes to read • [Edit Online](#)

A checksum value contains invalid hexadecimal digits or has an odd number of digits.

When ASP.NET generates a Visual Basic source file (extension .vb), it calculates a checksum and places it in a hidden source file identified by `#externalchecksum`. It is possible for a user generating a .vb file to do this also, but this process is best left to internal use.

Bad file mode

1/23/2019 • 2 minutes to read • [Edit Online](#)

Statements used in manipulating file contents must be appropriate to the mode in which the file was opened.

Possible causes include:

- A `FilePutObject` or `FileGetObject` statement specifies a sequential file.
- A `Print` statement specifies a file opened for an access mode other than `Output` or `Append`.
- An `Input` statement specifies a file opened for an access mode other than `Input`.
- An attempt to write to a read-only file.

To correct this error

- Make sure `FilePutObject` and `FileGetObject` are only referring to files open for `Random` or `Binary` access.
- Make sure `Print` specifies a file opened for either `Output` or `Append` access mode. If not, use a different statement to place data in the file, or reopen the file in an appropriate mode.
- Make sure `Input` specifies a file opened for `Input`. If not, use a different statement to place data in the file or reopen the file in an appropriate mode.

Bad file name or number

1/23/2019 • 2 minutes to read • [Edit Online](#)

An error occurred while trying to access the specified file. Among the possible causes for this error are:

- A statement refers to a file with a file name or number that was not specified in the `FileOpen` statement or that was specified in a `FileOpen` statement but was subsequently closed.
- A statement refers to a file with a number that is out of the range of file numbers.
- A statement refers to a file name or number that is not valid.

To correct this error

1. Make sure the file name is specified in a `FileOpen` statement. Note that if you invoked the `FileClose` statement without arguments, you may have inadvertently closed all open files.
2. If your code is generating file numbers algorithmically, make sure the numbers are valid.
3. Check the file names to make sure they conform to operating system conventions.

Bad record length

1/23/2019 • 2 minutes to read • [Edit Online](#)

Among the possible causes of this error are:

- The length of a record variable specified in a `FileGet`, `FileGetObject`, `FilePut` or `FilePutObject` statement differs from the length specified in the corresponding `FileOpen` statement.
- The variable in a `FilePut` or `FilePutObject` statement is or includes a variable-length string.
- The variable in a `FilePut` or `FilePutObject` is or includes a `Variant` type.

To correct this error

1. Make sure the sum of the sizes of fixed-length variables in the user-defined type defining the record variable's type is the same as the value stated in the `FileOpen` statement's `Len` clause.
2. If the variable in a `FilePut` or `FilePutObject` statement is or includes a variable-length string, make sure the variable-length string is at least 2 characters shorter than the record length specified in the `Len` clause of the `FileOpen` statement.
3. If the variable in a `FilePut` or `FilePutObject` is or includes a `Variant` make sure the variable-length string is at least 4 bytes shorter than the record length specified in the `Len` clause of the `FileOpen` statement.

Because this call is not awaited, the current method continues to run before the call is completed

1/23/2019 • 6 minutes to read • [Edit Online](#)

Because this call is not awaited, execution of the current method continues before the call is completed. Consider applying the 'Await' operator to the result of the call.

The current method calls an async method that returns a [Task](#) or a [Task<TResult>](#) and doesn't apply the [Await](#) operator to the result. The call to the async method starts an asynchronous task. However, because no [Await](#) operator is applied, the program continues without waiting for the task to complete. In most cases, that behavior isn't expected. Usually other aspects of the calling method depend on the results of the call or, minimally, the called method is expected to complete before you return from the method that contains the call.

An equally important issue is what happens with exceptions that are raised in the called async method. An exception that's raised in a method that returns a [Task](#) or [Task<TResult>](#) is stored in the returned task. If you don't await the task or explicitly check for exceptions, the exception is lost. If you await the task, its exception is rethrown.

As a best practice, you should always await the call.

By default, this message is a warning. For more information about hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42358

To address this warning

- You should consider suppressing the warning only if you're sure that you don't want to wait for the asynchronous call to complete and that the called method won't raise any exceptions. In that case, you can suppress the warning by assigning the task result of the call to a variable.

The following example shows how to cause the warning, how to suppress it, and how to await the call.

```

Async Function CallingMethodAsync() As Task

    ResultsTextBox.Text &= vbCrLf & " Entering calling method."

    ' Variable delay is used to slow down the called method so that you
    ' can distinguish between awaiting and not awaiting in the program's output.
    ' You can adjust the value to produce the output that this topic shows
    ' after the code.
    Dim delay = 5000

    ' Call #1.
    ' Call an async method. Because you don't await it, its completion isn't
    ' coordinated with the current method, CallingMethodAsync.
    ' The following line causes the warning.
    CalledMethodAsync(delay)

    ' Call #2.
    ' To suppress the warning without awaiting, you can assign the
    ' returned task to a variable. The assignment doesn't change how
    ' the program runs. However, the recommended practice is always to
    ' await a call to an async method.
    ' Replace Call #1 with the following line.
    'Task delayTask = CalledMethodAsync(delay)

    ' Call #3
    ' To contrast with an awaited call, replace the unawaited call
    ' (Call #1 or Call #2) with the following awaited call. The best
    ' practice is to await the call.

    'Await CalledMethodAsync(delay)

    ' If the call to CalledMethodAsync isn't awaited, CallingMethodAsync
    ' continues to run and, in this example, finishes its work and returns
    ' to its caller.
    ResultsTextBox.Text &= vbCrL & " Returning from calling method."
End Function

Async Function CalledMethodAsync(howLong As Integer) As Task

    ResultsTextBox.Text &= vbCrL & " Entering called method, starting and awaiting Task.Delay."
    ' Slow the process down a little so you can distinguish between awaiting
    ' and not awaiting. Adjust the value for howLong if necessary.
    Await Task.Delay(howLong)
    ResultsTextBox.Text &= vbCrL & " Task.Delay is finished--returning from called method."
End Function

```

In the example, if you choose Call #1 or Call #2, the unawaited async method (`CalledMethodAsync`) finishes after both its caller (`CallingMethodAsync`) and the caller's caller (`StartButton_Click`) are complete. The last line in the following output shows you when the called method finishes. Entry to and exit from the event handler that calls `CallingMethodAsync` in the full example are marked in the output.

```

Entering the Click event handler.
Entering calling method.
    Entering called method, starting and awaiting Task.Delay.
    Returning from calling method.
Exiting the Click event handler.
    Task.Delay is finished--returning from called method.

```

Example

The following Windows Presentation Foundation (WPF) application contains the methods from the previous example. The following steps set up the application.

- Create a WPF application, and name it `AsyncWarning`.
 - In the Visual Studio Code Editor, choose the **MainWindow.xaml** tab.
- If the tab isn't visible, open the shortcut menu for `MainWindow.xaml` in **Solution Explorer**, and then choose **View Code**.
- Replace the code in the **XAML** view of `MainWindow.xaml` with the following code.

```
<Window x:Class="MainWindow"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    Title="MainWindow" Height="350" Width="525">
<Grid>
    <Button x:Name="StartButton" Content="Start" HorizontalAlignment="Left" Margin="214,28,0,0"
    VerticalAlignment="Top" Width="75" HorizontalContentAlignment="Center" FontWeight="Bold"
    FontFamily="Aharoni" Click="StartButton_Click" />
    <TextBox x:Name="ResultsTextBox" Margin="0,80,0,0" TextWrapping="Wrap" FontFamily="Lucida
    Console"/>
</Grid>
</Window>
```

A simple window that contains a button and a text box appears in the **Design** view of `MainWindow.xaml`.

For more information about the XAML Designer, see [Creating a UI by using XAML Designer](#). For information about how to build your own simple UI, see the "To create a WPF application" and "To design a simple WPF MainWindow" sections of [Walkthrough: Accessing the Web by Using Async and Await](#).

- Replace the code in `MainWindow.xaml.vb` with the following code.

```
Class MainWindow

    Private Async Sub StartButton_Click(sender As Object, e As RoutedEventArgs)

        ResultsTextBox.Text &= vbCrLf & "Entering the Click event handler."
        Await CallingMethodAsync()
        ResultsTextBox.Text &= vbCrLf & "Exiting the Click event handler."
    End Sub

    Async Function CallingMethodAsync() As Task

        ResultsTextBox.Text &= vbCrLf & " Entering calling method."

        ' Variable delay is used to slow down the called method so that you
        ' can distinguish between awaiting and not awaiting in the program's output.
        ' You can adjust the value to produce the output that this topic shows
        ' after the code.
        Dim delay = 5000

        ' Call #1.

        ' coordinated with the current method, CallingMethodAsync.
        ' The following line causes the warning.
        CalledMethodAsync(delay)

        ' Call #2.
        ' To suppress the warning without awaiting, you can assign the
        ' returned task to a variable. The assignment doesn't change how
        ' the program runs. However, the recommended practice is always to
        ' await a call to an async method.

        ' Replace Call #1 with the following line.
        'Task delayTask = CalledMethodAsync(delay)

        ' Call #3
```

```

' To contrast with an awaited call, replace the unawaited call
' (Call #1 or Call #2) with the following awaited call. The best
' practice is to await the call.

'Await CalledMethodAsync(delay)

' If the call to CalledMethodAsync isn't awaited, CallingMethodAsync
' continues to run and, in this example, finishes its work and returns
' to its caller.
    ResultsTextBox.Text &= vbCrLf & " Returning from calling method."
End Function

Async Function CalledMethodAsync(howLong As Integer) As Task

    ResultsTextBox.Text &= vbCrLf & " Entering called method, starting and awaiting Task.Delay."
    ' Slow the process down a little so you can distinguish between awaiting
    ' and not awaiting. Adjust the value for howLong if necessary.
    Await Task.Delay(howLong)
    ResultsTextBox.Text &= vbCrLf & " Task.Delay is finished--returning from called method."
End Function

End Class

' Output

' Entering the Click event handler.
'   Entering calling method.
'     Entering called method, starting and awaiting Task.Delay.
'     Returning from calling method.
'   Exiting the Click event handler.
'     Task.Delay is finished--returning from called method.

5. Choose the F5 key to run the program, and then choose the **Start** button.

The expected output appears at the end of the code.

Cannot convert anonymous type to expression tree because it contains a field that is used in the initialization of another field

1/23/2019 • 2 minutes to read • [Edit Online](#)

The compiler does not accept conversion of an anonymous to an expression tree when one property of the anonymous type is used to initialize another property of the anonymous type. For example, in the following code, `Prop1` is declared in the initialization list and then used as the initial value for `Prop2`.

```
Module M2

Sub ExpressionExample(Of T)(ByVal x As Expressions.Expression(Of Func(Of T)))
End Sub

Sub Main()
    ' The following line causes the error.
    ' ExpressionExample(Function() New With {.Prop1 = 2, .Prop2 = .Prop1})

    End Sub
End Module
```

Error ID: BC36548

To correct this error

- Assign the initial value for `Prop1` to a local variable. Assign that variable to both `Prop1` and `Prop2`, as shown in the following code.

```
Sub Main()

    Dim temp = 2
    ExpressionExample(Function() New With {.Prop1 = temp, .Prop2 = temp})

    End Sub
```

Cannot refer to '<name>' because it is a member of the value-typed field '<name>' of class '<classname>' which has 'System.MarshalByRefObject' as a base class

1/30/2019 • 2 minutes to read • [Edit Online](#)

The `System.MarshalByRefObject` class enables applications that support remote access to objects across application domain boundaries. Types must inherit from the `MarshalByRejectObject` class when the type is used across application domain boundaries. The state of the object must not be copied because the members of the object are not usable outside the application domain in which they were created.

Error ID: BC30310

To correct this error

1. Check the reference to make sure the member being referred to is valid.
2. Explicitly qualify the member with the `Me` keyword.

- [Dim Statement](#)

Cannot refer to an instance member of a class from within a shared method or shared member initializer without an explicit instance of the class

1/23/2019 • 2 minutes to read • [Edit Online](#)

You have tried to refer to a non-shared member of a class from within a shared procedure. The following example demonstrates such a situation.

```
Class sample
    Public x as Integer
    Public Shared Sub setX()
        x = 10
    End Sub
End Class
```

In the preceding example, the assignment statement `x = 10` generates this error message. This is because a shared procedure is attempting to access an instance variable.

The variable `x` is an instance member because it is not declared as `Shared`. Each instance of class `sample` contains its own individual variable `x`. When one instance sets or changes the value of `x`, it does not affect the value of `x` in any other instance.

However, the procedure `setX` is `Shared` among all instances of class `sample`. This means it is not associated with any one instance of the class, but rather operates independently of individual instances. Because it has no connection with a particular instance, `setX` cannot access an instance variable. It must operate only on `Shared` variables. When `setX` sets or changes the value of a shared variable, that new value is available to all instances of the class.

Error ID: BC30369

To correct this error

1. Decide whether you want the member to be shared among all instances of the class, or kept individual for each instance.
2. If you want a single copy of the member to be shared among all instances, add the `Shared` keyword to the member declaration. Retain the `Shared` keyword in the procedure declaration.
3. If you want each instance to have its own individual copy of the member, do not specify `Shared` for the member declaration. Remove the `Shared` keyword from the procedure declaration.

Constants must be of an intrinsic or enumerated type, not a class, structure, type parameter, or array type

1/23/2019 • 2 minutes to read • [Edit Online](#)

You have attempted to declare a constant as a class, structure, or array type, or as a type parameter defined by a containing generic type.

Constants must be of an intrinsic type (`Boolean`, `Byte`, `Date`, `Decimal`, `Double`, `Integer`, `Long`, `Object`, `SByte`, `Short`, `Single`, `String`, `UInteger`, `ULong`, or `UShort`), or an `Enum` type based on one of the integral types.

Error ID: BC30424

To correct this error

1. Declare the constant as an intrinsic or `Enum` type.
2. A constant can also be a special value such as `True`, `False`, or `Nothing`. The compiler considers these predefined values to be of the appropriate intrinsic type.

Constructor '<name>' cannot call itself

1/30/2019 • 2 minutes to read • [Edit Online](#)

A `Sub New` procedure in a class or structure calls itself.

The purpose of a constructor is to initialize an instance of a class or structure when it is first created. A class or structure can have several constructors, provided they all have different parameter lists. A constructor is permitted to call another constructor to perform its functionality in addition to its own. But it is meaningless for a constructor to call itself, and in fact it would result in infinite recursion if permitted.

Error ID: BC30298

To correct this error

1. Check the parameter list of the constructor being called. It should be different from that of the constructor making the call.
2. If you do not intend to call a different constructor, remove the `Sub New` call entirely.

Copying the value of 'ByRef' parameter '`<parametername>`' back to the matching argument narrows from type '`<typename1>`' to type '`<typename2>`'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A procedure is called with an argument that widens to the corresponding parameter type, and the conversion from the parameter to the argument is narrowing.

When you define a class or structure, you can define one or more conversion operators to convert that class or structure type to other types. You can also define reverse conversion operators to convert those other types back to your class or structure type. When you use your class or structure type in a procedure call, Visual Basic can use these conversion operators to convert the type of an argument to the type of its corresponding parameter.

If you pass the argument [ByRef](#), Visual Basic sometimes copies the argument value into a local variable in the procedure instead of passing a reference. In such a case, when the procedure returns, Visual Basic must then copy the local variable value back into the argument in the calling code.

If a [ByRef](#) argument value is copied into the procedure and the argument and parameter are of the same type, no conversion is necessary. But if the types are different, Visual Basic must convert in both directions. If one of the types is your class or structure type, Visual Basic must convert it both to and from the other type. If one of these conversions is widening, the reverse conversion might be narrowing.

Error ID: BC32053

To correct this error

- If possible, use a calling argument of the same type as the procedure parameter, so Visual Basic does not need to do any conversion.
- If you need to call the procedure with an argument type different from the parameter type but do not need to return a value into the calling argument, define the parameter to be [ByVal](#) instead of [ByRef](#).
- If you need to return a value into the calling argument, define the reverse conversion operator as [Widening](#), if possible.

'Custom' modifier is not valid on events declared without explicit delegate types

2/28/2019 • 2 minutes to read • [Edit Online](#)

Unlike a non-custom event, a `Custom Event` declaration requires an `As` clause following the event name that explicitly specifies the delegate type for the event.

Non-custom events can be defined either with an `As` clause and an explicit delegate type, or with a parameter list immediately following the event name.

Error ID: BC31122

To correct this error

1. Define a delegate with the same parameter list as the custom event.

For example, if the `Custom Event` was defined by

`Custom Event Test(ByVal sender As Object, ByVal i As Integer)`, then the corresponding delegate would be the following.

```
Delegate Sub TestDelegate(ByVal sender As Object, ByVal i As Integer)
```

2. Replace the parameter list of the custom event with an `As` clause specifying the delegate type.

Continuing with the example, `Custom Event` declaration would be rewritten as follows.

```
Custom Event Test As TestDelegate
```

Example

This example declares a `Custom Event` and specifies the required `As` clause with a delegate type.

```
Delegate Sub TestDelegate(ByVal sender As Object, ByVal i As Integer)
Custom Event Test As TestDelegate
    AddHandler(ByVal value As TestDelegate)
        ' Code for adding an event handler goes here.
    End AddHandler

    RemoveHandler(ByVal value As TestDelegate)
        ' Code for removing an event handler goes here.
    End RemoveHandler

    RaiseEvent(ByVal sender As Object, ByVal i As Integer)
        ' Code for raising an event goes here.
    End RaiseEvent
End Event

Data type(s) of the type parameter(s) cannot be inferred from these arguments

1/23/2019 • 2 minutes to read • [Edit Online](#)

Data type(s) of the type parameter(s) cannot be inferred from these arguments. Specifying the data type(s) explicitly might correct this error.

This error occurs when overload resolution has failed. It occurs as a subordinate message that states why a particular overload candidate has been eliminated. The error message explains that the compiler cannot use type inference to find data types for the type parameters.

NOTE

When specifying arguments is not an option (for example, for query operators in query expressions), the error message appears without the second sentence.

The following code demonstrates the error.

```
Module Module1

Sub Main()

    '' Not Valid.
    'OverloadedGenericMethod("Hello", "World")

End Sub

Sub OverloadedGenericMethod(Of T)(ByVal x As String,
                                 ByVal y As InterfaceExample(Of T))
End Sub

Sub OverloadedGenericMethod(Of T, R)(ByVal x As T,
                                    ByVal y As InterfaceExample(Of R))
End Sub

End Module

Interface InterfaceExample(Of T)

Default property access is ambiguous between the inherited interface members '`<defaultpropertyname>`' of interface '`<interfacename1>`' and '`<defaultpropertyname>`' of interface '`<interfacename2>`'

1/30/2019 • 2 minutes to read • [Edit Online](#)

An interface inherits from two interfaces, each of which declares a default property with the same name. The compiler cannot resolve an access to this default property without qualification. The following example illustrates this.

```
Public Interface Iface1
    Default Property prop(ByVal arg As Integer) As Integer
End Interface
Public Interface Iface2
    Default Property prop(ByVal arg As Integer) As Integer
End Interface
Public Interface Iface3
    Inherits Iface1, Iface2
End Interface
Public Class testClass
    Public Sub accessDefaultProperty()
        Dim testObj As Iface3
        Dim testInt As Integer = testObj(1)
    End Sub
End Class
```

When you specify `testObj(1)`, the compiler tries to resolve it to the default property. However, there are two possible default properties because of the inherited interfaces, so the compiler signals this error.

Error ID: BC30686

To correct this error

- Avoid inheriting any members with the same name. In the preceding example, if `testObj` does not need any of the members of, say, `Iface2`, then declare it as follows:

```
Dim testObj As Iface1
```

-or-

- Implement the inheriting interface in a class. Then you can implement each of the inherited properties with different names. However, only one of them can be the default property of the implementing class. The following example illustrates this.

```
Public Class useIface3
    Implements Iface3
    Default Public Property prop1(ByVal arg As Integer) As Integer Implements Iface1.prop
        ' Insert code to define Get and Set procedures for prop1.
    End Property
    Public Property prop2(ByVal arg As Integer) As Integer Implements Iface2.prop
        ' Insert code to define Get and Set procedures for prop2.
    End Property
End Class
```

Delegate class '<classname>' has no Invoke method, so an expression of this type cannot be the target of a method call

1/30/2019 • 2 minutes to read • [Edit Online](#)

A call to `Invoke` through a delegate has failed because `Invoke` is not implemented on the delegate class.

Error ID: BC30220

To correct this error

1. Ensure that an instance of the delegate class has been created with a `Dim` statement and that a procedure has been assigned to the delegate instance with the `AddressOf` operator.
2. Locate the code that implements the delegate class and make sure it implements the `Invoke` procedure.

End of statement expected

1/23/2019 • 2 minutes to read • [Edit Online](#)

The statement is syntactically complete, but an additional programming element follows the element that completes the statement. A line terminator is required at the end of every statement.

A line terminator divides the characters of a Visual Basic source file into lines. Examples of line terminators are the Unicode carriage return character (&HD), the Unicode linefeed character (&HA), and the Unicode carriage return character followed by the Unicode linefeed character. For more information about line terminators, see the [Visual Basic Language Specification](#).

Error creating assembly manifest: <error message>

2/6/2019 • 2 minutes to read • [Edit Online](#)

The Visual Basic compiler calls the Assembly Linker (Al.exe, also known as Alink) to generate an assembly with a manifest. The linker has reported an error in the pre-emission stage of creating the assembly.

This can occur if there are problems with the key file or the key container specified. To fully sign an assembly, you must provide a valid key file that contains information about the public and private keys. To delay sign an assembly, you must select the **Delay sign only** check box and provide a valid key file that contains information about the public key information. The private key is not necessary when an assembly is delay-signed. For more information, see [How to: Sign an Assembly with a Strong Name](#).

Error in loading DLL (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

A dynamic-link library (DLL) is a library specified in the `Lib` clause of a `Declare` statement. Possible causes for this error include:

- The file is not DLL executable.
- The file is not a Microsoft Windows DLL.
- The DLL references another DLL that is not present.
- The DLL or referenced DLL is not in a directory specified in the path.

To correct this error

- If the file is a source-text file and therefore not DLL executable, it must be compiled and linked to a DLL-executable form.
- If the file is not a Microsoft Windows DLL, obtain the Microsoft Windows equivalent.
- If the DLL references another DLL that is not present, obtain the referenced DLL and make it available.
- If the DLL or referenced DLL is not in a directory specified by the path, move the DLL to a referenced directory.

Errors occurred while compiling the XML schemas in the project

1/23/2019 • 2 minutes to read • [Edit Online](#)

Errors occurred while compiling the XML schemas in the project. Because of this, XML IntelliSense is not available.

There is an error in an XML Schema Definition (XSD) schema included in the project. This error occurs when you add an XSD schema (.xsd) file that conflicts with the existing XSD schema set for the project.

Error ID: BC36810

To correct this error

- Double-click the warning in the **Errors List** window. Visual Basic will take you to the location in the XSD file that is the source of the warning. Correct the error in the XSD schema.
- Ensure that all required XSD schema (.xsd) files are included in the project. You may need to click **Show All Files** on the **Project** menu to see your .xsd files in **Solution Explorer**. Right-click an .xsd file and then click **Include In Project** to include the file in your project.
- If you are using the XML to Schema Wizard, this error can occur if you infer schemas more than one time from the same source. In this case, you can remove the existing XSD schema files from the project, add a new XML to Schema item template, and then provide the XML to Schema Wizard with all the applicable XML sources for your project.
- If no error is identified in your XSD schema, the XML compiler may not have enough information to provide a detailed error message. You may be able to get more detailed error information if you ensure that the XML namespaces for the .xsd files included in your project match the XML namespaces identified for the XML Schema set in Visual Studio.

Events of shared WithEvents variables cannot be handled by non-shared methods

1/23/2019 • 2 minutes to read • [Edit Online](#)

A variable declared with the `Shared` modifier is a shared variable. A shared variable identifies exactly one storage location. A variable declared with the `WithEvents` modifier asserts that the type to which the variable belongs handles the set of events the variable raises. When a value is assigned to the variable, the property created by the `WithEvents` declaration unhooks any existing event handler and hooks up the new event handler via the `Add` method.

Expression has the type '<typename>' which is a restricted type and cannot be used to access members inherited from 'Object' or 'ValueType'

1/30/2019 • 2 minutes to read • [Edit Online](#)

An expression evaluates to a type that cannot be boxed by the common language runtime (CLR) but accesses a member that requires boxing.

Boxing refers to the processing necessary to convert a type to `Object` or, on occasion, to `ValueType`. The common language runtime cannot box certain structure types, for example `ArgIterator`, `RuntimeArgumentHandle`, and `TypedReference`.

This expression attempts to use the restricted type to call a method inherited from `Object` or `ValueType`, such as `GetHashCode` or `ToString`. To access this method, Visual Basic has attempted an implicit boxing conversion that causes this error.

Error ID: BC31393

To correct this error

1. Locate the expression that evaluates to the cited type.
2. Locate the part of your statement that attempts to call the method inherited from `Object` or `ValueType`.
3. Rewrite the statement to avoid the method call.

See also

- [Implicit and Explicit Conversions](#)

Expression is a value and therefore cannot be the target of an assignment

1/23/2019 • 2 minutes to read • [Edit Online](#)

A statement attempts to assign a value to an expression. You can assign a value only to a writable variable, property, or array element at run time. The following example illustrates how this error can occur.

```
Dim yesterday As Integer
ReadOnly maximum As Integer = 45
yesterday + 1 = DatePart(DateInterval.Day, Now)
' The preceding line is an ERROR because of an expression on the left.
maximum = 50
' The preceding line is an ERROR because maximum is declared ReadOnly.
```

Similar examples could apply to properties and array elements.

Indirect Access. Indirect access through a value type can also generate this error. Consider the following code example, which attempts to set the value of [Point](#) by accessing it indirectly through [Location](#).

```
' Assume this code runs inside Form1.
Dim exitButton As New System.Windows.Forms.Button()
exitButton.Text = "Exit this form"
exitButton.Location.X = 140
' The preceding line is an ERROR because of no storage for Location.
```

The last statement of the preceding example fails because it creates only a temporary allocation for the [Point](#) structure returned by the [Location](#) property. A structure is a value type, and the temporary structure is not retained after the statement runs. The problem is resolved by declaring and using a variable for [Location](#), which creates a more permanent allocation for the [Point](#) structure. The following example shows code that can replace the last statement of the preceding example.

```
Dim exitLocation as New System.Drawing.Point(140, exitButton.Location.Y)
exitButton.Location = exitLocation
```

Error ID: BC30068

To correct this error

- If the statement assigns a value to an expression, replace the expression with a single writable variable, property, or array element.
- If the statement makes indirect access through a value type (usually a structure), create a variable to hold the value type.
- Assign the appropriate structure (or other value type) to the variable.
- Use the variable to access the property to assign it a value.

Expression of type <type> is not queryable

1/30/2019 • 2 minutes to read • [Edit Online](#)

Expression of type <type> is not queryable. Make sure you are not missing an assembly reference and/or namespace import for the LINQ provider.

Queryable types are defined in the [System.Linq](#), [System.Data.Linq](#), and [System.Xml.Linq](#) namespaces. You must import one or more of these namespaces to perform LINQ queries.

The [System.Linq](#) namespace enables you to query objects such as collections and arrays by using LINQ.

The [System.Data.Linq](#) namespace enables you to query ADO.NET Datasets and SQL Server databases by using LINQ.

The [System.Xml.Linq](#) namespace enables you to query XML by using LINQ and to use XML features in Visual Basic.

Error ID: BC36593

To correct this error

1. Add an `Import` statement for the [System.Linq](#), [System.Data.Linq](#), or [System.Xml.Linq](#) namespace to your code file. You can also import namespaces for your project by using the **References** page of the Project Designer ([My Project](#)).
2. Ensure that the type that you have identified as the source of your query is a queryable type. That is, a type that implements `IEnumerable<T>` or `IQueryable<T>`.

Expression recursively calls the containing property '`<propertyname>`'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A statement in the `Set` procedure of a property definition stores a value into the name of the property.

The recommended approach to holding the value of a property is to define a `Private` variable in the property's container and use it in both the `Get` and `Set` procedures. The `Set` procedure should then store the incoming value in this `Private` variable.

The `Get` procedure behaves like a `Function` procedure, so it can assign a value to the property name and return control by encountering the `End Get` statement. The recommended approach, however, is to include the `Private` variable as the value in a [Return Statement](#).

The `Set` procedure behaves like a `Sub` procedure, which does not return a value. Therefore, the procedure or property name has no special meaning within a `Set` procedure, and you cannot store a value into it.

The following example illustrates the approach that can cause this error, followed by the recommended approach.

```
Public Class illustrateProperties
    ' The code in the following property causes this error.
    Public Property badProp() As Char
        Get
            Dim charValue As Char
            ' Insert code to update charValue.
            badProp = charValue
        End Get
        Set(ByVal Value As Char)
            ' The following statement causes this error.
            badProp = Value
            ' The value stored in the local variable badProp
            ' is not used by the Get procedure in this property.
        End Set
    End Property
    ' The following code uses the recommended approach.
    Private propValue As Char
    Public Property goodProp() As Char
        Get
            ' Insert code to update propValue.
            Return propValue
        End Get
        Set(ByVal Value As Char)
            propValue = Value
        End Set
    End Property
End Class
```

'Extension' attribute can be applied only to 'Module', 'Sub', or 'Function' declarations

1/30/2019 • 2 minutes to read • [Edit Online](#)

The only way to extend a data type in Visual Basic is to define an extension method inside a standard module. The extension method can be a `Sub` procedure or a `Function` procedure. All extension methods must be marked with the extension attribute, `<Extension()>`, from the `System.Runtime.CompilerServices` namespace. Optionally, a module that contains an extension method may be marked in the same way. No other use of the extension attribute is valid.

Error ID: BC36550

To correct this error

- Remove the extension attribute.
- Redesign your extension as a method, defined in an enclosing module.

Example

First operand in a binary 'If' expression must be nullable or a reference type

1/30/2019 • 2 minutes to read • [Edit Online](#)

An `If` expression can take either two or three arguments. When you send only two arguments, the first argument must be a reference type or a nullable type. If the first argument evaluates to anything other than `Nothing`, its value is returned. If the first argument evaluates to `Nothing`, the second argument is evaluated and returned.

For example, the following code contains two `If` expressions, one with three arguments and one with two arguments. The expressions calculate and return the same value.

```
' firstChoice is a nullable value type.  
Dim firstChoice? As Integer = Nothing  
Dim secondChoice As Integer = 1128  
' If expression with three arguments.  
Console.WriteLine(If(firstChoice IsNot Nothing, firstChoice, secondChoice))  
' If expression with two arguments.  
Console.WriteLine(If(firstChoice, secondChoice))
```

The following expressions cause this error:

```
Dim choice1 = 4  
Dim choice2 = 5  
Dim booleanVar = True  
  
' Not valid.  
'Console.WriteLine(If(choice1 < choice2, 1))  
' Not valid.  
'Console.WriteLine(If(booleanVar, "Test returns True."))
```

Error ID: BC33107

To correct this error

- If you cannot change the code so that the first argument is a nullable type or reference type, consider converting to a three-argument `If` expression, or to an `If...Then...Else` statement.

```
Console.WriteLine(If(choice1 < choice2, 1, 2))  
Console.WriteLine(If(booleanVar, "Test returns True.", "Test returns False.))

First statement of this 'Sub New' must be a call to ' MyBase.New' or ' MyClass.New' (No Accessible Constructor Without Parameters)

3/5/2019 • 2 minutes to read • [Edit Online](#)

First statement of this 'Sub New' must be a call to ' MyBase.New' or ' MyClass.New' because base class '<basename>' of '<derivedname>' does not have an accessible 'Sub New' that can be called with no arguments.

In a derived class, every constructor must call a base class constructor (`MyBase.New`). If the base class has a constructor with no parameters that is accessible to derived classes, `MyBase.New` can be called automatically. If not, a base class constructor must be called with parameters, and this cannot be done automatically. In this case, the first statement of every derived class constructor must call a parameterized constructor on the base class, or call another constructor in the derived class that makes a base class constructor call.

Error ID: BC30148

To correct this error

- Either call `MyBase.New` supplying the required parameters, or call a peer constructor that makes such a call.

For example, if the base class has a constructor that's declared as `Public Sub New(ByVal index As Integer)`, the first statement in the derived class constructor might be `MyBase.New(100)`.

See also

- [Inheritance Basics](#)

First statement of this 'Sub New' must be an explicit call to 'MyBase.New' or 'MyClass.New' because the '<constructorname>' in the base class '<baseclassname>' of '<derivedclassname>' is marked obsolete: '<errormessage>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A class constructor does not explicitly call a base class constructor, and the implicit base class constructor is marked with the [ObsoleteAttribute](#) attribute and the directive to treat it as an error.

When a derived class constructor does not call a base class constructor, Visual Basic attempts to generate an implicit call to a parameterless base class constructor. If there is no accessible constructor in the base class that can be called without arguments, Visual Basic cannot generate an implicit call. In this case, the required constructor is marked with the [ObsoleteAttribute](#) attribute, so Visual Basic cannot call it.

You can mark any programming element as being no longer in use by applying [ObsoleteAttribute](#) to it. If you do this, you can set the attribute's [IsError](#) property to either `True` or `False`. If you set it to `True`, the compiler treats an attempt to use the element as an error. If you set it to `False`, or let it default to `False`, the compiler issues a warning if there is an attempt to use the element.

Error ID: BC30920

To correct this error

1. Examine the quoted error message and take appropriate action.
2. Include a call to `MyBase.New()` or `MyClass.New()` as the first statement of the `Sub New` in the derived class.

'For Each' on type '<typename>' is ambiguous because the type implements multiple instantiations of 'System.Collections.Generic.IEnumerable(Of T)'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A `For Each` statement specifies an iterator variable that has more than one [GetEnumerator](#) method.

The iterator variable must be of a type that implements the [System.Collections.IEnumerable](#) or [System.Collections.Generic.IEnumerable<T>](#) interface in one of the [Collections](#) namespaces of the .NET Framework. It is possible for a class to implement more than one constructed generic interface, using a different type argument for each construction. If a class that does this is used for the iterator variable, that variable has more than one [GetEnumerator](#) method. In such a case, Visual Basic cannot choose which method to call.

Error ID: BC32096

To correct this error

- Use [DirectCast Operator](#) or [TryCast Operator](#) to cast the iterator variable type to the interface defining the [GetEnumerator](#) method you want to use.

Function '<procedurename>' doesn't return a value on all code paths

1/30/2019 • 2 minutes to read • [Edit Online](#)

Function '<procedurename>' doesn't return a value on all code paths. Are you missing a 'Return' statement?

A `Function` procedure has at least one possible path through its code that does not return a value.

You can return a value from a `Function` procedure in any of the following ways:

- Include the value in a [Return Statement](#).
- Assign the value to the `Function` procedure name and then perform an `Exit Function` statement.
- Assign the value to the `Function` procedure name and then perform the `End Function` statement.

If control passes to `Exit Function` or `End Function` and you have not assigned any value to the procedure name, the procedure returns the default value of the return data type. For more information, see "Behavior" in [Function Statement](#).

By default, this message is a warning. For more information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42105

To correct this error

- Check your control flow logic and make sure you assign a value before every statement that causes a return.

It is easier to guarantee that every return from the procedure returns a value if you always use the `Return` statement. If you do this, the last statement before `End Function` should be a `Return` statement.

Function evaluation is disabled because a previous function evaluation timed out

1/23/2019 • 2 minutes to read • [Edit Online](#)

Function evaluation is disabled because a previous function evaluation timed out. To re-enable function evaluation, step again or restart debugging.

In the Visual Studio debugger, an expression specifies a procedure call, but another evaluation has timed out.

Possible causes for a procedure call to time out include an infinite loop or *endless loop*. For more information, see [For...Next Statement](#).

A special case of an infinite loop is *recursion*. For more information, see [Recursive Procedures](#).

Error ID: BC30957

To correct this error

1. If possible, determine what the previous function evaluation was and what caused it to time out. Otherwise, you might encounter this error again.
2. Either step the debugger again, or terminate and restart debugging.

Generic parameters used as optional parameter types must be class constrained

1/23/2019 • 2 minutes to read • [Edit Online](#)

A procedure is declared with an optional parameter that uses a type parameter that is not constrained to be a reference type.

You must always supply a default value for each optional parameter. If the parameter is of a reference type, the optional value must be `Nothing`, which is a valid value for any reference type. However, if the parameter is of a value type, that type must be an elementary data type predefined by Visual Basic. This is because a composite value type, such as a user-defined structure, has no valid default value.

When you use a type parameter for an optional parameter, you must guarantee that it is of a reference type to avoid the possibility of a value type with no valid default value. This means you must constrain the type parameter either with the `Class` keyword or with the name of a specific class.

Error ID: BC32124

To correct this error

- Constrain the type parameter to accept only a reference type, or do not use it for the optional parameter.

'Get' accessor of property '<propertyname>' is not accessible

1/30/2019 • 2 minutes to read • [Edit Online](#)

A statement attempts to retrieve the value of a property when it does not have access to the property's `Get` procedure.

If the [Get Statement](#) is marked with a more restrictive access level than its [Property Statement](#), an attempt to read the property value could fail in the following cases:

- The `Get` statement is marked [Private](#) and the calling code is outside the class or structure in which the property is defined.
- The `Get` statement is marked [Protected](#) and the calling code is not in the class or structure in which the property is defined, nor in a derived class.
- The `Get` statement is marked [Friend](#) and the calling code is not in the same assembly in which the property is defined.

Error ID: BC31103

To correct this error

- If you have control of the source code defining the property, consider declaring the `Get` procedure with the same access level as the property itself.
- If you do not have control of the source code defining the property, or you must restrict the `Get` procedure access level more than the property itself, try to move the statement that reads the property value to a region of code that has better access to the property.

Handles clause requires a WithEvents variable defined in the containing type or one of its base types

1/23/2019 • 2 minutes to read • [Edit Online](#)

You did not supply a `WithEvents` variable in your `Handles` clause. The `Handles` keyword at the end of a procedure declaration causes it to handle events raised by an object variable declared using the `WithEvents` keyword.

Error ID: BC30506

To correct this error

- Supply the necessary `WithEvents` variable.

A programming element that is not a recognizable declared element name occurs where the context requires an element name. One possible cause is that an attribute has been specified somewhere other than at the beginning of the statement.

Error ID: BC30203

Identifier is too long

1/23/2019 • 2 minutes to read • [Edit Online](#)

The name, or identifier, of every programming element is limited to 1023 characters. In addition, a fully qualified name cannot exceed 1023 characters. This means that the entire identifier string (`<namespace>.<...>.<namespace>.<class>.<element>`) cannot be more than 1023 characters long, including the member-access operator (`.`) characters.

Error ID: BC30033

To correct this error

- Reduce the length of the identifier.

Initializer expected

1/23/2019 • 2 minutes to read • [Edit Online](#)

You have tried to declare an instance of a class by using an object initializer in which the initialization list is empty, as shown in the following example.

```
' Not valid.
```

```
' Dim aStudent As New Student With {}
```

At least one field or property must be initialized in the initializer list, as shown in the following example.

```
Dim aStudent As New Student With {.year = "Senior"}
```

Error ID: BC30996

To correct this error

1. Initialize at least one field or property in the initializer, or do not use an object initializer.

Implicit conversion from '<typename1>' to '<typename2>' in copying the value of 'ByRef' parameter '<parametername>' back to the matching argument.

1/30/2019 • 2 minutes to read • [Edit Online](#)

A procedure is called with a [ByRef](#) argument of a different type than that of its corresponding parameter.

If you pass an argument [ByRef](#), Visual Basic sometimes copies the argument value into a local variable in the procedure instead of passing a reference. In such a case, when the procedure returns, Visual Basic must then copy the local variable value back into the argument in the calling code.

If a [ByRef](#) argument value is copied into the procedure and the argument and parameter are of the same type, no conversion is necessary. But if the types are different, Visual Basic must convert in both directions. Because you cannot use [CType](#) or any of the other conversion keywords on a procedure argument or parameter, such a conversion is always implicit.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC41999

To correct this error

- If possible, use a calling argument of the same type as the procedure parameter, so Visual Basic does not need to do any conversion.
- If you need to call the procedure with an argument type different from the parameter type but do not need to return a value into the calling argument, define the parameter to be [ByVal](#) instead of [ByRef](#).

'Is' requires operands that have reference types, but this operand has the value type '<typename>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

The `Is` comparison operator determines whether two object variables refer to the same instance. This comparison is not defined for value types.

Error ID: BC30020

' IsNot' operand of type 'typename' can only be compared to 'Nothing', because 'typename' is a nullable type

1/30/2019 • 2 minutes to read • [Edit Online](#)

A variable declared as nullable has been compared to an expression other than `Nothing` using the `IsNot` operator.

Error ID: BC32128

To correct this error

1. To compare a nullable type to an expression other than `Nothing` by using the `IsNot` operator, call the `GetType` method on the nullable type and compare the result to the expression, as shown in the following example.

```
Dim number? As Integer = 5

If number IsNot Nothing Then
    If number.GetType() IsNot Type.GetType("System.Int32") Then

        End If
    End If

Lambda expression will not be removed from this event handler

1/23/2019 • 2 minutes to read • [Edit Online](#)

Lambda expression will not be removed from this event handler. Assign the lambda expression to a variable and use the variable to add and remove the event.

When lambda expressions are used with event handlers, you may not see the behavior you expect. The compiler generates a new method for each lambda expression definition, even if they are identical. Therefore, the following code displays `False`.

```
Module Module1

    Sub Main()
        Dim fun1 As ChangeInteger = Function(p As Integer) p + 1
        Dim fun2 As ChangeInteger = Function(p As Integer) p + 1
        Console.WriteLine(fun1 = fun2)
    End Sub

    Delegate Function ChangeInteger(ByVal x As Integer) As Integer

End Module
```

When lambda expressions are used with event handlers, this may cause unexpected results. In the following example, the lambda expression added by `AddHandler` is not removed by the `RemoveHandler` statement.

```
Module Module1

    Event ProcessInteger(ByVal x As Integer)

    Sub Main()

        ' The following line adds one listener to the event.
        AddHandler ProcessInteger, Function(m As Integer) m

        ' The following statement searches the current listeners
        ' for a match to remove. However, this lambda is not the same
        ' as the previous one, so nothing is removed.
        RemoveHandler ProcessInteger, Function(m As Integer) m

    End Sub
End Module
```

By default, this message is a warning. For more information about how to hide warnings or treat warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42326

To correct this error

- To avoid the warning and remove the lambda expression, assign the lambda expression to a variable and use the variable in both the `AddHandler` and `RemoveHandler` statements, as shown in the following example.

```
Module Module1

    Event ProcessInteger(ByVal x As Integer)

    Dim PrintHandler As ProcessIntegerEventHandler

    Sub Main()

        ' Assign the lambda expression to a variable.
        PrintHandler = Function(m As Integer) m

        ' Use the variable to add the listener.
        AddHandler ProcessInteger, PrintHandler

        ' Use the variable again when you want to remove the listener.
        RemoveHandler ProcessInteger, PrintHandler

    End Sub
End Module
```

Lambda expressions are not valid in the first expression of a 'Select Case' statement

1/30/2019 • 2 minutes to read • [Edit Online](#)

You cannot use a lambda expression for the test expression in a `Select Case` statement. Lambda expression definitions return functions, and the test expression of a `Select Case` statement must be an elementary data type.

The following code causes this error:

```
' Select Case (Function(arg) arg Is Nothing)
    ' List of the cases.
' End Select
```

Error ID: BC36635

To correct this error

- Examine your code to determine whether a different conditional construction, such as an `If...Then...Else` statement, would work for you.
- You may have intended to call the function, as shown in the following code:

```
Dim num? As Integer
Select Case ((Function(arg? As Integer) arg Is Nothing)(num))
    ' List of the cases
End Select
```

Late bound resolution; runtime errors could occur

1/23/2019 • 2 minutes to read • [Edit Online](#)

An object is assigned to a variable declared to be of the [Object Data Type](#).

When you declare a variable as `Object`, the compiler must perform *late binding*, which causes extra operations at run time. It also exposes your application to potential run-time errors. For example, if you assign a [Form](#) to the `Object` variable and then try to access the [XmlDocument.NameTable](#) property, the runtime throws a [MemberAccessException](#) because the [Form](#) class does not expose a `NameTable` property.

If you declare the variable to be of a specific type, the compiler can perform *early binding* at compile time. This results in improved performance, controlled access to the members of the specific type, and better readability of your code.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42017

To correct this error

- If possible, declare the variable to be of a specific type.

See also

- [Early and Late Binding](#)
- [Object Variable Declaration](#)

Latebound overload resolution cannot be applied to '`<procedurename>`' because the accessing instance is an interface type

1/30/2019 • 2 minutes to read • [Edit Online](#)

The compiler is attempting to resolve a reference to an overloaded property or procedure, but the reference fails because an argument is of type `Object` and the referring object has the data type of an interface. The `Object` argument forces the compiler to resolve the reference as late-bound.

In these circumstances, the compiler resolves the overload through the implementing class instead of through the underlying interface. If the class renames one of the overloaded versions, the compiler does not consider that version to be an overload because its name is different. This in turn causes the compiler to ignore the renamed version when it might have been the correct choice to resolve the reference.

Error ID: BC30933

To correct this error

- Use `CType` to cast the argument from `Object` to the type specified by the signature of the overload you want to call.

Note that it does not help to cast the referring object to the underlying interface. You must cast the argument to avoid this error.

Example

The following example shows a call to an overloaded `Sub` procedure that causes this error at compile time.

```
Module m1
    Interface i1
        Sub s1(ByVal p1 As Integer)
        Sub s1(ByVal p1 As Double)
    End Interface
    Class c1
        Implements i1
        Public Overloads Sub s1(ByVal p1 As Integer) Implements i1.s1
        End Sub
        Public Overloads Sub s2(ByVal p1 As Double) Implements i1.s1
        End Sub
    End Class
    Sub Main()
        Dim refer As i1 = New c1
        Dim o1 As Object = 3.1415
        ' The following reference is INVALID and causes a compiler error.
        refer.s1(o1)
    End Sub
End Module
```

In the preceding example, if the compiler allowed the call to `s1` as written, the resolution would take place through the class `c1` instead of the interface `i1`. This would mean that the compiler would not consider `s2` because its name is different in `c1`, even though it is the correct choice as defined by `i1`.

You can correct the error by changing the call to either of the following lines of code:

```
refer.s1(CType(o1, Integer))
refer.s1(CType(o1, Double))
```

Each of the preceding lines of code explicitly casts the `Object` variable `o1` to one of the parameter types defined for the overloads.

Leading '.' or '!' can only appear inside a 'With' statement

1/30/2019 • 2 minutes to read • [Edit Online](#)

A period (.) or exclamation point (!) that is not inside a `With` block occurs without an expression on the left.

Member access (`.`) and dictionary member access (`!`) require an expression specifying the element that contains the member. This must appear immediately to the left of the accessor or as the target of a `With` block containing the member access.

Methods of 'System.Nullable(Of T)' cannot be used as operands of the 'AddressOf' operator

1/30/2019 • 2 minutes to read • [Edit Online](#)

A statement uses the `AddressOf` operator with an operand that represents a procedure of the `Nullable<T>` structure.

Error ID: BC32126

To correct this error

- Replace the procedure name in the `AddressOf` clause with an operand that is not a member of `Nullable<T>`.
- Write a class that wraps the method of `Nullable<T>` that you want to use. In the following example, the `NullableWrapper` class defines a new method named `GetValueOrDefault`. Because this new method is not a member of `Nullable<T>`, it can be applied to `nullInstance`, an instance of a nullable type, to form an argument for `AddressOf`.

```
Module Module1

    Delegate Function Deleg() As Integer

    Sub Main()
        Dim nullInstance As New Nullable(Of Integer)(1)

        Dim del As Deleg

        ' GetValueOrDefault is a method of the Nullable generic
        ' type. It cannot be used as an operand of AddressOf.
        ' del = AddressOf nullInstance.GetValueOrDefault

        ' The following line uses the GetValueOrDefault method
        ' defined in the NullableWrapper class.
        del = AddressOf (New NullableWrapper(
            Of Integer)(nullInstance)).GetValueOrDefault

        Console.WriteLine(del.Invoke())
    End Sub

    Class NullableWrapper(Of T As Structure)

Name <membername> is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

An assembly is marked as `<CLSCompliant(True)>` but exposes a member with a name that begins with an underscore (`_`).

A programming element can contain one or more underscores, but to be compliant with the [Language Independence and Language-Independent Components](#) (CLS), it must not begin with an underscore. See [Declared Element Names](#).

When you apply the [CLSCompliantAttribute](#) to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply the [CLSCompliantAttribute](#) to an element, it is considered to be noncompliant.

Error ID: BC40031

To correct this error

- If you have control over the source code, change the member name so that it does not begin with an underscore.
- If you require that the member name remain unchanged, remove the [CLSCompliantAttribute](#) from its definition or mark it as `<CLSCompliant(False)>`. You can still mark the assembly as `<CLSCompliant(True)>`.

Name '<name>' is not declared

1/30/2019 • 2 minutes to read • [Edit Online](#)

A statement refers to a programming element, but the compiler cannot find an element with that exact name.

Error ID: BC30451

To correct this error

1. Check the spelling of the name in the referring statement. Visual Basic is case-insensitive, but any other variation in the spelling is regarded as a completely different name. Note that the underscore (`_`) is part of the name and therefore part of the spelling.
2. Check that you have the member access operator (`.`) between an object and its member. For example, if you have a `TextBox` control named `TextBox1`, to access its `Text` property you should type `TextBox1.Text`. If instead you type `TextBox1Text`, you have created a different name.
3. If the spelling is correct and the syntax of any object member access is correct, verify that the element has been declared. For more information, see [Declared Elements](#).
4. If the programming element has been declared, check that it is in scope. If the referring statement is outside the region declaring the programming element, you might need to qualify the element name. For more information, see [Scope in Visual Basic](#).
5. If you are not using a fully qualified type or type and member name (for example, your code refers to a property as `MethodInfo.Name` instead of `System.Reflection.MethodInfo.Name`), add an [Imports statement](#).
6. If you are attempting to compile an SDK-style project (a project with a \*.vbproj file that begins with the line `<Project Sdk="Microsoft.NET.Sdk">`), and the error message refers to a type or member in the `Microsoft.VisualBasic.dll` assembly, configure your application to compile with a reference to the Visual Basic Runtime Library. By default, a subset of the library is embedded in your assembly in an SDK-style project.

For example, the following example fails to compile because the `Microsoft.VisualBasic.CompilerServices.Conversions.ToInt32` method cannot be found. It is not embedded in the subset of the Visual Basic Runtime included with your application.

```
Imports Microsoft.VisualBasic.CompilerServices

Public Module Example
    Sub Main(args As String())
        Dim originalValue = args(0)
        Dim t = GetType(Int32)
        Dim i = Conversions.ChangeType(originalValue, t)
        Console.WriteLine($"'{originalValue}' --> {i}")
    End Sub
End Module
```

To address this error, add the `<VBRuntime>Default</VBRuntime>` element to the projects `<PropertyGroup>` section, as the following Visual Basic project file shows.

```
<Project Sdk="Microsoft.NET.Sdk">
  <ItemGroup>
    <Reference Include="Microsoft.VisualBasic" />

  <PropertyGroup>
    <VBRuntime>Default</VBRuntime>

Namespace or type specified in the Imports '`<qualifiedelementname>`' doesn't contain any public member or cannot be found

3/5/2019 • 2 minutes to read • [Edit Online](#)

Namespace or type specified in the Imports '`<qualifiedelementname>`' doesn't contain any public member or cannot be found. Make sure the namespace or the type is defined and contains at least one public member. Make sure the alias name doesn't contain other aliases.

An `Imports` statement specifies a containing element that either cannot be found or does not define any `Public` members.

A *containing element* can be a namespace, class, structure, module, interface, or enumeration. The containing element contains members, such as variables, procedures, or other containing elements.

The purpose of importing is to allow your code to access namespace or type members without having to qualify them. Your project might also need to add a reference to the namespace or type. For more information, see "Importing Containing Elements" in [References to Declared Elements](#).

If the compiler cannot find the specified containing element, then it cannot resolve references that use it. If it finds the element but the element does not expose any `Public` members, then no reference can be successful. In either case it is meaningless to import the element.

Keep in mind that if you import a containing element and assign an import alias to it, then you cannot use that import alias to import another element. The following code generates a compiler error.

```
Imports winfrm = System.Windows.Forms  
' The following statement is INVALID because it reuses an import alias.  
Imports behave = winfrm.Design.Behavior'
```

Error ID: BC40056

To correct this error

1. Verify that the containing element is accessible from your project.
2. Verify that the specification of the containing element does not include any import alias from another import.
3. Verify that the containing element exposes at least one `Public` member.

Namespace or type specified in the project-level Imports '<qualifiedelementname>' doesn't contain any public member or cannot be found

1/30/2019 • 2 minutes to read • [Edit Online](#)

Namespace or type specified in the project-level Imports '<qualifiedelementname>' doesn't contain any public member or cannot be found. Make sure the namespace or the type is defined and contains at least one public member. Make sure the alias name doesn't contain other aliases.

An import property of a project specifies a containing element that either cannot be found or does not define any `Public` members.

A *containing element* can be a namespace, class, structure, module, interface, or enumeration. The containing element contains members, such as variables, procedures, or other containing elements.

The purpose of importing is to allow your code to access namespace or type members without having to qualify them. Your project might also need to add a reference to the namespace or type. For more information, see "Importing Containing Elements" in [References to Declared Elements](#).

If the compiler cannot find the specified containing element, then it cannot resolve references that use it. If it finds the element but the element does not expose any `Public` members, then no reference can be successful. In either case it is meaningless to import the element.

You use the **Project Designer** to specify elements to import. Use the **Imported namespaces** section of the **References** page. You can get to the **Project Designer** by double-clicking the **My Project** icon in **Solution Explorer**.

Error ID: BC40057

To correct this error

1. Open the **Project Designer** and switch to the **Reference** page.
2. In the **Imported namespaces** section, verify that the containing element is accessible from your project.
3. Verify that the containing element exposes at least one `Public` member.

Nested function does not have a signature that is compatible with delegate '<delegatename>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A lambda expression has been assigned to a delegate that has an incompatible signature. For example, in the following code, delegate `Del` has two integer parameters.

```
Delegate Function Del(ByVal p As Integer, ByVal q As Integer) As Integer
```

The error is raised if a lambda expression with one argument is declared as type `Del`:

```
' Neither of these is valid.  
' Dim lambda1 As Del = Function(n As Integer) n + 1  
' Dim lambda2 As Del = Function(n) n + 1
```

Error ID: BC36532

To correct this error

- Adjust either the delegate definition or the assigned lambda expression so that the signatures are compatible.

No accessible 'Main' method with an appropriate signature was found in '<name>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

Command-line applications must have a `Sub Main` defined. `Main` must be declared as `Public Shared` if it is defined in a class, or as `Public` if defined in a module.

Error ID: BC30737

To correct this error

- Define a `Public Sub Main` procedure for your project. Declare it as `Shared` if and only if you define it inside a class.

Non-CLS-compliant <membername> is not allowed in a CLS-compliant interface

1/30/2019 • 2 minutes to read • [Edit Online](#)

A property, procedure, or event in an interface is marked as `<CLSCompliant(True)>` when the interface itself is marked as `<CLSCompliant(False)>` or is not marked.

For an interface to be compliant with the [Language Independence and Language-Independent Components \(CLS\)](#), all its members must be compliant.

When you apply the [CLSCompliantAttribute](#) to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply the [CLSCompliantAttribute](#) to an element, it is considered to be noncompliant.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40033

To correct this error

- If you require CLS compliance and have control over the interface source code, mark the interface as `<CLSCompliant(True)>` if all its members are compliant.
- If you require CLS compliance and do not have control over the interface source code, or if it does not qualify to be compliant, define this member within a different interface.
- If you require that this member remain within its current interface, remove the [CLSCompliantAttribute](#) from its definition or mark it as `<CLSCompliant(False)>`.

Nullable type inference is not supported in this context

Value types and structures can be declared nullable.

```
Dim a? As Integer

Number of indices exceeds the number of dimensions of the indexed array

1/23/2019 • 2 minutes to read • [Edit Online](#)

The number of indices used to access an array element must be exactly the same as the rank of the array, that is, the number of dimensions declared for it.

Error ID: BC30106

To correct this error

- Remove subscripts from the array reference until the total number of subscripts equals the rank of the array.

For example:

```
Dim gameBoard(3, 3) As String

' Incorrect code. The array has two dimensions.
gameBoard(1, 1, 1) = "X"
gameBoard(2, 1, 1) = "O"

' Correct code.
gameBoard(0, 0) = "X"
gameBoard(1, 0) = "O"

Object or class does not support the set of events

1/23/2019 • 2 minutes to read • [Edit Online](#)

You tried to use a `WithEvents` variable with a component that cannot work as an event source for the specified set of events. For example, you wanted to sink the events of an object, then create another object that `Implements` the first object. Although you might think you could sink the events from the implemented object, this is not always the case. `Implements` only implements an interface for methods and properties. `WithEvents` is not supported for private `UserControls`, because the type info needed to raise the `ObjectEvent` is not available at run time.

To correct this error

1. You cannot sink events for a component that does not source events.

Object required (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

References to properties and methods often require an explicit object qualifier. This is such a case.

To correct this error

1. Check that references to an object property or method have valid object qualifier. Specify an object qualifier if you didn't provide one.
2. Check the spelling of the object qualifier and make sure the object is visible in the part of the program in which you are referencing it.
3. If a path is supplied to a host application's **File Open** command, check that the arguments in it are correct.
4. Check the object's documentation and make sure the action is valid.

Object variable or With block variable not set

1/23/2019 • 2 minutes to read • [Edit Online](#)

An invalid object variable is being referenced. This error can occur for several reasons:

- A variable was declared without specifying a type. If a variable is declared without specifying a type, it defaults to type `Object`.

For example, a variable declared with `Dim x` would be of type `Object`; a variable declared with `Dim x As String` would be of type `String`.

TIP

The `Option Strict` statement disallows implicit typing that results in an `Object` type. If you omit the type, a compile-time error will occur. See [Option Strict Statement](#).

- You are attempting to reference an object that has been set to `Nothing`.

- You are attempting to access an element of an array variable that wasn't properly declared.

For example, an array declared as `products() As String` will trigger the error if you try to reference an element of the array `products(3) = "Widget"`. The array has no elements and is treated as an object.

- You are attempting to access code within a `With...End With` block before the block has been initialized. A `With...End With` block must be initialized by executing the `With` statement entry point.

NOTE

In earlier versions of Visual Basic or VBA this error was also triggered by assigning a value to a variable without using the `Set` keyword (`x = "name"` instead of `Set x = "name"`). The `Set` keyword is no longer valid in Visual Basic .Net.

To correct this error

1. Set `Option Strict` to `On` by adding the following code to the beginning of the file:

```
Option Strict On
```

When you run the project, a compiler error will appear in the \*\*Error List\*\* for any variable that was specified without a type.

2. If you don't want to enable `Option Strict`, search your code for any variables that were specified without a type (`Dim x` instead of `Dim x As String`) and add the intended type to the declaration.
3. Make sure you aren't referring to an object variable that has been set to `Nothing`. Search your code for the keyword `Nothing`, and revise your code so that the object isn't set to `Nothing` until after you have referenced it.
4. Make sure that any array variables are dimensioned before you access them. You can either assign a

dimension when you first create the array (`Dim x(5) As String`) instead of (`Dim x() As String`), or use the `ReDim` keyword to set the dimensions of the array before you first access it.

5. Make sure your `With` block is initialized by executing the `With` statement entry point.

Ordinal is not valid

1/23/2019 • 2 minutes to read • [Edit Online](#)

Your call to a dynamic-link library (DLL) indicated to use a number instead of a procedure name, using the `#num` syntax. This error has the following possible causes:

- An attempt to convert the `#num` expression to an ordinal failed.
- The `#num` specified does not specify any function in the DLL.
- A type library has an invalid declaration resulting in internal use of an invalid ordinal number.

To correct this error

1. Make sure the expression represents a valid number, or call the procedure by name.
2. Make sure `#num` identifies a valid function in the DLL.
3. Isolate the procedure call causing the problem by commenting out the code. Write a `Declare` statement for the procedure, and report the problem to the type library vendor.

Out of stack space (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The stack is a working area of memory that grows and shrinks dynamically with the demands of your executing program. Its limits have been exceeded.

To correct this error

1. Check that procedures are not nested too deeply.
2. Make sure recursive procedures terminate properly.
3. If local variables require more local variable space than is available, try declaring some variables at the module level. You can also declare all variables in the procedure static by preceding the `Property`, `Sub`, or `Function` keyword with `Static`. Or you can use the `Static` statement to declare individual static variables within procedures.
4. Redefine some of your fixed-length strings as variable-length strings, as fixed-length strings use more stack space than variable-length strings. You can also define the string at module level where it requires no stack space.
5. Check the number of nested `DoEvents` function calls, by using the `Calls` dialog box to view which procedures are active on the stack.
6. Make sure you did not cause an "event cascade" by triggering an event that calls an event procedure already on the stack. An event cascade is similar to an unterminated recursive procedure call, but it is less obvious, since the call is made by Visual Basic rather than an explicit call in the code. Use the `Calls` dialog box to view which procedures are active on the stack.

Path/File access error

1/23/2019 • 2 minutes to read • [Edit Online](#)

During a file-access or disk-access operation, the operating system could not make a connection between the path and the file name.

To correct this error

1. Make sure the file specification is correctly formatted. A file name can contain a fully qualified (absolute) or relative path. A fully qualified path starts with the drive name (if the path is on another drive) and lists the explicit path from the root to the file. Any path that is not fully qualified is relative to the current drive and directory.
2. Make sure that you did not attempt to save a file that would replace an existing read-only file. If this is the case, change the read-only attribute of the target file, or save the file with a different file name.
3. Make sure you did not attempt to open a read-only file in sequential `Output` or `Append` mode. If this is the case, open the file in `Input` mode or change the read-only attribute of the file.

Property '<propertyname>' doesn't return a value on all code paths

1/30/2019 • 2 minutes to read • [Edit Online](#)

Property '<propertyname>' doesn't return a value on all code paths. A null reference exception could occur at run time when the result is used.

A property `Get` procedure has at least one possible path through its code that does not return a value.

You can return a value from a property `Get` procedure in any of the following ways:

- Assign the value to the property name and then perform an `Exit Property` statement.
- Assign the value to the property name and then perform the `End Get` statement.
- Include the value in a [Return Statement](#).

If control passes to `Exit Property` or `End Get` and you have not assigned any value to the property name, the `Get` procedure returns the default value of the property's data type. For more information, see "Behavior" in [Function Statement](#).

By default, this message is a warning. For more information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42107

To correct this error

- Check your control flow logic and make sure you assign a value before every statement that causes a return.

It is easier to guarantee that every return from the procedure returns a value if you always use the `Return` statement. If you do this, the last statement before `End Get` should be a `Return` statement.

Reference required to assembly '<assemblyidentity>' containing type '<typename>', but a suitable reference could not be found due to ambiguity between projects '<projectname1>' and '<projectname2>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

An expression uses a type, such as a class, structure, interface, enumeration, or delegate, that is defined outside your project. However, you have project references to more than one assembly defining that type.

The cited projects produce assemblies with the same name. Therefore, the compiler cannot determine which assembly to use for the type you are accessing.

To access a type defined in another assembly, the Visual Basic compiler must have a reference to that assembly. This must be a single, unambiguous reference that does not cause circular references among projects.

Error ID: BC30969

To correct this error

1. Determine which project produces the best assembly for your project to reference. For this decision, you might use criteria such as ease of file access and frequency of updates.
2. In your project properties, add a reference to the file that contains the assembly that defines the type you are using.

Return type of function '<procedurename>' is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

A `Function` procedure is marked as `<CLSCompliant(True)>` but returns a type that is marked as `<CLSCompliant(False)>`, is not marked, or does not qualify because it is a noncompliant type.

For a procedure to be compliant with the [Language Independence and Language-Independent Components \(CLS\)](#), it must use only CLS-compliant types. This applies to the types of the parameters, the return type, and the types of all its local variables.

The following Visual Basic data types are not CLS-compliant:

- [SByte Data Type](#)
- [UInteger Data Type](#)
- [ULong Data Type](#)
- [UShort Data Type](#)

When you apply the [CLSCompliantAttribute](#) to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply the [CLSCompliantAttribute](#) to an element, it is considered to be noncompliant.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40027

To correct this error

- If the `Function` procedure must return this particular type, remove the [CLSCompliantAttribute](#). The procedure cannot be CLS-compliant.
- If the `Function` procedure must be CLS-compliant, change the return type to the closest CLS-compliant type. For example, in place of `UInteger` you might be able to use `Integer` if you do not need the value range above 2,147,483,647. If you do need the extended range, you can replace `UInteger` with `Long`.
- If you are interfacing with Automation or COM objects, keep in mind that some types have different data widths than in the .NET Framework. For example, `int` is often 16 bits in other environments. If you are returning a 16-bit integer to such a component, declare it as `Short` instead of `Integer` in your managed Visual Basic code.

Error ID: BC31102

To correct this error

- If you have control of the source code defining the property, consider declaring the `Set` procedure with the same access level as the property itself.
- If you do not have control of the source code defining the property, or you must restrict the `Set` procedure access level more than the property itself, try to move the statement that sets the property value to a region of code that has better access to the property.

Structure '<structurename>' must contain at least one instance member variable or at least one instance event declaration not marked 'Custom'

1/30/2019 • 2 minutes to read • [Edit Online](#)

A structure definition does not include any nonshared variables or nonshared noncustom events.

Every structure must have either a variable or an event that applies to each specific instance (nonshared) instead of to all instances collectively ([Shared](#)). Nonshared constants, properties, and procedures do not satisfy this requirement. In addition, if there are no nonshared variables and only one nonshared event, that event cannot be a [Custom](#) event.

Error ID: BC30941

To correct this error

Sub or Function not defined (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

A `Sub` or `Function` must be defined in order to be called. Possible causes of this error include:

- Misspelling the procedure name.
- Trying to call a procedure from another project without explicitly adding a reference to that project in the **References** dialog box.
- Specifying a procedure that is not visible to the calling procedure.
- Declaring a Windows dynamic-link library (DLL) routine or Macintosh code-resource routine that is not in the specified library or code resource.

To correct this error

1. Make sure that the procedure name is spelled correctly.
2. Find the name of the project containing the procedure you want to call in the **References** dialog box. If it does not appear, click the **Browse** button to search for it. Select the check box to the left of the project name, and then click **OK**.
3. Check the name of the routine.

The type for variable '<variablename>' will not be inferred because it is bound to a field in an enclosing scope

1/30/2019 • 2 minutes to read • [Edit Online](#)

The type for variable '<variablename>' will not be inferred because it is bound to a field in an enclosing scope. Either change the name of '<variablename>', or use the fully qualified name (for example, 'Me.variablename' or 'MyBase.variablename').

A loop control variable in your code has the same name as a field of the class or other enclosing scope. Because the control variable is used without an `As` clause, it is bound to the field in the enclosing scope, and the compiler does not create a new variable for it or infer its type.

In the following example, `Index`, the control variable in the `For` statement, is bound to the `Index` field in the `Customer` class. The compiler does not create a new variable for the control variable `Index` or infer its type.

```
Class Customer

    ' The class has a field named Index.
    Private Index As Integer

    Sub Main()

        ' The following line will raise this warning.
        For Index = 1 To 10
            ' ...
        Next

    End Sub
End Class
```

By default, this message is a warning. For information about how to hide warnings or how to treat warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42110

To address this warning

- Make the loop control variable local by changing its name to an identifier that is not also the name of a field of the class.

```
For I = 1 To 10
```

- Clarify that the loop control variable binds to the class field by prefixing `Me.` to the variable name.

```
For Me.Index = 1 To 10
```

- Instead of relying on local type inference, use an `As` clause to specify a type for the loop control variable.

```
For Index As Integer = 1 To 10
```

Example

The following code shows the earlier example with the first correction in place.

```
Class Customer

    ' The class has a field named Index.
    Private Index As Integer

    Sub Main()

        For I = 1 To 10
            ' ...
        Next

    End Sub
End Class
```

This array is fixed or temporarily locked (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

This error has the following possible causes:

- Using `ReDim` to change the number of elements of a fixed-size array.
- Redimensioning a module-level dynamic array, in which one element has been passed as an argument to a procedure. If an element is passed, the array is locked to prevent deallocating memory for the reference parameter within the procedure.
- Attempting to assign a value to a `Variant` variable containing an array, but the `Variant` is currently locked.

To correct this error

1. Make the original array dynamic rather than fixed by declaring it with `ReDim` (if the array is declared within a procedure), or by declaring it without specifying the number of elements (if the array is declared at the module level).
2. Determine whether you really need to pass the element, since it is visible within all procedures in the module.
3. Determine what is locking the `Variant` and remedy it.

Type <typename> is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

A variable, property, or function return is declared with a data type that is not CLS-compliant.

For an application to be compliant with the [Language Independence and Language-Independent Components \(CLS\)](#), it must use only CLS-compliant types.

The following Visual Basic data types are not CLS-compliant:

- [SByte Data Type](#)
- [UInteger Data Type](#)
- [ULong Data Type](#)
- [UShort Data Type](#)

Error ID: BC40041

To correct this error

- If your application needs to be CLS-compliant, change the data type of this element to the closest CLS-compliant type. For example, in place of `UInteger` you might be able to use `Integer` if you do not need the value range above 2,147,483,647. If you do need the extended range, you can replace `UInteger` with `Long`.
- If your application does not need to be CLS-compliant, you do not need to change anything. You should be aware of its noncompliance, however.

Type '<typename>' is not defined

1/30/2019 • 2 minutes to read • [Edit Online](#)

The statement has made reference to a type that has not been defined. You can define a type in a declaration statement such as `Enum`, `Structure`, `Class`, or `Interface`.

Error ID: BC30002

To correct this error

- Ensure that the type definition and its reference both use the same spelling.
- Ensure that the type definition is accessible to the reference. For example, if the type is in another module and has been declared `Private`, move the type definition to the referencing module or declare it `Public`.
- Ensure that the namespace of the type is not redefined within your project. If it is, use the `Global` keyword to fully qualify the type name. For example, if a project defines a namespace named `System`, the `System.Object` type cannot be accessed unless it is fully qualified with the `Global` keyword:
`Global.System.Object`.
- If the type is defined, but the object library or type library in which it is defined is not registered in Visual Basic, click **Add Reference** on the **Project** menu, and then select the appropriate object library or type library.
- Ensure that the type is in an assembly that is part of the targeted .NET Framework profile. For more information, see [Troubleshooting .NET Framework Targeting Errors](#).

Type arguments could not be inferred from the delegate

1/23/2019 • 2 minutes to read • [Edit Online](#)

An assignment statement uses `AddressOf` to assign the address of a generic procedure to a delegate, but it does not supply any type arguments to the generic procedure.

Normally, when you invoke a generic type, you supply a type argument for each type parameter that the generic type defines. If you do not supply any type arguments, the compiler attempts to infer the types to be passed to the type parameters. If the context does not provide enough information for the compiler to infer the types, an error is generated.

Error ID: BC36564

To correct this error

- Specify the type arguments for the generic procedure in the `AddressOf` expression.

Type of '<variablename>' cannot be inferred because the loop bounds and the step variable do not widen to the same type

3/5/2019 • 2 minutes to read • [Edit Online](#)

You have written a `For...Next` loop in which the compiler cannot infer a data type for the loop control variable because the following conditions are true:

- The data type of the loop control variable is not specified with an `As` clause.
- The loop bounds and step variable contain at least two data types.
- No standard conversions exist between the data types.

Therefore, the compiler cannot infer the data type of a loop's control variable.

In the following example, the step variable is a character and the loop bounds are both integers. Because there is no standard conversion between characters and integers, this error is reported.

```
Dim stepVar = "1"c
Dim m = 0
Dim n = 20

' Not valid.
' For i = 1 To 10 Step stepVar
    ' Loop processing
' Next
```

Error ID: BC30982

To correct this error

- Change the types of the loop bounds and step variable as necessary so that at least one of them is a type that the others widen to. In the preceding example, change the type of `stepVar` to `Integer`.

```
Dim stepVar = 1
```

—or—

```
Dim stepVar As Integer = 1
```

- Use explicit conversion functions to convert the loop bounds and step variable to the appropriate types. In the preceding example, apply the `Val` function to `stepVar`.

```
For i = 1 To 10 Step Val(stepVar)
    ' Loop processing
Next
```

Type of member '<membername>' is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

The data type specified for this member is not part of the [Language Independence and Language-Independent Components](#) (CLS). This is not an error within your component, because the .NET Framework and Visual Basic support this data type. However, another component written in strictly CLS-compliant code might not support this data type. Such a component might not be able to interact successfully with your component.

The following Visual Basic data types are not CLS-compliant:

- [SByte Data Type](#)
- [UInteger Data Type](#)
- [ULong Data Type](#)
- [UShort Data Type](#)

By default, this message is a warning. For more information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40025

To correct this error

- If your component interfaces only with other .NET Framework components, or does not interface with any other components, you do not need to change anything.
- If you are interfacing with a component not written for the .NET Framework, you might be able to determine, either through reflection or from documentation, whether it supports this data type. If it does, you do not need to change anything.
- If you are interfacing with a component that does not support this data type, you must replace it with the closest CLS-compliant type. For example, in place of `UInteger` you might be able to use `Integer` if you do not need the value range above 2,147,483,647. If you do need the extended range, you can replace `UInteger` with `Long`.
- If you are interfacing with Automation or COM objects, keep in mind that some types have different data widths than in the .NET Framework. For example, `uint` is often 16 bits in other environments. If you are passing a 16-bit argument to such a component, declare it as `ushort` instead of `UInteger` in your managed Visual Basic code.

Type of optional value for optional parameter <parametername> is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

A procedure is marked as `<CLSCompliant(True)>` but declares an [Optional](#) parameter with default value of a noncompliant type.

For a procedure to be compliant with the [Language Independence and Language-Independent Components \(CLS\)](#), it must use only CLS-compliant types. This applies to the types of the parameters, the return type, and the types of all its local variables. It also applies to the default values of optional parameters.

The following Visual Basic data types are not CLS-compliant:

- [SByte Data Type](#)
- [UInteger Data Type](#)
- [ULong Data Type](#)
- [UShort Data Type](#)

When you apply the [CLSCompliantAttribute](#) attribute to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply [CLSCompliantAttribute](#) to an element, it is considered to be noncompliant.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40042

To correct this error

- If the optional parameter must have a default value of this particular type, remove [CLSCompliantAttribute](#). The procedure cannot be CLS-compliant.
- If the procedure must be CLS-compliant, change the type of this default value to the closest CLS-compliant type. For example, in place of `UInteger` you might be able to use `Integer` if you do not need the value range above 2,147,483,647. If you do need the extended range, you can replace `UInteger` with `Long`.
- If you are interfacing with Automation or COM objects, keep in mind that some types have different data widths than in the .NET Framework. For example, `int` is often 16 bits in other environments. If you are accepting a 16-bit integer from such a component, declare it as `short` instead of `Integer` in your managed Visual Basic code.

Type of parameter '<parametername>' is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

A procedure is marked as `<CLSCompliant(True)>` but declares a parameter with a type that is marked as `<CLSCompliant(False)>`, is not marked, or does not qualify because it is a noncompliant type.

For a procedure to be compliant with the [Language Independence and Language-Independent Components \(CLS\)](#), it must use only CLS-compliant types. This applies to the types of the parameters, the return type, and the types of all its local variables.

The following Visual Basic data types are not CLS-compliant:

When you apply the [CLSCompliantAttribute](#) to a programming element, you set the attribute's `isCompliant` parameter to either `True` or `False` to indicate compliance or noncompliance. There is no default for this parameter, and you must supply a value.

If you do not apply the [CLSCompliantAttribute](#) to an element, it is considered to be noncompliant.

By default, this message is a warning. For information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40028

To correct this error

- If the procedure must take a parameter of this particular type, remove the [CLSCompliantAttribute](#). The procedure cannot be CLS-compliant.
- If the procedure must be CLS-compliant, change the type of this parameter to the closest CLS-compliant type. For example, in place of `UInteger` you might be able to use `Integer` if you do not need the value range above 2,147,483,647. Type parameters cannot be used as qualifiers

1/23/2019 • 2 minutes to read • [Edit Online](#)

A programming element is qualified with a qualification string that includes a type parameter.

A type parameter represents a requirement for a type that is to be supplied when the generic type is constructed. It does not represent a specific defined type. A qualification string must include only elements that are defined at compile time.

The following statements can generate this error.

```
Public Function checkText(Of c As System.Windows.Forms.Control)()  
    ByVal badText As String) As Boolean  
  
    Dim saveText As c.Text  
    ' Insert code to look for badText within saveText.  
End Function
```

Error ID: BC32098

To correct this error

1. Remove the type parameter from the qualification string, or replace it with a defined type.
2. If you need to use a constructed type to locate the programming element being qualified, you must use additional program logic.

2. Delete the COM reference that is generating the error from your project.
3. Open the [Developer Command Prompt for Visual Studio](#).

In Windows 10, enter **Developer command prompt** into the search box on the task bar. Then, select **Developer Command Prompt for VS 2017** from the results list.

4. Change the directory to the directory where you want to place your assembly wrapper.
5. Enter the following command:

```
tlbimp <path to COM reference file> /out:<output assembly name> /keyfile:<path to .snk file>
```

An example of the actual command you might enter is:

```
tlbimp c:\windows\system32\msi.dll /out:Interop.WindowsInstaller.dll /keyfile:"c:\documents and settings\mykey.snk"
```

TIP

Use double quotation marks if a path or file contains spaces.

6. In Visual Studio, add a .NET Assembly reference to the file you just created.

Unable to write to output file '<filename>': <error>

1/30/2019 • 2 minutes to read • [Edit Online](#)

There was a problem creating the file.

An output file cannot be opened for writing. The file (or the folder containing the file) may be opened for exclusive use by another process, or it may have its read-only attribute set.

Common situations where a file is opened exclusively are:

- The application is already running and using its files. To solve this problem, make sure that the application is not running.
- Another application has opened the file. To solve this problem, make sure that no other application is accessing the files. It is not always obvious which application is accessing your files; in that case, restarting the computer might be the easiest way to terminate the application.

If even one of the project output files is marked as read-only, this exception will be thrown.

Error ID: BC31019

To correct this error

1. Compile the program again to see if the error recurs.
2. If the error continues, save your work and restart Visual Studio.
3. If the error continues, restart the computer.
4. If the error recurs, reinstall Visual Basic.
5. If the error persists after reinstallation, notify Microsoft Product Support Services.

To check file attributes in File Explorer

1. Open the folder you are interested in.
2. Click the **Views** icon and choose **Details**.
3. Right-click the column header, and choose **Attributes** from the drop-down list.

To change the attributes of a file or folder

1. In **File Explorer**, right-click the file or folder and choose **Properties**.
2. In the **Attributes** section of the **General** tab, clear the **Read-only** box.
3. Press **OK**.

Underlying type <typename> of Enum is not CLS-compliant

1/30/2019 • 2 minutes to read • [Edit Online](#)

The data type specified for this enumeration is not part of the [Language Independence and Language-Independent Components](#) (CLS). This is not an error within your component, because the .NET Framework and Visual Basic support this data type. However, another component written in strictly CLS-compliant code might not support this data type. Such a component might not be able to interact successfully with your component.

The following Visual Basic data types are not CLS-compliant:

- [SByte Data Type](#)
- [UInteger Data Type](#)
- [ULong Data Type](#)
- [UShort Data Type](#)

By default, this message is a warning. For more information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC40032

To correct this error

- If your component interfaces only with other .NET Framework components, or does not interface with any other components, you do not need to change anything.
- If you are interfacing with a component not written for the .NET Framework, you might be able to determine, either through reflection or from documentation, whether it supports this data type. If it does, you do not need to change anything.
- If you are interfacing with a component that does not support this data type, you must replace it with the closest CLS-compliant type. For example, in place of `UInteger` you might be able to use `Integer` if you do not need the value range above 2,147,483,647. If you do need the extended range, you can replace `UInteger` with `Long`.
- If you are interfacing with Automation or COM objects, keep in mind that some types have different data widths than in the .NET Framework. For example, `uint` is often 16 bits in other environments. If you are passing a 16-bit argument to such a component, declare it as `ushort` instead of `UInteger` in your managed Visual Basic code.

Using the iteration variable in a lambda expression may have unexpected results

1/23/2019 • 2 minutes to read • [Edit Online](#)

Using the iteration variable in a lambda expression may have unexpected results. Instead, create a local variable within the loop and assign it the value of the iteration variable.

This warning appears when you use a loop iteration variable in a lambda expression that is declared inside the loop. For example, the following example causes the warning to appear.

```
For i As Integer = 1 To 10
    ' The warning is given for the use of i.
    Dim exampleFunc As Func(Of Integer) = Function() i
Next
```

The following example shows the unexpected results that might occur.

```
Module Module1
    Sub Main()
        Dim array1 As Func(Of Integer)() = New Func(Of Integer)(4) {}

        For i As Integer = 0 To 4
            array1(i) = Function() i
        Next

        For Each funcElement In array1
            System.Console.WriteLine(funcElement())
        Next

    End Sub
End Module
```

The `For` loop creates an array of lambda expressions, each of which returns the value of the loop iteration variable `i`. When the lambda expressions are evaluated in the `For Each` loop, you might expect to see 0, 1, 2, 3, and 4 displayed, the successive values of `i` in the `For` loop. Instead, you see the final value of `i` displayed five times:

5
5
5
5
5

By default, this message is a warning. For more information about hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42324

To correct this error

- Assign the value of the iteration variable to a local variable, and use the local variable in the lambda expression.

```
Module Module1
Sub Main()
    Dim array1 As Func(Of Integer)() = New Func(Of Integer)(4) {}

    For i As Integer = 0 To 4
        Dim j = i
        array1(i) = Function() j
    Next

    For Each funcElement In array1
        System.Console.WriteLine(funcElement())
    Next

End Sub
End Module
```

Value of type '<typename1>' cannot be converted to '<typename2>'

1/30/2019 • 2 minutes to read • [Edit Online](#)

Value of type '<typename1>' cannot be converted to '<typename2>'. Type mismatch could be due to the mixing of a file reference with a project reference to assembly '<assemblyname>'. Try replacing the file reference to '<filepath>' in project '<projectname1>' with a project reference to '<projectname2>'.

In a situation where a project makes both a project reference and a file reference, the compiler cannot guarantee that one type can be converted to another.

The following pseudo-code illustrates a situation that can generate this error.

```
' ===== Visual Basic project P1 =====

' P1 makes a PROJECT REFERENCE to project P2

' and a FILE REFERENCE to project P3.

Public commonObject As P3.commonClass

commonObject = P2.getCommonClass()

' ===== Visual Basic project P2 =====

' P2 makes a PROJECT REFERENCE to project P3

Public Function getCommonClass() As P3.commonClass

Return New P3.commonClass

End Function

' ===== Visual Basic project P3 =====

Public Class commonClass

End Class
```

Project `P1` makes an indirect project reference through project `P2` to project `P3`, and also a direct file reference to `P3`. The declaration of `commonObject` uses the file reference to `P3`, while the call to `P2.getCommonClass` uses the project reference to `P3`.

The problem in this situation is that the file reference specifies a file path and name for the output file of `P3` (typically `p3.dll`), while the project references identify the source project (`P3`) by project name. Because of this, the compiler cannot guarantee that the type `P3.commonClass` comes from the same source code through the two different references.

This situation typically occurs when project references and file references are mixed. In the preceding illustration, the problem would not occur if `P1` made a direct project reference to `P3` instead of a file reference.

Error ID: BC30955

To correct this error

- Change the file reference to a project reference.

Value of type '<typename1>' cannot be converted to '<typename2>' (Multiple file references)

1/30/2019 • 2 minutes to read • [Edit Online](#)

Value of type '<typename1>' cannot be converted to '<typename2>'. Type mismatch could be due to mixing a file reference to '<filepath1>' in project '<projectname1>' with a file reference to '<filepath2>' in project '<projectname2>'. If both assemblies are identical, try replacing these references so both references are from the same location.

In a situation where a project makes more than one file reference to an assembly, the compiler cannot guarantee that one type can be converted to another.

Each file reference specifies a file path and name for the output file of a project (typically a DLL file). The compiler cannot guarantee that the output files come from the same source, or that they represent the same version of the same assembly. Therefore, it cannot guarantee that the types in the different references are the same type, or even that one can be converted to the other.

You can use a single file reference if you know that the referenced assemblies have the same assembly identity. The *assembly identity* includes the assembly's name, version, public key if any, and culture. This information uniquely identifies the assembly.

Error ID: BC30961

To correct this error

- If the referenced assemblies have the same assembly identity, then remove or replace one of the file references so that there is only a single file reference.
- If the referenced assemblies do not have the same assembly identity, then change your code so that it does not attempt to convert a type in one to a type in the other.

Value of type 'type1' cannot be converted to 'type2'

1/30/2019 • 2 minutes to read • [Edit Online](#)

Value of type 'type1' cannot be converted to 'type2'. You can use the 'Value' property to get the string value of the first element of '<parentElement>'.

An attempt has been made to implicitly cast an XML literal to a specific type. The XML literal cannot be implicitly cast to the specified type.

Error ID: BC31194

Variable '<variablename>' hides a variable in an enclosing block

1/30/2019 • 2 minutes to read • [Edit Online](#)

A variable enclosed in a block has the same name as another local variable.

Error ID: BC30616

To correct this error

- Rename the variable in the enclosed block so that it is not the same as any other local variables. For example:

```
Dim a, b, x As Integer
If a = b Then
    Dim y As Integer = 20 ' Uniquely named block variable.
End If
```

- A common cause for this error is the use of `Catch e As Exception` inside an event handler. If this is the case, name the `Catch` block variable `ex` rather than `e`.
- Another common source of this error is an attempt to access a local variable declared within a `Try` block in a separate `Catch` block. To correct this, declare the variable outside the `Try...Catch...Finally` structure.

Variable '<variablename>' is used before it has been assigned a value

1/30/2019 • 2 minutes to read • [Edit Online](#)

Variable '<variablename>' is used before it has been assigned a value. A null reference exception could result at run time.

An application has at least one possible path through its code that reads a variable before any value is assigned to it.

If a variable has never been assigned a value, it holds the default value for its data type. For a reference data type, that default value is [Nothing](#). Reading a reference variable that has a value of [Nothing](#) can cause a [NullReferenceException](#) in some circumstances.

By default, this message is a warning. For more information on hiding warnings or treating warnings as errors, see [Configuring Warnings in Visual Basic](#).

Error ID: BC42104

To correct this error

- Check your control flow logic and make sure the variable has a valid value before control passes to any statement that reads it.

Building from the Command Line (Visual Basic)

2/5/2019 • 2 minutes to read • [Edit Online](#)

A Visual Basic project is made up of one or more separate source files. During the process known as compilation, these files are brought together into one package—a single executable file that can be run as an application.

Visual Basic provides a command-line compiler as an alternative to compiling programs from within the Visual Studio integrated development environment (IDE). The command-line compiler is designed for situations in which you do not require the full set of features in the IDE—for example, when you are using or writing for computers with limited system memory or storage space.

To compile source files from within the Visual Studio IDE, choose the **Build** command from the **Build** menu.

TIP

When you build project files by using the Visual Studio IDE, you can display information about the associated **vbc** command and its switches in the output window. To display this information, open the [Options Dialog Box, Projects and Solutions, Build and Run](#), and then set the **MSBuild project build output verbosity** to **Normal** or a higher level of verbosity. How to: Invoke the Command-Line Compiler (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

You can invoke the command-line compiler by typing the name of its executable file into the command line, also known as the MS-DOS prompt. If you compile from the default Windows Command Prompt, you must type the fully qualified path to the executable file. To override this default behavior, you can either use the Developer Command Prompt for Visual Studio, or modify the PATH environment variable. Both allow you to compile from any directory by simply typing the compiler name.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To invoke the compiler using the Developer Command Prompt for Visual Studio

1. Open the Visual Studio Tools program folder within the Microsoft Visual Studio program group.
2. You can use the Developer Command Prompt for Visual Studio to access the compiler from any directory on your machine, if Visual Studio is installed.
3. Invoke the Developer Command Prompt for Visual Studio.
4. At the command line, type `vbc.exe sourceFileName` and then press ENTER.

For example, if you stored your source code in a directory called `SourceFiles`, you would open the Command Prompt and type `cd SourceFiles` to change to that directory. If the directory contained a source file named `Source.vb`, you could compile it by typing `vbc.exe Source.vb`.

To set the PATH environment variable to the compiler for the Windows Command Prompt

1. Use the Windows Search feature to find Vbc.exe on your local disk.
The exact name of the directory where the compiler is located depends on the location of the Windows directory and the version of the ".NET Framework" installed. If you have more than one version of the ".NET Framework" installed, you must determine which version to use (typically the latest version).
2. From your **Start** Menu, right-click **My Computer**, and then click **Properties** from the shortcut menu.
3. Click the **Advanced** tab, and then click **Environment Variables**.
4. In the **System** variables pane, select **Path** from the list and click **Edit**.
5. In the **Edit System** Variable dialog box, move the insertion point to the end of the string in the **Variable Value** field and type a semicolon (;) followed by the full directory name found in Step 1.
6. Click **OK** to confirm your edits and close the dialog boxes.

After you change the PATH environment variable, you can run the Visual Basic compiler at the Windows Command Prompt from any directory on the computer.

To invoke the compiler using the Windows Command Prompt

1. From the **Start** menu, click on the **Accessories** folder, and then open the **Windows Command Prompt**.

2. At the command line, type `vbc.exe sourceFileName` and then press ENTER.

For example, if you stored your source code in a directory called `SourceFiles`, you would open the Command Prompt and type `cd SourceFiles` to change to that directory. If the directory contained a source file named `Source.vb`, you could compile it by typing `vbc.exe Source.vb`.

Sample compilation command lines (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

As an alternative to compiling Visual Basic programs from within Visual Studio, you can compile from the command line to produce executable (.exe) files or dynamic-link library (.dll) files.

The Visual Basic command-line compiler supports a complete set of options that control input and output files, assemblies, and debug and preprocessor options. Each option is available in two interchangeable forms: `-option` and `/option`. This documentation shows only the `-option` form.

The following table lists some sample command lines you can modify for your own use.

TO	USE
Compile File.vb and create File.exe	<code>vbc -reference:Microsoft.VisualBasic.dll File.vb</code>
Compile File.vb and create File.dll	<code>vbc -target:library File.vb</code>
Compile File.vb and create My.exe	<code>vbc -out:My.exe File.vb</code>
Compile File.vb and create both a library and a reference assembly named File.dll	<code>vbc -target:library -ref:.\debug\bin\ref\file.dll File.vb</code>
Compile all Visual Basic files in the current directory, with optimizations on and the <code>DEBUG</code> symbol defined, producing File2.exe	<code>vbc -define:DEBUG=1 -optimize -out:File2.exe *.vb</code>
Compile all Visual Basic files in the current directory, producing a debug version of File2.dll without displaying the logo or warnings	<code>vbc -target:library -out:File2.dll -nowarn -nologo -debug *.vb</code>
Compile all Visual Basic files in the current directory to Something.dll	<code>vbc -target:library -out:Something.dll *.vb</code>

TIP

When you build a project by using the Visual Studio IDE, you can display information about the associated `vbc` command with its compiler options in the output window. To display this information, open the [Options Dialog Box, Projects and Solutions, Build and Run](#), and then set the **MSBuild project build output verbosity** to **Normal** or a higher level of verbosity.

Visual Basic compiler options listed alphabetically

2/5/2019 • 3 minutes to read • [Edit Online](#)

The Visual Basic command-line compiler is provided as an alternative to compiling programs from the Visual Studio integrated development environment (IDE). The following is a list of the Visual Basic command-line compiler options sorted alphabetically.

Every compiler option is available in two forms: **-option** and **/option**. The documentation only shows the -option form.

OPTION	PURPOSE
@ (Specify Response File)	Specifies a response file.
-?	Displays compiler options. This command is the same as specifying the -help option. No compilation occurs.
-additionalfile	Names additional files that don't directly affect code generation but may be used by analyzers for producing errors or warnings.
-addmodule	Causes the compiler to make all type information from the specified file(s) available to the project you are currently compiling.
-analyzer	Run the analyzers from this assembly (Short form: -a)
-baseaddress	Specifies the base address of a DLL.
-bugreport	Creates a file that contains information that makes it easy to report a bug.
-checksumalgorithm:<alg>	Specify the algorithm for calculating the source file checksum stored in PDB. Supported values are: SHA1 (default) or SHA256.
-codepage	Specifies the code page to use for all source code files in the compilation.
-debug	Produces debugging information.
-define	Defines symbols for conditional compilation.
-delaysign	Specifies whether the assembly will be fully or partially signed.
-deterministic	Causes the compiler to output an assembly whose binary content is identical across compilations if inputs are identical.
-doc	Processes documentation comments to an XML file.

OPTION	PURPOSE
-errorreport	Specifies how the Visual Basic compiler should report internal compiler errors.
-filealign	Specifies where to align the sections of the output file.
-help	Displays compiler options. This command is the same as specifying the <code>-?</code> option. No compilation occurs.
-highentropyva	Indicates whether a particular executable supports high entropy Address Space Layout Randomization (ASLR).
-imports	Imports a namespace from a specified assembly.
-keycontainer	Specifies a key container name for a key pair to give an assembly a strong name.
-keyfile	Specifies a file that contains a key or key pair to give an assembly a strong name.
-langversion	Specify language version: 9 9.0 10 10.0 11 11.0.
-libpath	Specifies the location of assemblies referenced by the <code>-reference</code> option.
-linkresource	Creates a link to a managed resource.
-main	Specifies the class that contains the <code>Sub Main</code> procedure to use at startup.
-moduleassemblyname	Specifies the name of the assembly that a module will be a part of.
<code>-modulename:<string></code>	Specify the name of the source module
-netcf	Sets the compiler to target the .NET Compact Framework.
-noconfig	Do not compile with Vbc.rsp.
-nologo	Suppresses compiler banner information.
-nostdlib	Causes the compiler not to reference the standard libraries.
-nowarn	Suppresses the compiler's ability to generate warnings.
-nowin32manifest	Instructs the compiler not to embed any application manifest into the executable file.
-optimize	Enables/disables code optimization.
-optioncompare	Specifies whether string comparisons should be binary or use locale-specific text semantics.

OPTION	PURPOSE
-optionexplicit	Enforces explicit declaration of variables.
-optioninfer	Enables the use of local type inference in variable declarations.
-optionstrict	Enforces strict language semantics.
-out	Specifies an output file.
-parallel[+ -]	Specifies whether to use concurrent build (+).
-platform	Specifies the processor platform the compiler targets for the output file.
-preferreuilang	Specify the preferred output language name.
-quiet	Prevents the compiler from displaying code for syntax-related errors and warnings.
-recurse	Searches subdirectories for source files to compile.
-reference	Imports metadata from an assembly.
-refonly	Outputs only a reference assembly.
-refout	Specifies the output path of a reference assembly.
-removeintchecks	Disables integer overflow checking.
-resource	Embeds a managed resource in an assembly.
-rootnamespace	Specifies a namespace for all type declarations.
-ruleset:<file>	Specify a ruleset file that disables specific diagnostics.
-sdkpath	Specifies the location of MsCorlib.dll and Microsoft.VisualBasic.dll.
-subsystemversion	Specifies the minimum version of the subsystem that the generated executable file can use.
-target	Specifies the format of the output file.
-utf8output	Displays compiler output using UTF-8 encoding.
-vbruntime	Specifies that the compiler should compile without a reference to the Visual Basic Runtime Library, or with a reference to a specific runtime library.
-verbose	Outputs extra information during compilation.
-warnaserror	Promotes warnings to errors.

OPTION	PURPOSE
-win32icon	Inserts an .ico file into the output file.
-win32manifest	Identifies a user-defined Win32 application manifest file to be embedded into a project's portable executable (PE) file.
-win32resource	Inserts a Win32 resource into the output file.

@ (Specify Response File) (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies a file that contains compiler options and source-code files to compile.

Syntax

```
@response_file
```

Arguments

`response_file`

Required. A file that lists compiler options or source-code files to compile. Enclose the file name in quotation marks (" ") if it contains a space.

Remarks

The compiler processes the compiler options and source-code files specified in a response file as if they had been specified on the command line.

To specify more than one response file in a compilation, specify multiple response-file options, such as the following.

```
@file1.rsp @file2.rsp
```

In a response file, multiple compiler options and source-code files can appear on one line. A single compiler-option specification must appear on one line (cannot span multiple lines). Response files can have comments that begin with the `#` symbol.

You can combine options specified on the command line with options specified in one or more response files. The compiler processes the command options as it encounters them. Therefore, command-line arguments can override previously listed options in response files. Conversely, options in a response file override options listed previously on the command line or in other response files.

Visual Basic provides the Vbc.rsp file, which is located in the same directory as the Vbc.exe file. The Vbc.rsp file is included by default unless the `-noconfig` option is used. For more information, see [-noconfig](#).

NOTE

The `@` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following lines are from a sample response file.

```
# build the first output file
-target:exe
-out:MyExe.exe
source1.vb
source2.vb
```

Example

The following example demonstrates how to use the `@` option with the response file named `File1.rsp`.

```
vbc @file1.rsp
```

-addmodule

3/1/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to make all type information from the specified file(s) available to the project you are currently compiling.

Syntax

```
-addmodule:fileList
```

Arguments

`fileList`

Required. Comma-delimited list of files that contain metadata but do not contain assembly manifests. File names containing spaces should be surrounded by quotation marks (" ").

Remarks

The files listed by the `fileList` parameter must be created with the `-target:module` option, or with another compiler's equivalent to `-target:module`.

All modules added with `-addmodule` must be in the same directory as the output file at run time. That is, you can specify a module in any directory at compile time, but the module must be in the application directory at run time. If it is not, you get a [TypeLoadException](#) error.

If you specify (implicitly or explicitly) any [-target \(Visual Basic\)](#) option other than `-target:module` with `-addmodule`, the files you pass to `-addmodule` become part of the project's assembly. An assembly is required to run an output file that has one or more files added with `-addmodule`.

Use [/reference \(Visual Basic\)](#) to import metadata from a file that contains an assembly.

NOTE

The `-addmodule` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code creates a module.

```
' t1.vb
' Compile with vbc /target:module t1.vb.
' Outputs t1.netmodule.

Public Class TestClass
    Public i As Integer
End Class
```

The following code imports the module's types.

```
' t2.vb
' Compile with vbc /addmodule:t1.netmodule t2.vb.
Option Strict Off

Namespace NetmoduleTest
    Module Module1
        Sub Main()
            Dim x As TestClass
            x = New TestClass
            x.i = 802
            System.Console.WriteLine(x.i)
        End Sub
    End Module
End Namespace
```

When you run `t1`, it outputs `802`.

-baseaddress

2/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies a default base address when creating a DLL.

Syntax

```
-baseaddress:address
```

Arguments

TERM	DEFINITION
address	Required. The base address for the DLL. This address must be specified as a hexadecimal number.

Remarks

The default base address for a DLL is set by the .NET Framework.

Be aware that the lower-order word in this address is rounded. For example, if you specify 0x11110001, it is rounded to 0x11110000.

To complete the signing process for a DLL, use the `-R` option of the Strong Naming tool (Sn.exe).

This option is ignored if the target is not a DLL.

TO SET -BASEADDRESS IN THE VISUAL STUDIO IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Click **Advanced**.
4. Modify the value in the **DLL base address:** box. **Note:** The **DLL base address:** box is read-only unless the target is a DLL.

-bugreport

2/5/2019 • 2 minutes to read • [Edit Online](#)

Creates a file that you can use when you file a bug report.

Syntax

```
-bugreport:file
```

Arguments

TERM	DEFINITION
<code>file</code>	Required. The name of the file that will contain your bug report. Enclose the file name in quotation marks (" ") if the name contains a space.

Remarks

The following information is added to `file`:

- A copy of all source-code files in the compilation.
- A list of the compiler options used in the compilation.
- Version information about your compiler, common language runtime, and operating system.
- Compiler output, if any.
- A description of the problem, for which you are prompted.
- A description of how you think the problem should be fixed, for which you are prompted.

Because a copy of all source-code files is included in `file`, you may want to reproduce the (suspected) code defect in the shortest possible program.

IMPORTANT

The `-bugreport` option produces a file that contains potentially sensitive information. This includes current time, compiler version, .NET Framework version, OS version, user name, the command-line arguments with which the compiler was run, all source code, and the binary form of any referenced assembly. This option can be accessed by specifying command-line options in the Web.config file for a server-side compilation of an ASP.NET application. To prevent this, modify the Machine.config file to disallow users from compiling on the server.

If this option is used with `-errorreport:prompt`, `-errorreport:queue`, or `-errorreport:send`, and your application encounters an internal compiler error, the information in `file` is sent to Microsoft Corporation. That information will help Microsoft engineers identify the cause of the error and may help improve the next release of Visual Basic. By default, no information is sent to Microsoft. However, when you compile an application by using `-errorreport:queue`, which is enabled by default, the application collects its error reports. Then, when the computer's administrator logs in, the error reporting system displays a pop-up window that enables the

administrator to forward to Microsoft any error reports that occurred since the logon.

NOTE

The `/bugreport` option is not available from within the Visual Studio development environment; it is available only when you compile from the command line.

Example

The following example compiles `t2.vb` and puts all bug-reporting information in the file `Problem.txt`.

```
vbc -bugreport:problem.txt t2.vb
```

-codepage (Visual Basic)

9/7/2018 • 2 minutes to read • [Edit Online](#)

Specifies the code page to use for all source-code files in the compilation.

Syntax

```
-codepage:id
```

Arguments

TERM	DEFINITION
<code>id</code>	Required. The compiler uses the code page specified by <code>id</code> to interpret the encoding of the source files.

Remarks

To compile source code saved with a specific encoding, you can use `-codepage` to specify which code page should be used. The `-codepage` option applies to all source-code files in your compilation. For more information, see [Character Encoding in the .NET Framework](#).

The `-codepage` option is not needed if the source-code files were saved using the current ANSI code page, Unicode, or UTF-8 with a signature. Visual Studio saves all source-code files with the current ANSI code page by default, unless the user specifies another encoding in the **Encoding** dialog box. Visual Studio uses the **Encoding** dialog box to open source-code files saved with a different code page.

NOTE

The `-codepage` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

-debug (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to generate debugging information and place it in the output file(s).

Syntax

```
-debug[+ | -]  
' -or -  
-debug:[full | pdbonly]
```

Arguments

TERM	DEFINITION
+ -	Optional. Specifying + or /debug causes the compiler to generate debugging information and place it in a .pdb file. Specifying - has the same effect as not specifying /debug.
full pdbonly	Optional. Specifies the type of debugging information generated by the compiler. If you do not specify /debug:pdbonly, the default is full, which enables you to attach a debugger to the running program. The pdbonly argument allows source-code debugging when the program is started in the debugger, but it displays assembly-language code only when the running program is attached to the debugger.

Remarks

Use this option to create debug builds. If you do not specify /debug, /debug+, or /debug:full, you will be unable to debug the output file of your program.

By default, debugging information is not emitted (/debug-). To emit debugging information, specify /debug or /debug+.

For information on how to configure the debug performance of an application, see [Making an Image Easier to Debug](#).

TO SET -DEBUG IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. With a project selected in **Solution Explorer**, on the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Click **Advanced Compile Options**.
4. Modify the value in the **Generate Debug Info** box.

Example

The following example puts debugging information in output file App.exe.

```
vbc -debug -out:app.exe test.vb
```

-define (Visual Basic)

3/1/2019 • 2 minutes to read • [Edit Online](#)

Defines conditional compiler constants.

Syntax

```
-define:["]symbol[=value][,symbol[=value]]["]
' -or-
-d:["]symbol[=value][,symbol[=value]]["]
```

Arguments

TERM	DEFINITION
<code>symbol</code>	Required. The symbol to define.
<code>value</code>	Optional. The value to assign <code>symbol</code> . If <code>value</code> is a string, it must be surrounded by backslash/quotation-mark sequences (\") instead of quotation marks. If no value is specified, then it is taken to be True.

Remarks

The `-define` option has an effect similar to using a `#Const` preprocessor directive in your source file, except that constants defined with `-define` are public and apply to all files in the project.

You can use symbols created by this option with the `#If ... Then ... #Else` directive to compile source files conditionally.

`-d` is the short form of `-define`.

You can define multiple symbols with `-define` by using a comma to separate symbol definitions.

TO SET /DEFINE IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Click **Advanced**.
4. Modify the value in the **Custom Constants** box.

Example

The following code defines and then uses two conditional compiler constants.

```
' Vbc /define:DEBUGMODE=True,TRAPERRORS=False test.vb
Sub mysub()
#If debugmode Then
    ' Insert debug statements here.
    MsgBox("debug mode")
#Else
    ' Insert default statements here.
#End If
End Sub
```

-delaysign

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies whether the assembly will be fully or partially signed.

Syntax

```
-delaysign[+ | -]
```

Arguments

+ | -

Optional. Use `-delaysign-` if you want a fully signed assembly. Use `-delaysign+` if you want to place the public key in the assembly and reserve space for the signed hash. The default is `-delaysign-`.

Remarks

The `-delaysign` option has no effect unless used with [-keyfile](#) or [-keycontainer](#).

When you request a fully signed assembly, the compiler hashes the file that contains the manifest (assembly metadata) and signs that hash with the private key. The resulting digital signature is stored in the file that contains the manifest. When an assembly is delay signed, the compiler does not compute and store the signature but reserves space in the file so the signature can be added later.

For example, by using `-delaysign+`, a developer in an organization can distribute unsigned test versions of an assembly that testers can register with the global assembly cache and use. When work on the assembly is completed, the person responsible for the organization's private key can fully sign the assembly. This compartmentalization protects the organization's private key from disclosure, while allowing all developers to work on the assemblies.

See [Creating and Using Strong-Named Assemblies](#) for more information on signing an assembly.

To set `-delaysign` in the Visual Studio integrated development environment

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Signing** tab.
3. Set the value in the **Delay sign only** box.

-deterministic

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to produce an assembly whose byte-for-byte output is identical across compilations for identical inputs.

Syntax

```
-deterministic
```

Remarks

By default, compiler output from a given set of inputs is unique, since the compiler adds a timestamp and a GUID that is generated from random numbers. You use the `-deterministic` option to produce a *deterministic assembly*, one whose binary content is identical across compilations as long as the input remains the same.

The compiler considers the following inputs for the purpose of determinism:

- The sequence of command-line parameters.
- The contents of the compiler's .rsp response file.
- The precise version of the compiler used, and its referenced assemblies.
- The current directory path.
- The binary contents of all files explicitly passed to the compiler either directly or indirectly, including:
 - Source files
 - Referenced assemblies
 - Referenced modules
 - Resources
 - The strong name key file
 - @ response files
 - Analyzers
 - Rulesets
 - Additional files that may be used by analyzers
- The current culture (for the language in which diagnostics and exception messages are produced).
- The default encoding (or the current code page) if the encoding is not specified.
- The existence, non-existence, and contents of files on the compiler's search paths (specified, for example, by `/lib` or `/recurse`).
- The CLR platform on which the compiler is run.
- The value of `%LIBPATH%`, which can affect analyzer dependency loading.

When sources are publicly available, deterministic compilation can be used for establishing whether a binary is compiled from a trusted source. It can also be useful in a continuous build system for determining whether build steps that are dependent on changes to a binary need to be executed.

-doc

1/23/2019 • 2 minutes to read • [Edit Online](#)

Processes documentation comments to an XML file.

Syntax

```
-doc[+ | -]  
' -or -  
-doc:file
```

Arguments

TERM	DEFINITION
+ -	Optional. Specifying +, or just <code>-doc</code> , causes the compiler to generate documentation information and place it in an XML file. Specifying <code>-</code> is the equivalent of not specifying <code>-doc</code> , causing no documentation information to be created.
file	Required if <code>-doc:</code> is used. Specifies the output XML file, which is populated with the comments from the source-code files of the compilation. If the file name contains a space, surround the name with quotation marks ("").

Remarks

The `-doc` option controls whether the compiler generates an XML file containing the documentation comments. If you use the `-doc:file` syntax, the `file` parameter specifies the name of the XML file. If you use `-doc` or `-doc+`, the compiler takes the XML file name from the executable file or library that the compiler is creating. If you use `-doc-` or do not specify the `-doc` option, the compiler does not create an XML file.

In source-code files, documentation comments can precede the following definitions:

- User-defined types, such as a [class](#) or [interface](#)
- Members, such as a field, [event](#), [property](#), [function](#), or [subroutine](#).

To use the generated XML file with the Visual Studio [IntelliSense](#) feature, let the file name of the XML file be the same as the assembly you want to support. Make sure the XML file is in the same directory as the assembly so that when the assembly is referenced in the Visual Studio project, the .xml file is found as well. XML documentation files are not required for IntelliSense to work for code within a project or within projects referenced by a project.

Unless you compile with `/target:module`, the XML file contains the tags `<assembly></assembly>`. These tags specify the name of the file containing the assembly manifest for the output file of the compilation.

See [XML Comment Tags](#) for ways to generate documentation from comments in your code.

TO SET -DOC IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Set the value in the **Generate XML documentation file** box.

Example

See [Documenting Your Code with XML](#) for a sample.

-errorreport

10/24/2018 • 2 minutes to read • [Edit Online](#)

Specifies how the Visual Basic compiler should report internal compiler errors.

Syntax

```
-errorreport:{ prompt | queue | send | none }
```

Remarks

This option provides a convenient way to report a Visual Basic internal compiler error (ICE) to the Visual Basic team at Microsoft. By default, the compiler sends no information to Microsoft. However, if you do encounter an internal compiler error, this option allows you to report the error to Microsoft. That information will help Microsoft engineers identify the cause and may help improve the next release of Visual Basic.

A user's ability to send reports depends on machine and user policy permissions.

The following table summarizes the effect of the `-errorreport` option.

OPTION	BEHAVIOR
<code>prompt</code>	If an internal compiler error occurs, a dialog box comes up so that you can view the exact data that the compiler collected. You can determine if there is any sensitive information in the error report and make a decision on whether to send it to Microsoft. If you decide to send it, and the machine and user policy settings allow it, the compiler sends the data to Microsoft.
<code>queue</code>	Queues the error report. When you log in with administrator privileges, you can report any failures since the last time you were logged in (you will not be prompted to send reports for failures more than once every three days). This is the default behavior when the <code>-errorreport</code> option is not specified.
<code>send</code>	If an internal compiler error occurs, and the machine and user policy settings allow it, the compiler sends the data to Microsoft. The option <code>-errorreport:send</code> attempts to automatically send error information to Microsoft if reporting is enabled by the Windows Error Reporting system settings.
<code>none</code>	If an internal compiler error occurs, it will not be collected or sent to Microsoft.

The compiler sends data that includes the stack at the time of the error, which usually includes some source code.

If `-errorreport` is used with the `-bugreport` option, then the entire source file is sent.

This option is best used with the `/bugreport` option, because it allows Microsoft engineers to more easily reproduce the error.

NOTE

The `-errorreport` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code attempts to compile `t2.vb`, and if the compiler encounters an internal compiler error, it prompts you to send the error report to Microsoft.

```
vbc -errorreport:prompt t2.vb
```

-filealign

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies where to align the sections of the output file.

Syntax

```
-filealign:number
```

Arguments

number

Required. A value that specifies the alignment of sections in the output file. Valid values are 512, 1024, 2048, 4096, and 8192. These values are in bytes.

Remarks

You can use the `-filealign` option to specify the alignment of sections in your output file. Sections are blocks of contiguous memory in a Portable Executable (PE) file that contains either code or data. The `-filealign` option lets you compile your application with a nonstandard alignment; most developers do not need to use this option.

Each section is aligned on a boundary that is a multiple of the `-filealign` value. There is no fixed default. If `-filealign` is not specified, the compiler picks a default at compile time.

By specifying the section size, you can change the size of the output file. Modifying section size may be useful for programs that will run on smaller devices.

NOTE

The `-filealign` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

-help, -? (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Displays the compiler options.

Syntax

```
-help  
' -or-  
-?
```

Remarks

If you include this option in a compilation, no output file is created and no compilation takes place.

NOTE

The `-help` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code displays help from the command line.

```
vbc -help
```

See also

- [Visual Basic Command-Line Compiler](#)

-highentropyva (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Indicates whether a 64-bit executable or an executable that's marked by the [/platform:anycpu](#) compiler option supports high entropy Address Space Layout Randomization (ASLR).

Syntax

```
-highentropyva[+ | -]
```

Arguments

+ | -

Optional. The option is off by default or if you specify `-highentropyva-`. The option is on if you specify `-highentropyva` or `-highentropyva+`.

Remarks

If you specify this option, compatible versions of the Windows kernel can use higher degrees of entropy when the kernel randomizes the address space layout of a process as part of ASLR. If the kernel uses higher degrees of entropy, a larger number of addresses can be allocated to memory regions such as stacks and heaps. As a result, it is more difficult to guess the location of a particular memory region.

When the option is on, the target executable and any modules on which it depends must be able to handle pointer values that are larger than 4 gigabytes (GB) when those modules are running as 64-bit processes.

-imports (Visual Basic)

3/5/2019 • 2 minutes to read • [Edit Online](#)

Imports namespaces from a specified assembly.

Syntax

```
-imports:namespaceList
```

Arguments

TERM	DEFINITION
namespaceList	Required. Comma-delimited list of namespaces to be imported.

Remarks

The `-imports` option imports any namespace defined within the current set of source files or from any referenced assembly.

The members in a namespace specified with `-imports` are available to all source-code files in the compilation. Use the [Imports Statement \(.NET Namespace and Type\)](#) to use a namespace in a single source-code file.

TO SET /IMPORTS IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **References** tab.
3. Enter the namespace name in the box beside the **Add User Import** button.
4. Click the **Add User Import** button.

Example

The following code compiles when `/imports:system.globalization` is specified. Without it, successful compilation requires either that an `Imports System.Globalization` statement be included at the beginning of the source code file, or that the property be fully qualified as `System.Globalization.CultureInfo.CurrentCulture.Name`.

```
Module Example
    Public Sub Main()
        Console.WriteLine($"The current culture is {CultureInfo.CurrentCulture.Name}")
    End Sub
End Module
```

-keycontainer

2/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies a key container name for a key pair to give an assembly a strong name.

Syntax

```
-keycontainer:container
```

Arguments

TERM	DEFINITION
container	Required. Container file that contains the key. Enclose the file name in quotation marks ("") if the name contains a space.

Remarks

The compiler creates the sharable component by inserting a public key into the assembly manifest and by signing the final assembly with the private key. To generate a key file, type `sn -k file` at the command line. The `-i` option installs the key pair into a container. For more information, see [Sn.exe \(Strong Name Tool\)](#)).

If you compile with `-target:module`, the name of the key file is held in the module and incorporated into the assembly that is created when you compile an assembly with [-addmodule](#).

You can also specify this option as a custom attribute ([AssemblyKeyNameAttribute](#)) in the source code for any Microsoft intermediate language (MSIL) module.

You can also pass your encryption information to the compiler with [-keyfile](#). Use [-delaysign](#) if you want a partially signed assembly.

See [Creating and Using Strong-Named Assemblies](#) for more information on signing an assembly.

NOTE

The `-keycontainer` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles source file `Input.vb` and specifies a key container.

```
vbc -keycontainer:key1 input.vb
```

See also

- [Assemblies in .NET](#)
- [Visual Basic Command-Line Compiler](#)

- [Sample Compilation Command Lines](#)

-keyfile

2/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies a file containing a key or key pair to give an assembly a strong name.

Syntax

```
-keyfile:file
```

Arguments

`file`

Required. File that contains the key. If the file name contains a space, enclose the name in quotation marks ("").

Remarks

The compiler inserts the public key into the assembly manifest and then signs the final assembly with the private key. To generate a key file, type `sn -k file` at the command line. For more information, see [Sn.exe \(Strong Name Tool\)](#).

If you compile with `-target:module`, the name of the key file is held in the module and incorporated into the assembly that is created when you compile an assembly with [/addmodule](#).

You can also pass your encryption information to the compiler with [-keycontainer](#). Use [-delaysign](#) if you want a partially signed assembly.

You can also specify this option as a custom attribute ([AssemblyKeyFileAttribute](#)) in the source code for any Microsoft intermediate language module.

In case both [-keyfile](#) and [-keycontainer](#) are specified (either by command-line option or by custom attribute) in the same compilation, the compiler first tries the key container. If that succeeds, then the assembly is signed with the information in the key container. If the compiler does not find the key container, it tries the file specified with [-keyfile](#). If this succeeds, the assembly is signed with the information in the key file, and the key information is installed in the key container (similar to `sn -i`) so that on the next compilation, the key container will be valid.

Note that a key file might contain only the public key.

See [Creating and Using Strong-Named Assemblies](#) for more information on signing an assembly.

NOTE

The [-keyfile](#) option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles source file `Input.vb` and specifies a key file.

```
vbc -keyfile:myfile.sn input.vb
```

-langversion (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to accept only syntax that is included in the specified Visual Basic language version.

Syntax

```
-langversion:version
```

Arguments

version

Required. The language version to be used during the compilation. Accepted values are 9, 10, 11, 12, 14, 15, 15.3, 15.5, default and latest.

Any of the whole numbers may also be specified using .0 as the minor version, for example, 11.0.

You can see the list of all possible values by specifying -langversion:? on the command line.

Remarks

The -langversion option specifies what syntax the compiler accepts. For example, if you specify that the language version is 9.0, the compiler generates errors for syntax that is valid only in version 10.0 and later.

You can use this option when you develop applications that target different versions of the .NET Framework. For example, if you are targeting .NET Framework 3.5, you could use this option to ensure that you do not use syntax from language version 10.0.

You can set -langversion directly only by using the command line. For more information, see [Targeting a Specific .NET Framework Version](#).

Example

The following code compiles sample.vb for Visual Basic 9.0.

```
vbc -langversion:9.0 sample.vb
```

-libpath

2/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies the location of referenced assemblies.

Syntax

```
-libpath:dirList
```

Arguments

TERM	DEFINITION
dirList	Required. Semicolon-delimited list of directories for the compiler to look in if a referenced assembly is not found in either the current working directory (the directory from which you are invoking the compiler) or the common language runtime's system directory. If the directory name contains a space, enclose the name in quotation marks ("").

Remarks

The `-libpath` option specifies the location of assemblies referenced by the `-reference` option.

The compiler searches for assembly references that are not fully qualified in the following order:

1. Current working directory. This is the directory from which the compiler is invoked.
2. The common language runtime system directory.
3. Directories specified by `/libpath`.
4. Directories specified by the LIB environment variable.

The `-libpath` option is additive; specifying it more than once appends to any prior values.

Use `-reference` to specify an assembly reference.

TO SET /LIBPATH IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **References** tab.
3. Click the **Reference Paths...** button.
4. In the **Reference Paths** dialog box, enter the directory name in the **Folder:** box.
5. Click **Add Folder**.

Example

The following code compiles `T2.vb` to create an .exe file. The compiler looks in the working directory, in the root directory of the C: drive, and in the New Assemblies directory of the C: drive for assembly references.

```
vbc -libpath:c:\;"c:\New Assemblies" -reference:t2.dll t2.vb
```

-link (Visual Basic)

3/1/2019 • 3 minutes to read • [Edit Online](#)

Causes the compiler to make COM type information in the specified assemblies available to the project that you are currently compiling.

Syntax

```
-link:fileList  
' -or-  
-l:fileList
```

Arguments

TERM	DEFINITION
fileList	Required. Comma-delimited list of assembly file names. If the file name contains a space, enclose the name in quotation marks.

Remarks

The `-link` option enables you to deploy an application that has embedded type information. The application can then use types in a runtime assembly that implement the embedded type information without requiring a reference to the runtime assembly. If various versions of the runtime assembly are published, the application that contains the embedded type information can work with the various versions without having to be recompiled. For an example, see [Walkthrough: Embedding Types from Managed Assemblies](#).

Using the `-link` option is especially useful when you are working with COM interop. You can embed COM types so that your application no longer requires a primary interop assembly (PIA) on the target computer. The `-link` option instructs the compiler to embed the COM type information from the referenced interop assembly into the resulting compiled code. The COM type is identified by the CLSID (GUID) value. As a result, your application can run on a target computer that has installed the same COM types with the same CLSID values. Applications that automate Microsoft Office are a good example. Because applications like Office usually keep the same CLSID value across different versions, your application can use the referenced COM types as long as .NET Framework 4 or later is installed on the target computer and your application uses methods, properties, or events that are included in the referenced COM types.

The `-link` option embeds only interfaces, structures, and delegates. Embedding COM classes is not supported.

NOTE

When you create an instance of an embedded COM type in your code, you must create the instance by using the appropriate interface. Attempting to create an instance of an embedded COM type by using the `CoClass` causes an error.

To set the `-link` option in Visual Studio, add an assembly reference and set the `Embed Interop Types` property to **true**. The default for the `Embed Interop Types` property is **false**.

If you link to a COM assembly (Assembly A) which itself references another COM assembly (Assembly B), you

also have to link to Assembly B if either of the following is true:

- A type from Assembly A inherits from a type or implements an interface from Assembly B.
- A field, property, event, or method that has a return type or parameter type from Assembly B is invoked.

Use `-libpath` to specify the directory in which one or more of your assembly references is located.

Like the `/reference` compiler option, the `-link` compiler option uses the Vbc.rsp response file, which references frequently used .NET Framework assemblies. Use the `-noconfig` compiler option if you do not want the compiler to use the Vbc.rsp file.

The short form of `-link` is `-l`.

Generics and Embedded Types

The following sections describe the limitations on using generic types in applications that embed interop types.

Generic Interfaces

Generic interfaces that are embedded from an interop assembly cannot be used. This is shown in the following example.

```
' The following code causes an error if ISampleInterface is an embedded interop type.  
Dim sample As ISampleInterface(Of SampleType)
```

Types That Have Generic Parameters

Types that have a generic parameter whose type is embedded from an interop assembly cannot be used if that type is from an external assembly. This restriction does not apply to interfaces. For example, consider the `Range` interface that is defined in the `Microsoft.Office.Interop.Excel` assembly. If a library embeds interop types from the `Microsoft.Office.Interop.Excel` assembly and exposes a method that returns a generic type that has a parameter whose type is the `Range` interface, that method must return a generic interface, as shown in the following code example.

```
Imports System.Collections.Generic  
Imports Microsoft.Office.Interop.Excel  
  
Class Utility  
    ' The following code causes an error when called by a client assembly.  
    Public Function GetRange1() As List(Of Range)
```

```
End Function  
  
' The following code is valid for calls from a client assembly.  
Public Function GetRange2() As IList(Of Range)
```

```
End Function  
End Class
```

In the following example, client code can call the method that returns the `IList` generic interface without error.

```
Module Client
    Public Sub Main()
        Dim util As New Utility()

        ' The following code causes an error.
        Dim rangeList1 As List(Of Range) = util.GetRange1()

        ' The following code is valid.
        Dim rangeList2 As List(Of Range) = CType(util.GetRange2(), List(Of Range))
    End Sub
End Module
```

Example

The following command line compiles source file `OfficeApp.vb` and reference assemblies from `COMData1.dll` and `COMData2.dll` to produce `OfficeApp.exe`.

```
vbc -link:COMData1.dll,COMData2.dll /out:OfficeApp.exe OfficeApp.vb
```

-linkresource (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Creates a link to a managed resource.

Syntax

```
-linkresource:filename[,identifier[,public|private]]  
' -or-  
-linkres:filename[,identifier[,public|private]]
```

Arguments

`filename`

Required. The resource file to link to the assembly. If the file name contains a space, enclose the name in quotation marks (" ").

`identifier`

Optional. The logical name for the resource. The name that is used to load the resource. The default is the name of the file. Optionally, you can specify whether the file is public or private in the assembly manifest, for example:

`-linkres:filename.res,myname.res,public`. By default, `filename` is public in the assembly.

Remarks

The `-linkresource` option does not embed the resource file in the output file; use the `-resource` option to do this.

The `-linkresource` option requires one of the `-target` options other than `-target:module`.

If `filename` is a .NET Framework resource file created, for example, by the [Resgen.exe \(Resource File Generator\)](#) or in the development environment, it can be accessed with members in the [System.Resources](#) namespace. (For more information, see [ResourceManager](#).) To access all other resources at run time, use the methods that begin with `GetManifestResource` in the [Assembly](#) class.

The file name can be any file format. For example, you may want to make a native DLL part of the assembly, so that it can be installed into the global assembly cache and accessed from managed code in the assembly.

The short form of `-linkresource` is `-linkres`.

NOTE

The `-linkresource` option is not available from the Visual Studio development environment; it is available only when you compile from the command line.

Example

The following code compiles `in.vb` and links to resource file `rf.resource`.

```
vbc -linkresource:rf.resource in.vb
```

-main

2/28/2019 • 2 minutes to read • [Edit Online](#)

Specifies the class or module that contains the `Sub Main` procedure.

Syntax

```
-main:location
```

Arguments

`location`

Required. The name of the class or module that contains the `Sub Main` procedure to be called when the program starts. This may be in the form **-main:module** or **-main:namespace.module**.

Remarks

Use this option when you create an executable file or Windows executable program. If the **-main** option is omitted, the compiler searches for a valid shared `Sub Main` in all public classes and modules.

See [Main Procedure in Visual Basic](#) for a discussion of the various forms of the `Main` procedure.

When `location` is a class that inherits from `Form`, the compiler provides a default `Main` procedure that starts the application if the class has no `Main` procedure. This lets you compile code at the command line that was created in the development environment.

```
' Compile with /r:System.dll,SYSTEM.WINDOWS.FORMS.DLL /main:MyC
Public Class MyC
    Inherits System.Windows.Forms.Form
End Class
```

To set -main in the Visual Studio integrated development environment

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Application** tab.
3. Make sure the **Enable application framework** check box is not checked.
4. Modify the value in the **Startup object** box.

Example

The following code compiles `t2.vb` and `t3.vb`, specifying that the `Sub Main` procedure will be found in the `Test2` class.

```
vbc t2.vb t3.vb -main:Test2
```

-moduleassemblyname

3/5/2019 • 2 minutes to read • [Edit Online](#)

Specifies the name of the assembly that this module will be a part of.

Syntax

```
-moduleassemblyname:assembly_name
```

Arguments

TERM	DEFINITION
assembly_name	The name of the assembly that this module will be a part of.

Remarks

The compiler processes the `-moduleassemblyname` option only if the `-target:module` option has been specified. This causes the compiler to create a module. The module created by the compiler is valid only for the assembly specified with the `-moduleassemblyname` option. If you place the module in a different assembly, run-time errors will occur.

The `-moduleassemblyname` option is needed only when the following are true:

- A data type in the module needs access to a `Friend` type in a referenced assembly.
- The referenced assembly has granted friend assembly access to the assembly into which the module will be built.

For more information about creating a module, see [/target \(Visual Basic\)](#). For more information about friend assemblies, see [Friend Assemblies](#).

NOTE

The `-moduleassemblyname` option is not available from within the Visual Studio development environment; it is available only when you compile from a command prompt.

-netcf

3/1/2019 • 2 minutes to read • [Edit Online](#)

Sets the compiler to target the .NET Compact Framework.

Syntax

```
-netcf
```

Remarks

The `-netcf` option causes the Visual Basic compiler to target the .NET Compact Framework rather than the full .NET Framework. Language functionality that is present only in the full .NET Framework is disabled.

The `-netcf` option is designed to be used with `-sdkpath`. The language features disabled by `-netcf` are the same language features not present in the files targeted with `-sdkpath`.

NOTE

The `-netcf` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. The `-netcf` option is set when a Visual Basic device project is loaded.

The `-netcf` option changes the following language features:

- The `End <keyword> Statement` keyword, which terminates execution of a program, is disabled. The following program compiles and runs without `-netcf` but fails at compile time with `-netcf`.

```
Module Module1
    Sub Main()
        End      ' not valid to terminate execution with /netcf
    End Sub
End Module
```

- Late binding, in all forms, is disabled. Compile-time errors are generated when recognized late-binding scenarios are encountered. The following program compiles and runs without `-netcf` but fails at compile time with `-netcf`.

```

Class LateBoundClass
    Sub S1()
        End Sub

    Default Property P1(ByVal s As String) As Integer
        Get
        End Get
        Set(ByVal Value As Integer)
        End Set
    End Property
End Class

Module Module1
    Sub Main()
        Dim o1 As Object
        Dim o2 As Object
        Dim o3 As Object
        Dim IntArr(3) As Integer

        o1 = New LateBoundClass
        o2 = 1
        o3 = IntArr

        ' Late-bound calls
        o1.S1()
        o1.P1("member") = 1

        ' Dictionary member access
        o1!member = 1

        ' Late-bound overload resolution
        LateBoundSub(o2)

        ' Late-bound array
        o3(1) = 1
    End Sub

    Sub LateBoundSub(ByVal n As Integer)
    End Sub

    Sub LateBoundSub(ByVal s As String)
    End Sub
End Module

```

- The **Auto**, **Ansi**, and **Unicode** modifiers are disabled. The syntax of the **Declare Statement** statement is also modified to `Declare Sub|Function name Lib "library" [Alias "alias"] [(arglist)]`. The following code shows the effect of `-netcf` on a compilation.

```

' compile with: /target:library
Module Module1
    ' valid with or without /netcf
    Declare Sub DllSub Lib "SomeLib.dll" ()

    ' not valid with /netcf
    Declare Auto Sub DllSub1 Lib "SomeLib.dll" ()
    Declare Ansi Sub DllSub2 Lib "SomeLib.dll" ()
    Declare Unicode Sub DllSub3 Lib "SomeLib.dll" ()
End Module

```

- Using Visual Basic 6.0 keywords that were removed from Visual Basic generates a different error when `-netcf` is used. This affects the error messages for the following keywords:

○ [Open](#)

- [Close](#)
- [Put](#)
- [Print](#)
- [Write](#)
- [Input](#)
- [Lock](#)
- [Unlock](#)
- [Seek](#)
- [Width](#)
- [Name](#)
- [FreeFile](#)
- [EOF](#)
- [Loc](#)
- [LOF](#)
- [Line](#)

Example

The following code compiles `Myfile.vb` with the .NET Compact Framework, using the versions of mscorlib.dll and Microsoft.VisualBasic.dll found in the default installation directory of the .NET Compact Framework on the C drive. Typically, you would use the most recent version of the .NET Compact Framework.

```
vbc -netcf -sdkpath:"c:\Program Files\Microsoft Visual Studio .NET 2003\CompactFrameworkSDK\v1.0.5000\Windows  
CE " myfile.vb
```

-noconfig

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies that the compiler should not automatically reference the commonly used .NET Framework assemblies or import the `System` and `Microsoft.VisualBasic` namespaces.

Syntax

```
-noconfig
```

Remarks

The `-noconfig` option tells the compiler not to compile with the Vbc.rsp file, which is located in the same directory as the Vbc.exe file. The Vbc.rsp file references the commonly used .NET Framework assemblies and imports the `System` and `Microsoft.VisualBasic` namespaces. The compiler implicitly references the System.dll assembly unless the `-nostdlib` option is specified. The `-nostdlib` option tells the compiler not to compile with Vbc.rsp or automatically reference the System.dll assembly.

NOTE

The Mscorlib.dll and Microsoft.VisualBasic.dll assemblies are always referenced.

You can modify the Vbc.rsp file to specify additional compiler options that should be included in every Vbc.exe compilation (except when specifying the `-noconfig` option). For more information, see [@\(Specify Response File\)](#).

The compiler processes the options passed to the `vbc` command last. Therefore, any option on the command line overrides the setting of the same option in the Vbc.rsp file.

NOTE

The `-noconfig` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

-nologo (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Suppresses display of the copyright banner and informational messages during compilation.

Syntax

```
-nologo
```

Remarks

If you specify `-nologo`, the compiler does not display a copyright banner. By default, `-nologo` is not in effect.

NOTE

The `-nologo` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles `t2.vb` and does not display a copyright banner.

```
vbc -nologo t2.vb
```

See also

- [Visual Basic Command-Line Compiler](#)
- [Sample Compilation Command Lines](#)

-nostdlib (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler not to automatically reference the standard libraries.

Syntax

```
-nostdlib
```

Remarks

The `-nostdlib` option removes the automatic reference to the System.dll assembly and prevents the compiler from reading the Vbc.rsp file. The Vbc.rsp file, which is located in the same directory as the Vbc.exe file, references the commonly used .NET Framework assemblies and imports the `System` and `Microsoft.VisualBasic` namespaces.

NOTE

The MsCorLib.dll and Microsoft.VisualBasic.dll assemblies are always referenced.

NOTE

The `-nostdlib` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles `T2.vb` without referencing the standard libraries. You must set the `_MYTYPE` conditional-compilation constant to the string "Empty" to remove the `My` object.

```
vbc -nostdlib -define:_MYTYPE=\"Empty\" T2.vb
```

-nowarn

1/23/2019 • 2 minutes to read • [Edit Online](#)

Suppresses the compiler's ability to generate warnings.

Syntax

```
-nowarn[:numberList]
```

Arguments

TERM	DEFINITION
numberList	Optional. Comma-delimited list of the warning ID numbers that the compiler should suppress. If the warning IDs are not specified, all warnings are suppressed.

Remarks

The `-nowarn` option causes the compiler to not generate warnings. To suppress an individual warning, supply the warning ID to the `-nowarn` option following the colon. Separate multiple warning numbers with commas.

You need to specify only the numeric part of the warning identifier. For example, if you want to suppress BC42024, the warning for unused local variables, specify `-nowarn:42024`.

For more information on the warning ID numbers, see [Configuring Warnings in Visual Basic](#).

TO SET -NOWARN IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Select the **Disable all warnings** check box to disable all warnings.
- or -

To disable a particular warning, click **None** from the drop-down list adjacent to the warning.

Example

The following code compiles `T2.vb` and does not display any warnings.

```
vbc -nowarn t2.vb
```

Example

The following code compiles `T2.vb` and does not display the warnings for unused local variables (42024).

```
vbc -nowarn:42024 t2.vb
```

-nowin32manifest (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Instructs the compiler not to embed any application manifest into the executable file.

Syntax

```
-nowin32manifest
```

Remarks

When this option is used, the application will be subject to virtualization on Windows Vista unless you provide an application manifest in a Win32 Resource file or during a later build step. For more information about virtualization, see [ClickOnce Deployment on Windows Vista](#).

For more information about manifest creation, see [-win32manifest \(Visual Basic\)](#).

See also

- [Visual Basic Command-Line Compiler](#)

-optimize

1/23/2019 • 2 minutes to read • [Edit Online](#)

Enables or disables compiler optimizations.

Syntax

```
-optimize[ + | - ]
```

Arguments

TERM	DEFINITION
+ -	Optional. The <code>-optimize-</code> option disables compiler optimizations. The <code>-optimize+</code> option enables optimizations. By default, optimizations are disabled.

Remarks

Compiler optimizations make your output file smaller, faster, and more efficient. However, because optimizations result in code rearrangement in the output file, `-optimize+` can make debugging difficult.

All modules generated with `-target:module` for an assembly must use the same `-optimize` settings as the assembly. For more information, see [-target \(Visual Basic\)](#).

You can combine the `-optimize` and `-debug` options.

TO SET -OPTIMIZE IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Click the **Advanced** button.
4. Modify the **Enable optimizations** check box.

Example

The following code compiles `t2.vb` and enables compiler optimizations.

```
vbc t2.vb -optimize
```

-optioncompare

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies how string comparisons are made.

Syntax

```
-optioncompare:{binary | text}
```

Remarks

You can specify `-optioncompare` in one of two forms: `-optioncompare:binary` to use binary string comparisons, and `-optioncompare:text` to use text string comparisons. By default, the compiler uses `-optioncompare:binary`.

In Microsoft Windows, the current code page determines the binary sort order. A typical binary sort order is as follows:

```
A < B < E < Z < a < b < e < z < À < È < Ø < à < è < ø
```

Text-based string comparisons are based on a case-insensitive text sort order determined by your system's locale. A typical text sort order is as follows:

```
(A = a) < (À = à) < (B=b) < (E=e) < (È = ê) < (Z=z) < (Ø = ø)
```

To set -optioncompare in the Visual Studio IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Modify the value in the **Option Compare** box.

To set -optioncompare programmatically

- See [Option Compare Statement](#).

Example

The following code compiles `ProjFile.vb` and uses binary string comparisons.

```
vbc -optioncompare:binary projFile.vb
```

-optionexplicit

2/28/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to report errors if variables are not declared before they are used.

Syntax

```
-optionexplicit[+ | -]
```

Arguments

+ | -

Optional. Specify `-optionexplicit+` to require explicit declaration of variables. The `-optionexplicit+` option is the default and is the same as `-optionexplicit`. The `-optionexplicit-` option enables implicit declaration of variables.

Remarks

If the source code file contains an [Option Explicit statement](#), the statement overrides the `-optionexplicit` command-line compiler setting.

To set `-optionexplicit` in the Visual Studio IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Modify the value in the **Option Explicit** box.

Example

The following code compiles when `-optionexplicit-` is used.

```
Module Module1
    Sub Main()
        i = 99
        System.Console.WriteLine(i)
    End Sub
End Module
```

- [Visual Basic Defaults, Projects, Options Dialog Box](#)

-optioninfer

1/23/2019 • 2 minutes to read • [Edit Online](#)

Enables the use of local type inference in variable declarations.

Syntax

```
-optioninfer[+ | -]
```

Arguments

TERM	DEFINITION
+ -	Optional. Specify <code>-optioninfer+</code> to enable local type inference, or <code>-optioninfer-</code> to block it. The <code>-optioninfer</code> option, with no value specified, is the same as <code>-optioninfer+</code> . The default value when the <code>-optioninfer</code> switch is not present is also <code>-optioninfer+</code> . The default value is set in the Vbc.rsp response file.

NOTE

You can use the `-noconfig` option to retain the compiler's internal defaults instead of those specified in vbc.rsp. The compiler default for this option is `-optioninfer-`.

Remarks

If the source code file contains an [Option Infer Statement](#), the statement overrides the `-optioninfer` command-line compiler setting.

To set `-optioninfer` in the Visual Studio IDE

1. Select a project in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. On the **Compile** tab, modify the value in the **Option infer** box.

Example

The following code compiles `test.vb` with local type inference enabled.

```
vbc -optioninfer+ test.vb
```

-optionstrict

1/23/2019 • 2 minutes to read • [Edit Online](#)

Enforces strict type semantics to restrict implicit type conversions.

Syntax

```
-optionstrict[+ | -]  
-optionstrict[:custom]
```

Arguments

+ | -

Optional. The `-optionstrict+` option restricts implicit type conversion. The default for this option is `-optionstrict-`. The `-optionstrict+` option is the same as `-optionstrict`. You can use both for permissive type semantics.

custom

Required. Warn when strict language semantics are not respected.

Remarks

When `-optionstrict+` is in effect, only widening type conversions can be made implicitly. Implicit narrowing type conversions, such as assigning a `Decimal` type object to an integer type object, are reported as errors.

To generate warnings for implicit narrowing type conversions, use `-optionstrict:custom`. Use `-nowarn:numberlist` to ignore particular warnings and `-warnaserror:numberlist` to treat particular warnings as errors.

To set `-optionstrict` in the Visual Studio IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Modify the value in the **Option Strict** box.

To set `-optionstrict` programmatically

- See [Option Strict Statement](#).

Example

The following code compiles `Test.vb` using strict type semantics.

```
vbc -optionstrict+ test.vb
```

-out (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies the name of the output file.

Syntax

```
-out:filename
```

Arguments

TERM	DEFINITION
<code>filename</code>	Required. The name of the output file the compiler creates. If the file name contains a space, enclose the name in quotation marks ("").

Remarks

Specify the full name and extension of the file to create. If you do not, the .exe file takes its name from the source-code file containing the `Sub Main` procedure, and the .dll file takes its name from the first source-code file.

If you specify a file name without an .exe or .dll extension, the compiler automatically adds the extension for you, depending on the value specified for the `-target` compiler option.

TO SET -OUT IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Application** tab.
3. Modify the value in the **Assembly Name** box.

Example

The following code compiles `T2.vb` and creates output file `T2.exe`.

```
vbc t2.vb -out:t3.exe
```

-platform (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies which platform version of common language runtime (CLR) can run the output file.

Syntax

```
-platform:{ x86 | x64 | Itanium | arm | anycpu | anycpu32bitpreferred }
```

Arguments

TERM	DEFINITION
x86	Compiles your assembly to be run by the 32-bit, x86-compatible CLR.
x64	Compiles your assembly to be run by the 64-bit CLR on a computer that supports the AMD64 or EM64T instruction set.
Itanium	Compiles your assembly to be run by the 64-bit CLR on a computer with an Itanium processor.
arm	Compiles your assembly to be run on a computer with an ARM (Advanced RISC Machine) processor.
anycpu	Compiles your assembly to run on any platform. The application will run as a 32-bit application on 32-bit versions of Windows and as a 64-bit application on 64-bit versions of Windows. This flag is the default value.
anycpu32bitpreferred	Compiles your assembly to run on any platform. The application will run as a 32-bit application on both 32-bit and 64-bit versions of Windows. This flag is valid only for executables (.EXE) and requires .NET Framework 4.5.

Remarks

Use the `-platform` option to specify the type of processor targeted by the output file.

In general, .NET Framework assemblies written in Visual Basic will run the same regardless of the platform.

However, there are some cases that behave differently on different platforms. These common cases are:

- Structures that contain members that change size depending on the platform, such as any pointer type.
- Pointer arithmetic that includes constant sizes.
- Incorrect platform invoke or COM declarations that use `Integer` for handles instead of `IntPtr`.
- Casting `IntPtr` to `Integer`.
- Using platform invoke or COM interop with components that do not exist on all platforms.

The **-platform** option will mitigate some issues if you know you have made assumptions about the architecture your code will run on. Specifically:

- If you decide to target a 64-bit platform, and the application is run on a 32-bit machine, the error message comes much earlier and is more targeted at the problem than the error that occurs without using this switch.
- If you set the `x86` flag on the option and the application is subsequently run on a 64-bit machine, the application will run in the WOW subsystem instead of running natively.

On a 64-bit Windows operating system:

- Assemblies compiled with `-platform:x86` will execute on the 32-bit CLR running under WOW64.
- Executables compiled with the `-platform:anycpu` will execute on the 64-bit CLR.
- A DLL compiled with the `-platform:anycpu` will execute on the same CLR as the process into which it loaded.
- Executables that are compiled with `-platform:anycpu32bitpreferred` will execute on the 32-bit CLR.

For more information about how to develop an application to run on a 64-bit version of Windows, see [64-bit Applications](#).

To set **-platform** in the Visual Studio IDE

1. In **Solution Explorer**, choose the project, open the **Project** menu, and then click **Properties**.
2. On the **Compile** tab, select or clear the **Prefer 32-bit** check box, or, in the **Target CPU** list, choose a value.

For more information, see [Compile Page, Project Designer \(Visual Basic\)](#).

Example

The following example illustrates how to use the `-platform` compiler option.

```
vbc -platform:x86 myFile.vb
```

-quiet

1/23/2019 • 2 minutes to read • [Edit Online](#)

Prevents the compiler from displaying code for syntax-related errors and warnings.

Syntax

```
-quiet
```

Remarks

By default, `-quiet` is not in effect. When the compiler reports a syntax-related error or warning, it also outputs the line from source code. For applications that parse compiler output, it may be more convenient for the compiler to output only the text of the diagnostic.

In the following example, `Module1` outputs an error that includes source code when compiled without `-quiet`.

```
Module Module1
    Sub Main()
        x()
    End Sub
End Module
```

Output:

```
C:\projects\vb2.vb(3) : error BC30451: 'x' is not declared. It may be inaccessible due to its protection
level.

        x()
        ~
```

Compiled with `-quiet`, the compiler outputs only the following:

```
E:\test\t2.vb(3) : error BC30451: Name 'x' is not declared.
```

NOTE

The `-quiet` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles `t2.vb` and does not display code for syntax-related compiler diagnostics:

```
vbc -quiet t2.vb
```

-recurse

1/23/2019 • 2 minutes to read • [Edit Online](#)

Compiles source-code files in all child directories of either the specified directory or the project directory.

Syntax

```
-recurse:[dir\]file
```

Arguments

`dir`

Optional. The directory in which you want the search to begin. If not specified, the search begins in the project directory.

`file`

Required. The file(s) to search for. Wildcard characters are allowed.

Remarks

You can use wildcards in a file name to compile all matching files in the project directory without using `-recurse`. If no output file name is specified, the compiler bases the output file name on the first input file processed. This is generally the first file in the list of files compiled when viewed alphabetically. For this reason, it is best to specify an output file using the `-out` option.

NOTE

The `-recurse` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following command compiles all Visual Basic files in the current directory.

```
vbc *.vb
```

The following command compiles all Visual Basic files in the `Test\ABC` directory and any directories below it, and then generates `Test.ABC.dll`.

```
vbc -target:library -out:Test.ABC.dll -recurse:Test\ABC*.vb
```

-reference (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to make type information in the specified assemblies available to the project you are currently compiling.

Syntax

```
-reference:fileList  
' -or-  
-r:fileList
```

Arguments

TERM	DEFINITION
<code>fileList</code>	Required. Comma-delimited list of assembly file names. If the file name contains a space, enclose the name in quotation marks.

Remarks

The file(s) you import must contain assembly metadata. Only public types are visible outside the assembly. The [/addmodule](#) option imports metadata from a module.

If you reference an assembly (Assembly A) which itself references another assembly (Assembly B), you need to reference Assembly B if:

- A type from Assembly A inherits from a type or implements an interface from Assembly B.
- A field, property, event, or method that has a return type or parameter type from Assembly B is invoked.

Use [-libpath](#) to specify the directory in which one or more of your assembly references is located.

For the compiler to recognize a type in an assembly (not a module), it must be forced to resolve the type. One example of how you can do this is to define an instance of the type. Other ways are available to resolve type names in an assembly for the compiler. For example, if you inherit from a type in an assembly, the type name then becomes known to the compiler.

The Vbc.rsp response file, which references commonly used .NET Framework assemblies, is used by default.

Use `-noconfig` if you do not want the compiler to use Vbc.rsp.

The short form of `-reference` is `/r`.

Example

The following command compiles source file `Input.vb` and reference assemblies from `Metad1.dll` and `Metad2.dll` to produce `Out.exe`.

```
vbc -reference:metad1.dll,metad2.dll -out:out.exe input.vb
```

-refonly (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The **-refonly** option indicates that the primary output of the compilation should be a reference assembly instead of an implementation assembly. The `-refonly` parameter silently disables outputting PDBs, as reference assemblies cannot be executed.

Every compiler option is available in two forms: **-option** and **/option**. The documentation only shows the -option form.

Syntax

```
-refonly
```

Remarks

Visual Basic supports the `-refout` switch starting with version 15.3.

Reference assemblies are metadata-only assemblies that contain metadata but no implementation code. They include type and member information for everything except anonymous types. The reason for using `throw null` bodies (as opposed to no bodies) is so that PEVerify could run and pass (thus validating the completeness of the metadata).

Reference assemblies include an assembly-level [ReferenceAssembly](#) attribute. This attribute may be specified in source (then the compiler won't need to synthesize it). Because of this attribute, runtimes will refuse to load reference assemblies for execution (but they can still be loaded in a reflection-only context). Tools that reflect on assemblies need to ensure they load reference assemblies as reflection-only; otherwise, the runtime throws a [BadImageFormatException](#).

The `-refonly` and `-refout` options are mutually exclusive.

-refout (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

The **-refout** option specifies a file path where the reference assembly should be output.

Every compiler option is available in two forms: **-option** and **/option**. The documentation only shows the -option form.

Syntax

```
-refout:filepath
```

Arguments

`filepath` The path and filename of the reference assembly. It should generally be in a sub-folder of the primary assembly. The recommended convention (used by MSBuild) is to place the reference assembly in a "ref/" sub-folder relative to the primary assembly. All folders in `filepath` must exist; the compiler does not create them.

Remarks

Visual Basic supports the `-refout` switch starting with version 15.3.

Reference assemblies are metadata-only assemblies that contain metadata but no implementation code. They include type and member information for everything except anonymous types. Their method bodies are replaced with a single `throw null` statement. The reason for using `throw null` method bodies (as opposed to no bodies) is so that PEVerify can run and pass (thus validating the completeness of the metadata).

Reference assemblies include an assembly-level [ReferenceAssembly](#) attribute. This attribute may be specified in source (then the compiler won't need to synthesize it). Because of this attribute, runtimes refuse to load reference assemblies for execution (but they can still be loaded in a reflection-only context). Tools that reflect on assemblies need to ensure they load reference assemblies as reflection-only; otherwise, the runtime throws a [BadImageFormatException](#).

The `-refout` and `-refonly` options are mutually exclusive.

-removeintchecks

1/23/2019 • 2 minutes to read • [Edit Online](#)

Turns overflow-error checking for integer operations on or off.

Syntax

```
-removeintchecks[+ | -]
```

Arguments

TERM	DEFINITION
+ -	<p>Optional. The <code>-removeintchecks-</code> option causes the compiler to check all integer calculations for overflow errors. The default is <code>-removeintchecks-</code>.</p> <p>Specifying <code>-removeintchecks</code> or <code>-removeintchecks+</code> prevents error checking and can make integer calculations faster. However, without error checking, and if data type capacities are overflowed, incorrect results may be stored without raising an error.</p>

TO SET -REMOVEINTCHECKS IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Click the **Advanced** button.
4. Modify the value of the **Remove integer overflow checks** box.

Example

The following code compiles `Test.vb` and turns off integer overflow-error checking.

```
vbc -removeintchecks+ test.vb
```

-resource (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Embeds a managed resource in an assembly.

Syntax

```
-resource:filename[,identifier[,public|private]]
' -or-
-res:filename[,identifier[,public|private]]
```

Arguments

TERM	DEFINITION
<code>filename</code>	Required. The name of the resource file to embed in the output file. By default, <code>filename</code> is public in the assembly. Enclose the file name in quotation marks (" ") if it contains a space.
<code>identifier</code>	Optional. The logical name for the resource; the name used to load it. The default is the name of the file. Optionally, you can specify whether the resource is public or private in the assembly manifest, as with the following: <code>-res:filename.res, myname.res, public</code>

Remarks

Use `-linkresource` to link a resource to an assembly without placing the resource file in the output file.

If `filename` is a .NET Framework resource file created, for example, by the [Resgen.exe \(Resource File Generator\)](#) or in the development environment, it can be accessed with members in the [System.Resources](#) namespace (see [ResourceManager](#) for more information). To access all other resources at run time, use one of the following methods: [GetManifestResourceInfo](#), [GetManifestResourceNames](#), or [GetManifestResourceStream](#).

The short form of `-resource` is `-res`.

For information about how to set `-resource` in the Visual Studio IDE, see [Managing Application Resources \(.NET\)](#).

Example

The following code compiles `In.vb` and attaches resource file `Rf.resource`.

```
vbc -res:rf.resource in.vb
```

-rootnamespace

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies a namespace for all type declarations.

Syntax

```
-rootnamespace:namespace
```

Arguments

TERM	DEFINITION
namespace	The name of the namespace in which to enclose all type declarations for the current project.

Remarks

If you use the Visual Studio executable file (Devenv.exe) to compile a project created in the Visual Studio integrated development environment, use `-rootnamespace` to specify the value of the [RootNamespace](#) property. See [Devenv Command Line Switches](#) for more information.

Use the common language runtime MSIL Disassembler (`Ildasm.exe`) to view the namespace names in your output file.

TO SET -ROOTNAMESPACE IN THE VISUAL STUDIO INTEGRATED DEVELOPMENT ENVIRONMENT

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Application** tab.
3. Modify the value in the **Root Namespace** box.

Example

The following code compiles `In.vb` and encloses all type declarations in the namespace `mynamespace`.

```
vbc -rootnamespace:mynamespace in.vb
```

-sdkpath

1/23/2019 • 2 minutes to read • [Edit Online](#)

Specifies the location of msclib.dll and Microsoft.VisualBasic.dll.

Syntax

```
-sdkpath: path
```

Arguments

path

The directory containing the versions of msclib.dll and Microsoft.VisualBasic.dll to use for compilation. This path is not verified until it is loaded. Enclose the directory name in quotation marks (" ") if it contains a space.

Remarks

This option tells the Visual Basic compiler to load the msclib.dll and Microsoft.VisualBasic.dll files from a non-default location. The `-sdkpath` option was designed to be used with `-netcf`. The .NET Compact Framework uses different versions of these support libraries to avoid the use of types and language features not found on the devices.

NOTE

The `-sdkpath` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. The `-sdkpath` option is set when a Visual Basic device project is loaded.

You can specify that the compiler should compile without a reference to the Visual Basic Runtime Library by using the `-vbruntime` compiler option. For more information, see [-vbruntime](#).

Example

The following code compiles `Myfile.vb` with the .NET Compact Framework, using the versions of Msclib.dll and Microsoft.VisualBasic.dll found in the default installation directory of the .NET Compact Framework on the C drive. Typically, you would use the most recent version of the .NET Compact Framework.

```
vbc -netcf -sdkpath:"c:\Program Files\Microsoft Visual Studio .NET 2003\CompactFrameworkSDK\v1.0.5000\Windows CE" myfile.vb
```

-target (Visual Basic)

3/25/2019 • 4 minutes to read • [Edit Online](#)

Specifies the format of compiler output.

Syntax

```
-target:{exe | library | module | winexe | appcontainerexe | winmdobj}
```

Remarks

The following table summarizes the effect of the `-target` option.

OPTION	BEHAVIOR
<code>-target:exe</code>	<p>Causes the compiler to create an executable console application.</p> <p>This is the default option when no <code>-target</code> option is specified. The executable file is created with an .exe extension.</p> <p>Unless otherwise specified with the <code>/out</code> option, the output file name takes the name of the input file that contains the <code>Sub Main</code> procedure.</p> <p>Only one <code>Sub Main</code> procedure is required in the source-code files that are compiled into an .exe file. Use the <code>-main</code> compiler option to specify which class contains the <code>Sub Main</code> procedure.</p>
<code>-target:library</code>	<p>Causes the compiler to create a dynamic-link library (DLL).</p> <p>The dynamic-link library file is created with a .dll extension.</p> <p>Unless otherwise specified with the <code>-out</code> option, the output file name takes the name of the first input file.</p> <p>When building a DLL, a <code>Sub Main</code> procedure is not required.</p>

OPTION	BEHAVIOR
<code>-target:module</code>	<p>Causes the compiler to generate a module that can be added to an assembly.</p> <p>The output file is created with an extension of .netmodule.</p> <p>The .NET common language runtime cannot load a file that does not have an assembly. However, you can incorporate such a file into the assembly manifest of an assembly by using <code>-reference</code>.</p> <p>When code in one module references internal types in another module, both modules must be incorporated into an assembly manifest by using <code>-reference</code>.</p> <p>The <code>-addmodule</code> option imports metadata from a module.</p>
<code>-target:winexe</code>	<p>Causes the compiler to create an executable Windows-based application.</p> <p>The executable file is created with an .exe extension. A Windows-based application is one that provides a user interface from either the .NET Framework class library or with the Windows APIs.</p> <p>Unless otherwise specified with the <code>-out</code> option, the output file name takes the name of the input file that contains the <code>Sub Main</code> procedure.</p> <p>Only one <code>Sub Main</code> procedure is required in the source-code files that are compiled into an .exe file. In cases where your code has more than one class that has a <code>Sub Main</code> procedure, use the <code>-main</code> compiler option to specify which class contains the <code>Sub Main</code> procedure</p>
<code>-target:appcontainerexe</code>	<p>Causes the compiler to create an executable Windows-based application that must be run in an app container. This setting is designed to be used for Windows 8.x Store applications.</p> <p>The appcontainerexe setting sets a bit in the Characteristics field of the Portable Executable file. This bit indicates that the app must be run in an app container. When this bit is set, an error occurs if the <code>CreateProcess</code> method tries to launch the application outside of an app container. Aside from this bit setting, -target:appcontainerexe is equivalent to -target:winexe.</p> <p>The executable file is created with an .exe extension.</p> <p>Unless you specify otherwise by using the <code>-out</code> option, the output file name takes the name of the input file that contains the <code>Sub Main</code> procedure.</p> <p>Only one <code>Sub Main</code> procedure is required in the source-code files that are compiled into an .exe file. If your code contains more than one class that has a <code>Sub Main</code> procedure, use the <code>-main</code> compiler option to specify which class contains the <code>Sub Main</code> procedure</p>

OPTION	BEHAVIOR
<code>-target:winmdobj</code>	<p>Causes the compiler to create an intermediate file that you can convert to a Windows Runtime binary (.winmd) file. The .winmd file can be consumed by JavaScript and C++ programs, in addition to managed language programs.</p> <p>The intermediate file is created with a .winmdobj extension.</p> <p>Unless you specify otherwise by using the <code>-out</code> option, the output file name takes the name of the first input file. A <code>Sub Main</code> procedure isn't required.</p> <p>The .winmdobj file is designed to be used as input for the WinMDExp export tool to produce a Windows metadata (WinMD) file. The WinMD file has a .winmd extension and contains both the code from the original library and the WinMD definitions that JavaScript, C++, and the Windows Runtime use.</p>

Unless you specify `-target:module`, `-target` causes a .NET Framework assembly manifest to be added to an output file.

Each instance of Vbc.exe produces, at most, one output file. If you specify a compiler option such as `-out` or `-target` more than one time, the last one the compiler processes is put into effect. Information about all files in a compilation is added to the manifest. All output files except those created with `-target:module` contain assembly metadata in the manifest. Use [Ildasm.exe \(IL Disassembler\)](#) to view the metadata in an output file.

The short form of `-target` is `-t`.

To set `-target` in the Visual Studio IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Application** tab.
3. Modify the value in the **Application Type** box.

Example

The following code compiles `in.vb`, creating `in.dll`:

```
vbc -target:library in.vb
```

-subsystemversion (Visual Basic)

3/6/2019 • 2 minutes to read • [Edit Online](#)

Specifies the minimum version of the subsystem on which the generated executable file can run, thereby determining the versions of Windows on which the executable file can run. Most commonly, this option ensures that the executable file can leverage particular security features that aren't available with older versions of Windows.

NOTE

To specify the subsystem itself, use the [-target](#) compiler option.

Syntax

```
-subsystemversion:major.minor
```

Parameters

`major.minor`

The minimum required version of the subsystem, as expressed in a dot notation for major and minor versions. For example, you can specify that an application can't run on an operating system that's older than Windows 7 if you set the value of this option to 6.01, as the table later in this topic describes. You must specify the values for `major` and `minor` as integers.

Leading zeroes in the `minor` version don't change the version, but trailing zeroes do. For example, 6.1 and 6.01 refer to the same version, but 6.10 refers to a different version. We recommend expressing the minor version as two digits to avoid confusion.

Remarks

The following table lists common subsystem versions of Windows.

WINDOWS VERSION	SUBSYSTEM VERSION
Windows 2000	5.00
Windows XP	5.01
Windows Server 2003	5.02
Windows Vista	6.00
Windows 7	6.01
Windows Server 2008	6.01
Windows 8	6.02

Default values

The default value of the **-subsystemversion** compiler option depends on the conditions in the following list:

- The default value is 6.02 if any compiler option in the following list is set:
 - [-target:appcontainerexe](#)
 - [-targetwinmdobj](#)
 - [-platform:arm](#)
- The default value is 6.00 if you're using MSBuild, you're targeting .NET Framework 4.5, and you haven't set any of the compiler options that were specified earlier in this list.
- The default value is 4.00 if none of the previous conditions is true.

Setting this option

To set the **-subsystemversion** compiler option in Visual Studio, you must open the .vbproj file and specify a value for the `SubsystemVersion` property in the MSBuild XML. You can't set this option in the Visual Studio IDE. For more information, see "Default values" earlier in this topic or [Common MSBuild Project Properties](#).

-utf8output (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Displays compiler output using UTF-8 encoding.

Syntax

```
-utf8output[+ | -]
```

Arguments

+ | -

Optional. The default for this option is `-utf8output-`, which means compiler output does not use UTF-8 encoding. Specifying `-utf8output` is the same as specifying `-utf8output+`.

Remarks

In some international configurations, compiler output cannot be displayed correctly in the console. In such situations, use `-utf8output` and redirect compiler output to a file.

NOTE

The `-utf8output` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles `In.vb` and directs the compiler to display output using UTF-8 encoding.

```
vbc -utf8output in.vb
```

-vbruntime

3/9/2019 • 2 minutes to read • [Edit Online](#)

Specifies that the compiler should compile without a reference to the Visual Basic Runtime Library, or with a reference to a specific runtime library.

Syntax

```
-vbruntime:{ - | + | * | path }
```

Arguments

- Compile without a reference to the Visual Basic Runtime Library.

+ Compile with a reference to the default Visual Basic Runtime Library.

\* Compile without a reference to the Visual Basic Runtime Library, and embed core functionality from the Visual Basic Runtime Library into the assembly.

path

Compile with a reference to the specified library (DLL).

Remarks

The `-vbruntime` compiler option enables you to specify that the compiler should compile without a reference to the Visual Basic Runtime Library. If you compile without a reference to the Visual Basic Runtime Library, errors or warnings are logged on code or language constructs that generate a call to a Visual Basic runtime helper. (A *Visual Basic runtime helper* is a function defined in Microsoft.VisualBasic.dll that is called at runtime to execute a specific language semantic.)

The `-vbruntime+` option produces the same behavior that occurs if no `-vbruntime` switch is specified. You can use the `-vbruntime+` option to override previous `-vbruntime` switches.

Most objects of the `My` type are unavailable when you use the `-vbruntime-` or `-vbruntime:path` options.

Embedding Visual Basic Runtime core functionality

The `-vbruntime*` option enables you to compile without a reference to a runtime library. Instead, core functionality from the Visual Basic Runtime Library is embedded in the user assembly. You can use this option if your application runs on platforms that do not contain the Visual Basic runtime.

The following runtime members are embedded:

- [Conversions](#) class
- [AscW\(Char\)](#) method
- [AscW\(String\)](#) method

- [ChrW\(Int32\) method](#)
- [vbBack constant](#)
- [vbCr constant](#)
- [vbCrLf constant](#)
- [vbFormFeed constant](#)
- [vbLf constant](#)
- [vbNewLine constant](#)
- [vbNullChar constant](#)
- [vbNullString constant](#)
- [vbTab constant](#)
- [vbVerticalTab constant](#)
- Some objects of the `My` type

If you compile using the `-vbruntime*` option and your code references a member from the Visual Basic Runtime Library that is not embedded with the core functionality, the compiler returns an error that indicates that the member is not available.

Referencing a specified library

You can use the `path` argument to compile with a reference to a custom runtime library instead of the default Visual Basic Runtime Library.

If the value for the `path` argument is a fully qualified path to a DLL, the compiler will use that file as the runtime library. If the value for the `path` argument is not a fully qualified path to a DLL, the Visual Basic compiler will search for the identified DLL in the current folder first. It will then search in the path that you have specified by using the `-sdkpath` compiler option. If the `-sdkpath` compiler option is not used, the compiler will search for the identified DLL in the .NET Framework folder (`%systemroot%\Microsoft.NET\Framework\versionNumber`).

Example

The following example shows how to use the `-vbruntime` option to compile with a reference to a custom library.

```
vbc -vbruntime:C:\VBLibraries\CustomVBLibrary.dll
```

-verbose

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to produce verbose status and error messages.

Syntax

```
-verbose[+ | -]
```

Arguments

+ | -

Optional. Specifying `-verbose` is the same as specifying `-verbose+`, which causes the compiler to emit verbose messages. The default for this option is `-verbose-`.

Remarks

The `-verbose` option displays information about the total number of errors issued by the compiler, reports which assemblies are being loaded by a module, and displays which files are currently being compiled.

NOTE

The `-verbose` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles `In.vb` and directs the compiler to display verbose status information.

```
vbc -verbose in.vb
```

-warnaserror (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Causes the compiler to treat the first occurrence of a warning as an error.

Syntax

```
-warnaserror[+ | -][:numberList]
```

Arguments

TERM	DEFINITION
+ -	Optional. By default, <code>-warnaserror-</code> is in effect; warnings do not prevent the compiler from producing an output file. The <code>-warnaserror</code> option, which is the same as <code>-warnaserror+</code> , causes warnings to be treated as errors.
numberList	Optional. Comma-delimited list of the warning ID numbers to which the <code>-warnaserror</code> option applies. If no warning ID is specified, the <code>-warnaserror</code> option applies to all warnings.

Remarks

The `-warnaserror` option treats all warnings as errors. Any messages that would ordinarily be reported as warnings are instead reported as errors. The compiler reports subsequent occurrences of the same warning as warnings.

By default, `-warnaserror-` is in effect, which causes the warnings to be informational only. The `-warnaserror` option, which is the same as `-warnaserror+`, causes warnings to be treated as errors.

If you want only a few specific warnings to be treated as errors, you may specify a comma-separated list of warning numbers to treat as errors.

NOTE

The `-warnaserror` option does not control how warnings are displayed. Use the `-nowarn` option to disable warnings.

TO SET -WARNASERROR TO TREAT ALL WARNINGS AS ERRORS IN THE VISUAL STUDIO IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Make sure the **Disable all warnings** check box is unchecked.
4. Check the **Treat all warnings as errors** check box.

TO SET -WARNASERROR TO TREAT SPECIFIC WARNINGS AS ERRORS IN THE VISUAL STUDIO IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Compile** tab.
3. Make sure the **Disable all warnings** check box is unchecked.
4. Make sure the **Treat all warnings as errors** check box is unchecked.
5. Select **Error** from the **Notification** column adjacent to the warning that should be treated as an error.

Example

The following code compiles `In.vb` and directs the compiler to display an error for the first occurrence of every warning it finds.

```
vbc -warnaserror in.vb
```

Example

The following code compiles `T2.vb` and treats only the warning for unused local variables (42024) as an error.

```
vbc -warnaserror:42024 t2.vb
```

-win32icon

1/23/2019 • 2 minutes to read • [Edit Online](#)

Inserts an .ico file in the output file. This .ico file represents the output file in **File Explorer**.

Syntax

```
-win32icon:filename
```

Arguments

TERM	DEFINITION
<code>filename</code>	The .ico file to add to your output file. Enclose the file name in quotation marks (" ") if it contains a space.

Remarks

You can create an .ico file with the Microsoft Windows Resource Compiler (RC). The resource compiler is invoked when you compile a Visual C++ program; an .ico file is created from the .rc file. The `-win32icon` and `-win32resource` options are mutually exclusive.

See [-linkresource \(Visual Basic\)](#) to reference a .NET Framework resource file, or [-resource \(Visual Basic\)](#) to attach a .NET Framework resource file. See [-win32resource](#) to import a .res file.

TO SET -WIN32ICON IN THE VISUAL STUDIO IDE

1. Have a project selected in **Solution Explorer**. On the **Project** menu, click **Properties**.
2. Click the **Application** tab.
3. Modify the value in the **Icon** box.

Example

The following code compiles `In.vb` and attaches an .ico file, `Rf.ico`.

```
vbc -win32icon:rf.ico in.vb
```

-win32manifest (Visual Basic)

1/23/2019 • 2 minutes to read • [Edit Online](#)

Identifies a user-defined Win32 application manifest file to be embedded into a project's portable executable (PE) file.

Syntax

```
-win32manifest: fileName
```

Arguments

TERM	DEFINITION
fileName	The path of the custom manifest file.

Remarks

By default, the Visual Basic compiler embeds an application manifest that specifies a requested execution level of asInvoker. It creates the manifest in the same folder in which the executable file is built, typically the bin\Debug or bin\Release folder when you use Visual Studio. If you want to supply a custom manifest, for example to specify a requested execution level of highestAvailable or requireAdministrator, use this option to specify the name of the file.

NOTE

This option and the [-win32resource](#) option are mutually exclusive. If you try to use both options in the same command line, you will get a build error.

An application that has no application manifest that specifies a requested execution level will be subject to file/registry virtualization under the User Account Control feature in Windows Vista. For more information about virtualization, see [ClickOnce Deployment on Windows Vista](#).

Your application will be subject to virtualization if either of the following conditions is true:

1. You use the `-nowin32manifest` option and you do not provide a manifest in a later build step or as part of a Windows Resource (.res) file by using the `-win32resource` option.
2. You provide a custom manifest that does not specify a requested execution level.

Visual Studio creates a default .manifest file and stores it in the debug and release directories alongside the executable file. You can view or edit the default app.manifest file by clicking **View UAC Settings** on the **Application** tab in the Project Designer. For more information, see [Application Page, Project Designer \(Visual Basic\)](#).

You can provide the application manifest as a custom post-build step or as part of a Win32 resource file by using the `-nowin32manifest` option. Use that same option if you want your application to be subject to file or registry virtualization on Windows Vista. This will prevent the compiler from creating and embedding a default manifest in the PE file.

Example

The following example shows the default manifest that the Visual Basic compiler inserts into a PE.

NOTE

The compiler inserts a standard application name `MyApplication.app` into the manifest XML. This is a workaround to enable applications to run on Windows Server 2003 Service Pack 3.

```
<?xml version="1.0" encoding="utf-8" standalone="yes"?>
<assembly xmlns="urn:schemas-microsoft-com:asm.v1" manifestVersion="1.0">
  <assemblyIdentity version="1.0.0.0" name="MyApplication.app"/>
  <trustInfo xmlns="urn:schemas-microsoft-com:asm.v2">
    <security>
      <requestedPrivileges xmlns="urn:schemas-microsoft-com:asm.v3">
        <requestedExecutionLevel level="asInvoker"/>
      </requestedPrivileges>
    </security>
  </trustInfo>
</assembly>
```

-win32resource

1/23/2019 • 2 minutes to read • [Edit Online](#)

Inserts a Win32 resource file in the output file.

Syntax

```
-win32resource:filename
```

Arguments

`filename`

The name of the resource file to add to your output file. Enclose the file name in quotation marks (" ") if it contains a space.

Remarks

You can create a Win32 resource file with the Microsoft Windows Resource Compiler (RC).

A Win32 resource can contain version or bitmap (icon) information that helps identify your application in **File Explorer**. If you do not specify `-win32resource`, the compiler generates version information based on the assembly version. The `-win32resource` and `-win32icon` options are mutually exclusive.

See [-linkresource \(Visual Basic\)](#) to reference a .NET Framework resource file, or [-resource \(Visual Basic\)](#) to attach a .NET Framework resource file.

NOTE

The `-win32resource` option is not available from within the Visual Studio development environment; it is available only when compiling from the command line.

Example

The following code compiles `In.vb` and attaches a Win32 resource file, `Rf.res`:

```
vbc -win32resource:rf.res in.vb
```

Visual Basic compiler options listed by category

2/5/2019 • 3 minutes to read • [Edit Online](#)

The Visual Basic command-line compiler is provided as an alternative to compiling programs from within the Visual Studio integrated development environment (IDE). The following is a list of the Visual Basic command-line compiler options sorted by functional category.

Every compiler option is available in two forms: **-option** and **/option**. The documentation only shows the -option form.

Compiler output

OPTION	PURPOSE
<code>-nologo</code>	Suppresses compiler banner information.
<code>-utf8output</code>	Displays compiler output using UTF-8 encoding.
<code>-verbose</code>	Outputs extra information during compilation.
<code>-modulename:<string></code>	Specify the name of the source module
<code>-preferreduilang</code>	Specify a language for compiler output.

Optimization

OPTION	PURPOSE
<code>-filealign</code>	Specifies where to align the sections of the output file.
<code>-optimize</code>	Enables/disables optimizations.

Output files

OPTION	PURPOSE
<code>-doc</code>	Process documentation comments to an XML file.
<code>-deterministic</code>	Causes the compiler to output an assembly whose binary content is identical across compilations if inputs are identical.
<code>-netcf</code>	Sets the compiler to target the .NET Compact Framework.
<code>-out</code>	Specifies an output file.
<code>-refonly</code>	Outputs only a reference assembly.
<code>-refout</code>	Specifies the output path of a reference assembly.

OPTION	PURPOSE
-target	Specifies the format of the output.

.NET assemblies

OPTION	PURPOSE
-addmodule	Causes the compiler to make all type information from the specified file(s) available to the project you are currently compiling.
-delaysign	Specifies whether the assembly will be fully or partially signed.
-imports	Imports a namespace from a specified assembly.
-keycontainer	Specifies a key container name for a key pair to give an assembly a strong name.
-keyfile	Specifies a file containing a key or key pair to give an assembly a strong name.
-libpath	Specifies the location of assemblies referenced by the -reference option.
-reference	Imports metadata from an assembly.
-moduleassemblyname	Specifies the name of the assembly that a module will be a part of.
-analyzer	Run the analyzers from this assembly (Short form: -a)
-additionalfile	Names additional files that don't directly affect code generation but may be used by analyzers for producing errors or warnings.

Debugging/error checking

OPTION	PURPOSE
-bugreport	Creates a file that contains information that makes it easy to report a bug.
-debug	Produces debugging information.
-nowarn	Suppresses the compiler's ability to generate warnings.
-quiet	Prevents the compiler from displaying code for syntax-related errors and warnings.
-removeintchecks	Disables integer overflow checking.
-warnaserror	Promotes warnings to errors.

OPTION	PURPOSE
<code>-ruleset:<file></code>	Specify a ruleset file that disables specific diagnostics.

Help

OPTION	PURPOSE
<code>-?</code>	Displays the compiler options. This command is the same as specifying the <code>-help</code> option. No compilation occurs.
<code>-help</code>	Displays the compiler options. This command is the same as specifying the <code>-?</code> option. No compilation occurs.

Language

OPTION	PURPOSE
<code>-langversion</code>	Specify language version: 9 9.0 10 10.0 11 11.0.
<code>-optionexplicit</code>	Enforces explicit declaration of variables.
<code>-optionstrict</code>	Enforces strict type semantics.
<code>-optioncompare</code>	Specifies whether string comparisons should be binary or use locale-specific text semantics.
<code>-optioninfer</code>	Enables the use of local type inference in variable declarations.

Preprocessor

OPTION	PURPOSE
<code>-define</code>	Defines symbols for conditional compilation.

Resources

OPTION	PURPOSE
<code>-linkresource</code>	Creates a link to a managed resource.
<code>-resource</code>	Embeds a managed resource in an assembly.
<code>-win32icon</code>	Inserts an .ico file into the output file.
<code>-win32resource</code>	Inserts a Win32 resource into the output file.

Miscellaneous

OPTION	PURPOSE
@ (Specify Response File)	Specifies a response file.
-baseaddress	Specifies the base address of a DLL.
-codepage	Specifies the code page to use for all source code files in the compilation.
-errorreport	Specifies how the Visual Basic compiler should report internal compiler errors.
-highentropyva	Tells the Windows kernel whether a particular executable supports high entropy Address Space Layout Randomization (ASLR).
-main	Specifies the class that contains the <code>Sub Main</code> procedure to use at startup.
-noconfig	Do not compile with Vbc.rsp
-nostdlib	Causes the compiler not to reference the standard libraries.
-nowin32manifest	Instructs the compiler not to embed any application manifest into the executable file.
-platform	Specifies the processor platform the compiler targets for the output file.
-recurse	Searches subdirectories for source files to compile.
-rootnamespace	Specifies a namespace for all type declarations.
-sdkpath	Specifies the location of Mscorlib.dll and Microsoft.VisualBasic.dll.
-vbruntime	Specifies that the compiler should compile without a reference to the Visual Basic Runtime Library, or with a reference to a specific runtime library.
-win32manifest	Identifies a user-defined Win32 application manifest file to be embedded into a project's portable executable (PE) file.
<code>-parallel[+ -]</code>	Specifies whether to use concurrent build (+).
<code>-checksumalgorithm:<alg></code>	Specify the algorithm for calculating the source file checksum stored in PDB. Supported values are: SHA1 (default) or SHA256.

What is ML.NET and how do I understand Machine Learning basics?

3/6/2019 • 2 minutes to read • [Edit Online](#)

ML.NET is a free, open-source, and cross-platform machine learning framework that enables you to build custom machine learning solutions and integrate them into your .NET applications. With the ML.NET APIs, you can incorporate AI into your apps using the .NET skills you already have and without leaving .NET.

NOTE

This documentation refers to ML.NET, which is currently in Preview. Material may be subject to change. For more information, see the [ML.NET introduction](#).

What is machine learning?

Machine learning is a data science technique that allows computers to use existing data to forecast future behaviors, outcomes, and trends. Using machine learning, computers learn without being explicitly programmed.

Forecasts or predictions from machine learning can make apps and devices smarter. When you shop online, machine learning helps recommend other products you might like based on what you've purchased. When your credit card is swiped, machine learning compares the transaction to a database of transactions and helps detect fraud. When your robot vacuum cleaner vacuums a room, machine learning helps it decide whether the job is done.

Basic concepts for model training in ML.NET

3/8/2019 • 5 minutes to read • [Edit Online](#)

This article explains the basic concepts covering *model training* scenarios in ML.NET. Not all concepts are relevant to the more simple scenario of *prediction with an existing model*.

This article and related sample are currently using **ML.NET version 0.10**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#).

Model training concepts

This document covers the following concepts related to model training in ML.NET:

- *Data* represented as an `IDataView` interface.
 - In ML.NET, data is similar to a SQL view: It's a lazily evaluated, immutable, cursorable, heterogenous, schematized dataset.
 - An excellent document about the data interface is [IDataView Design Principles](#).
- *Transformer* represented as `ITransformer` interface.
 - A transformer is a component that takes data, does some work on it, and returns new transformed data.
 - For example, you can think of a machine learning model as a transformer that takes features and returns predictions.
 - Another example, text tokenizer takes a single text column and outputs a vector column with individual words extracted out of the texts.
- *Data reader* represented as an `IDataReader<T>` interface.
 - The data reader is ML.NET component to create data. It takes an instance of `T` and returns data out of it.
 - For example, a *TextLoader* is an `IDataReader<IMultiStreamSource>`. It takes the source and produces data.
- *Estimator* represented as an `IEstimator<T>` interface.
 - This is an object that learns from data. The result of the learning is a *transformer*.
 - You can think of a machine learning *algorithm* as an estimator that learns on data and produces a machine learning *model*.
- *Prediction function* represented as a `PredictionEngine<TSrc, TDst>` class.
 - The prediction function can be seen as a machine that applies a transformer to one row, such as at prediction time.

Data

In ML.NET, data is similar to a SQL view: It's a lazily evaluated, cursorable, heterogenous, schematized dataset.

- It has *Schema* (an instance of an `ISchema` interface) that contains the information about the data view's columns.
 - Each column has a *Name*, a *Type*, and an arbitrary set of *metadata* associated with it.
 - The column's *metadata* contains information like slot names of a vector column and the like. The metadata itself is represented as another one-row *data* that is unique to each column.
 - The data view is a source of *ursors*. Think SQL cursors: A cursor is an object that iterates through the data, one row at a time, and presents the available data.
 - Naturally, data can have as many active cursors over it as needed. Since data itself is immutable, cursors are truly independent.
 - Cursors typically access only a subset of columns: For efficiency, ML.NET computes only the values of

columns that are needed by the cursor.

Transformer

A transformer is a component that takes data, does some work on it, and returns new transformed data.

Most transformers in ML.NET tend to operate on one *input column* at a time, and produce the *output column*. For example, a `new HashTransformer("bar", "foo")` takes the values from column "foo", hashes them, and puts them into column "bar".

It's also common that the input and output column names are the same. In this case, the old column is replaced with the new one. For example, a `new HashTransformer("foo")` takes the values from column "foo", hashes them, and puts them back into "foo".

Any transformer, produces a new data view when `Transform` is called. Remember, data views are immutable.

Another important consideration is that, because data is lazily evaluated, *transformers are lazy too*. Essentially, after you call

```
var newData = transformer.Transform(oldData)
```

no actual computation happens. Only after you get a cursor from `newData` and start consuming the value does `newData` invoke the `transformer` transformation logic (and even then, it only happens if the `transformer` in question is needed to produce the requested columns).

Transformer chains

A useful property of a transformer is that *you can build a sequential application of transformers as yet another transformer*:

```
var fullTransformer = transformer1.Append(transformer2).Append(transformer3);
```

This property is commonly used in ML.NET: typically, the trained ML.NET model is a chain of transformers, which is, for all intents and purposes, a *transformer*.

Data reader

The data reader is an ML.NET component to 'create' data: it takes an instance of `T` and returns data out of it.

An interesting property to note is that you can create a data reader by attaching a transformer to an existing data reader. This way you can have a reader with transformation behavior baked in:

```
var newReader = reader.Append(transformer1).Append(transformer2)
```

Another similarity to transformers is that, since data is lazily evaluated, *readers are lazy*: no (or minimal) actual 'reading' happens when you call `reader.Read()`: only when a cursor is requested on the resulting data does the reader begin to work.

Estimator

The *estimator* is an object that learns from data. The result of the learning is a *transformer*.

In ML.NET, use this property to create learning pipelines that chain together different estimators:

```

MLContext mlContext = new MLContext(seed: 0);

var pipeline = mlContext.Transforms.CopyColumns("Label", "FareAmount")
    .Append(mlContext.Transforms.Categorical.OneHotEncoding("VendorId"))
    .Append(mlContext.Transforms.Categorical.OneHotEncoding("RateCode"))
    .Append(mlContext.Transforms.Categorical.OneHotEncoding("PaymentType"))

    .Append(mlContext.Transforms.Concatenate("Features", "VendorId", "RateCode", "PassengerCount", "TripTime", "TripDistance", "PaymentType"))
    .Append(mlContext.Regression.Trainers.FastTree("Label", "Features"));

var model = pipeline.Fit(dataView);

```

One important property of estimators is that *estimators are eager, not lazy*: every call to `Fit` is causing learning to happen, which is potentially a time-consuming operation.

Prediction function

The prediction function can be seen as a component that applies a transformer to one row.

Once you get the model (a *transformer* either trained via `Fit()`, or loaded from somewhere), you can use it to make predictions using the normal calls to `model.Transform(data)`. However, when you use this model in a real-life scenario, you often don't have many examples to predict on. Instead, you have one example at a time, and you need to make timely predictions on them immediately.

Of course, you can reduce this to the batch prediction:

- Create a data view with exactly one row.
- Call `model.Transform(data)` to get the predicted data view.
- Get a cursor over the resulting data.
- Advance the cursor one step to get to the first (and only) row.
- Extract the predicted values out of it.

The preceding algorithm can be implemented using the [schema comprehension](#), with two user-defined objects

`InputExample` and `OutputPrediction` as follows:

```

var inputData = mlContext.Data.ReadFromEnumerable(new InputExample[] { example });
var outputData = model.Transform(inputData);
var output = mlContext.CreateEnumerable<OutputPrediction>(outputData, reuseRowObject:false).First();

```

But this is cumbersome and incurs performance costs. Instead, a prediction function object performs the same work, but faster and more convenient, via an extension method `CreatePredictionEngine`:

```

var predictionEngine = model.CreatePredictionEngine<InputExample,OutputPrediction>(mlContext);
var prediction = predictionEngine.Predict(example);

```

The prediction function is *not re-entrant/thread-safe*. If you want to conduct predictions simultaneously with multiple threads, you need to have a prediction function per thread.

Tutorial: Use ML.NET in a sentiment analysis binary classification scenario

3/21/2019 • 18 minutes to read • [Edit Online](#)

This sample tutorial illustrates using ML.NET to create a sentiment classifier to predict either positive or negative sentiment via a .NET Core console application using C# in Visual Studio 2017. In the world of machine learning, this type of prediction is known as binary classification.

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit [the ML.NET introduction](#).

This tutorial and related sample are currently using **ML.NET version 0.11**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#)

In this tutorial, you learn how to:

- Understand the problem
- Select the appropriate machine learning algorithm
- Prepare your data
- Transform the data
- Train the model
- Evaluate the model
- Predict with the trained model
- Deploy and Predict with a loaded model

Sentiment analysis sample overview

The sample is a console app that uses ML.NET to train a model that classifies and predicts sentiment as either positive or negative. The Yelp sentiment dataset is from University of California, Irvine (UCI), which is split into a train dataset and a test dataset. The sample evaluates the model with the test dataset for quality analysis.

You can find the source code for this tutorial at the [dotnet/samples](#) repository.

Prerequisites

- [Visual Studio 2017 15.6 or later](#) with the ".NET Core cross-platform development" workload installed.
- [The UCI Sentiment Labeled Sentences dataset zip file](#)

Machine learning workflow

This tutorial follows a machine learning workflow that enables the process to move in an orderly fashion.

The workflow phases are as follows:

1. **Understand the problem**
2. **Prepare your data**
 - **Load the data**

- Extract features (Transform your data)
3. Build and train
 - Train the model
 - Evaluate the model
 4. Deploy Model
 - Use the Model to predict

Understand the problem

You first need to understand the problem, so you can break it down to parts that can support building and training the model. Breaking the problem down allows you to predict and evaluate the results.

The problem for this tutorial is to understand incoming website comment sentiment to take the appropriate action.

You can break down the problem to the sentiment text and sentiment value for the data you want to train the model with, and a predicted sentiment value that you can evaluate and then use operationally.

You then need to **determine** the sentiment, which helps you with the machine learning task selection.

Select the appropriate machine learning algorithm

With this problem, you know the following facts:

Training data: website comments can be positive (1) or negative (0) (**sentiment**).

Predict the **sentiment** of a new website comment, either positive or negative, such as in the following examples:

- I love the wait staff here. They rock.
- This place has the worst soup.

The classification machine learning algorithm is best suited for this scenario.

About the classification algorithm

Classification is a machine learning algorithm that uses data to **determine** the category, type, or class of an item or row of data. For example, you can use classification to:

- Identify sentiment as positive or negative.
- Classify email as spam, junk, or good.
- Determine whether a patient's lab sample is cancerous.
- Categorize customers by their propensity to respond to a sales campaign.

Classification algorithms are frequently one of the following types:

- Binary: either A or B.
- Multiclass: multiple categories that can be predicted by using a single model.

Because the website comments need to be classified as either positive or negative, you use the Binary Classification algorithm.

Create a console application

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the **New Project** dialog, select the **Visual C#** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "SentimentAnalysis" and then select the **OK** button.
2. Create a directory named *Data* in your project to save your data set files:

In **Solution Explorer**, right-click on your project and select **Add > New Folder**. Type "Data" and hit Enter.

3. Install the **Microsoft.ML NuGet Package**:

In Solution Explorer, right-click on your project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the Browse tab, search for **Microsoft.ML**, select that package in the list, and select the **Install** button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the **License Acceptance** dialog if you agree with the license terms for the packages listed.

Prepare your data

1. Download [The UCI Sentiment Labeled Sentences dataset zip file \(see citations in the following note\)](#), and unzip.
2. Copy the `yelp_labelled.txt` file into the *Data* directory you created.

NOTE

The datasets this tutorial uses are from the 'From Group to Individual Labels using Deep Features', Kotzias et. al., KDD 2015, and hosted at the UCI Machine Learning Repository - Dua, D. and Karra Taniskidou, E. (2017). UCI Machine Learning Repository [<http://archive.ics.uci.edu/ml>]. Irvine, CA: University of California, School of Information and Computer Science.

3. In Solution Explorer, right-click the `yelp_labelled.txt` file and select **Properties**. Under **Advanced**, change the value of **Copy to Output Directory** to **Copy if newer**.

Create classes and define paths

Add the following additional `using` statements to the top of the *Program.cs* file:

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Linq;
using Microsoft.Data.DataView;
using Microsoft.ML;
using Microsoft.ML.Data;
using Microsoft.ML.Trainers;
using Microsoft.ML.Transforms.Text;
```

You need to create two global fields to hold the recently downloaded dataset file path and the saved model file path:

- `_dataPath` has the path to the dataset used to train the model.
- `_modelPath` has the path where the trained model is saved.

Add the following code to the line right above the `Main` method to specify those paths:

```
static readonly string _dataPath = Path.Combine(Environment.CurrentDirectory, "Data", "yelp_labelled.txt");
static readonly string _modelPath = Path.Combine(Environment.CurrentDirectory, "Data", "Model.zip");
```

You need to create some classes for your input data and predictions. Add a new class to your project:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *SentimentData.cs*. Then, select the **Add** button.

The *SentimentData.cs* file opens in the code editor. Add the following `using` statement to the top of

SentimentData.cs:

```
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code, which has two classes `SentimentData` and `SentimentPrediction`, to the *SentimentData.cs* file:

```
public class SentimentData
{
    [LoadColumn(0)]
    public string SentimentText;

    [LoadColumn(1), ColumnName("Label")]
    public bool Sentiment;
}

public class SentimentPrediction
{
    [ColumnName("PredictedLabel")]
    public bool Prediction { get; set; }

    // [ColumnName("Probability")]
    public float Probability { get; set; }

    // [ColumnName("Score")]
    public float Score { get; set; }
}
```

The input dataset class, `SentimentData`, has a `string` for the comment (`SentimentText`) and a `bool` (`Sentiment`) that has a value for sentiment of either positive or negative. Both fields have `LoadColumnAttribute(Int32)` attributes attached to them. This attribute describes the order of each field in the data file. In addition, the `Sentiment` property has a `ColumnNameAttribute` to designate it as the `Label` field. `SentimentPrediction` is the class used for prediction after the model has been trained. It has a single boolean (`Sentiment`) and a `PredictedLabel` `ColumnName` attribute. The `Label` is used to create and train the model, and it's also used with the split out test dataset to evaluate the model. The `PredictedLabel` is used during prediction and evaluation. For evaluation, an input with training data, the predicted values, and the model are used.

When building a model with ML.NET you start by creating an `MLContext`. `MLContext` is comparable conceptually to using `DbContext` in Entity Framework. The environment provides a context for your ML job that can be used for exception tracking and logging.

Initialize variables in Main

Create a variable called `mlContext` and initialize it with a new instance of `MLContext`. Replace the `Console.WriteLine("Hello World!")` line with the following code in the `Main` method:

```
MLContext mlContext = new MLContext();
```

Add the following as the next line of code in the `Main` method:

```
TrainCatalogBase.TrainTestData splitDataView = LoadData(mlContext);
```

The `LoadData` method executes the following tasks:

- Loads the data.
- Splits the loaded dataset into train and test datasets.

- Returns the split train and test datasets.

Create the `LoadData` method, just after the `Main` method, using the following code:

```
public static TrainCatalogBase.TrainTestData LoadData(MLContext mlContext)
{
}
```

Load the data

Since your previously created `SentimentData` data model type matches the dataset schema, you can combine the initialization, mapping, and dataset loading into one line of code using the `MLContext.Data.LoadFromTextFile` wrapper for the [LoadFromTextFile method](#). It returns a `IDataView`.

As the input and output of `Transforms`, a `DataView` is the fundamental data pipeline type, comparable to `IEnumerable` for `LINQ`.

In ML.NET, data is similar to a SQL view. It is lazily evaluated, schematized, and heterogenous. The object is the first part of the pipeline, and loads the data. For this tutorial, it loads a dataset with comments and corresponding toxic or non toxic sentiment. This is used to create the model, and train it.

Add the following code as the first line of the `LoadData` method:

```
IDataView dataView = mlContext.Data.LoadFromTextFile<SentimentData>(_dataPath, hasHeader:false);
```

Split the dataset for model training and testing

Next, you need both a training dataset to train the model and a test dataset to evaluate the model. Use the `MLContext.BinaryClassification.TrainTestSplit` which wraps `TrainTestSplit` to split the loaded dataset into train and test datasets and return them inside of a `TrainCatalogBase.TrainTestData`. You can specify the fraction of data for the test set with the `testFraction` parameter. The default is 10% but you use 20% in this case to use more data for the evaluation.

To split the loaded data into the needed datasets, add the following code as the next line in the `LoadData` method:

```
TrainCatalogBase.TrainTestData splitDataView = mlContext.BinaryClassification.TrainTestSplit(dataView,
testFraction: 0.2);
```

Return the `splitDataView` at the end of the `LoadData` method:

```
return splitDataView;
```

Build and train the model

Add the following call to the `BuildAndTrainModel` method as the next line of code in the `Main` method:

```
ITransformer model = BuildAndTrainModel(mlContext, splitDataView.TrainSet);
```

The `BuildAndTrainModel` method executes the following tasks:

- Extracts and transforms the data.
- Trains the model.

- Predicts sentiment based on test data.
- Returns the model.

Create the `BuildAndTrainModel` method, just after the `Main` method, using the following code:

```
public static ITransformer BuildAndTrainModel(MLContext mlContext, IDataView splitTrainSet)
{
}
```

Notice that two parameters are passed into the `Train` method; a `MLContext` for the context (`mlContext`), and an `IDataView` for the training dataset (`splitTrainSet`).

Extract and transform the data

Pre-processing and cleaning data are important tasks that occur before a dataset is used effectively for machine learning. Raw data is often noisy and unreliable, and may be missing values. Using data without these modeling tasks can produce misleading results.

ML.NET's transform pipelines compose a custom set of transforms that are applied to your data before training or testing. The transforms' primary purpose is data **featurization**. Machine learning algorithms understand **featurized** data, so the next step is to transform our textual data into a format that our ML algorithms recognize. That format is a **numeric vector**.

Next, call `mlContext.Transforms.Text.FeaturizeText` which featurizes the text column (`SentimentText`) column into a numeric vector called `Features` used by the machine learning algorithm. This is a wrapper call that returns an `EstimatorChain<TLastTransformer>` that will effectively be a pipeline. Name this `pipeline` as you will then append the trainer to the `EstimatorChain`. Add this as the next line of code:

```
var pipeline = mlContext.Transforms.Text.FeaturizeText(outputColumnName: DefaultColumnNames.Features,
    inputColumnName: nameof(SentimentData.SentimentText))
```

WARNING

ML.NET Version 0.10 changed the order of the Transform parameters. This will not error out until you run the application and build the model. Use the parameter names for Transforms as illustrated in the previous code snippet.

This is the preprocessing/featurization step. Using additional components available in ML.NET can enable better results with your model.

Choose a learning algorithm

To add the trainer, call the `mlContext.BinaryClassification.Trainers.FastTree` wrapper method which returns a `FastTreeBinaryClassificationTrainer` object. This is a decision tree learner you'll use in this pipeline. The `FastTreeBinaryClassificationTrainer` is appended to the `pipeline` and accepts the featurized `SentimentText` (`Features`) and the `Label` input parameters to learn from the historic data.

Add the following code to the `BuildAndTrainModel` method:

```
.Append(mlContext.BinaryClassification.Trainers.FastTree(numLeaves: 50, numTrees: 50, minDatapointsInLeaves:
20));
```

Train the model

You train the model, `TransformerChain<TLastTransformer>`, based on the dataset that has been loaded and transformed. Once the estimator has been defined, you train your model using the `Fit` method while providing the already loaded training data. This returns a model to use for predictions. `pipeline.Fit()` trains the pipeline and returns a `Transformer` based on the `DataView` passed in. The experiment is not executed until the `.Fit()` method runs.

Add the following code to the `BuildAndTrainModel` method:

```
Console.WriteLine("===== Create and Train the Model =====");
var model = pipeline.Fit(splitTrainSet);
Console.WriteLine("===== End of training =====");
Console.WriteLine();
```

Save and Return the model trained to use for evaluation

At this point, you have a model of type `TransformerChain<TLastTransformer>` that can be integrated into any of your existing or new .NET applications. Return the model at the end of the `BuildAndTrainModel` method.

```
return model;
```

Evaluate the model

Now that you've created and trained the model, you need to evaluate it with a different dataset for quality assurance and validation. In the `Evaluate` method, the model created in `BuildAndTrainModel` is passed in to be evaluated. Create the `Evaluate` method, just after `BuildAndTrainModel`, as in the following code:

```
public static void Evaluate(MLContext mlContext, ITransformer model, IDataView splitTestSet)
{
```

The `Evaluate` method executes the following tasks:

- Loads the test dataset.
- Creates the binaryclassification evaluator.
- Evaluates the model and creates metrics.
- Displays the metrics.

Add a call to the new method from the `Main` method, right under the `Train` method call, using the following code:

```
Evaluate(mlContext, model, splitDataView.TestSet);
```

Next, you'll use the machine learning `model` parameter (a transformer) and the `splitTestSet` parameter to input the features and return predictions. Add the following code to the `Evaluate` method as the next line:

```
Console.WriteLine("===== Evaluating Model accuracy with Test data=====");
IDataView predictions = model.Transform(splitTestSet);
```

The `mlContext.BinaryClassification.Evaluate` method computes the quality metrics for the `PredictionModel` using the specified dataset. It returns a `CalibratedBinaryClassificationMetrics` object that contains the overall metrics

computed by binary classification evaluators. To display these to determine the quality of the model, you need to get the metrics first. Add the following code as the next line in the `Evaluate` method:

```
CalibratedBinaryClassificationMetrics metrics = mlContext.BinaryClassification.Evaluate(predictions, "Label");
```

Displaying the metrics for model validation

Use the following code to display the metrics, share the results, and then act on them:

```
Console.WriteLine();
Console.WriteLine("Model quality metrics evaluation");
Console.WriteLine("-----");
Console.WriteLine($"Accuracy: {metrics.Accuracy:P2}");
Console.WriteLine($"Auc: {metrics.Auc:P2}");
Console.WriteLine($"F1Score: {metrics.F1Score:P2}");
Console.WriteLine("===== End of model evaluation =====");
```

To save your model to a .zip file before returning, add the following code to call the `SaveModelAsFile` method as the next line in `Evaluate`:

```
SaveModelAsFile(mlContext, model);
```

Save the model as a.zip file

Create the `SaveModelAsFile` method, just after the `Evaluate` method, using the following code:

```
private static void SaveModelAsFile(MLContext mlContext, ITransformer model)
{
}
```

The `SaveModelAsFile` method executes the following tasks:

- Saves the model as a .zip file.

Next, create a method to save the model so that it can be reused and consumed in other applications. The `ITransformer` has a `SaveTo(IHostEnvironment, Stream)` method that takes in the `_modelPath` global field, and a `Stream`. To save this as a zip file, you'll create the `FileStream` immediately before calling the `SaveTo` method. Add the following code to the `SaveModelAsFile` method as the next line:

```
using (var fs = new FileStream(_modelPath, FileMode.Create, FileAccess.Write, FileShare.Write))
    mlContext.Model.Save(model, fs);
```

You could also display where the file was written by writing a console message with the `_modelPath`, using the following code:

```
Console.WriteLine("The model is saved to {0}", _modelPath);
```

Predict the test data outcome with the saved model

Create the `UseModelWithSingleItem` method, just after the `Evaluate` method, using the following code:

```
private static void UseModelWithSingleItem(MLContext mlContext, ITransformer model)
{
}
```

The `UseModelWithSingleItem` method executes the following tasks:

- Creates a single comment of test data.
- Predicts sentiment based on test data.
- Combines test data and predictions for reporting.
- Displays the predicted results.

Add a call to the new method from the `Main` method, right under the `Evaluate` method call, using the following code:

```
UseModelWithSingleItem(mlContext, model);
```

While the `model` is a `transformer` that operates on many rows of data, a very common production scenario is a need for predictions on individual examples. The `PredictionEngine<TSrc,TDst>` is a wrapper that is returned from the `CreatePredictionEngine` method. Let's add the following code to create the `PredictionEngine` as the first line in the `Predict` Method:

```
PredictionEngine<SentimentData, SentimentPrediction> predictionFunction =
model.CreatePredictionEngine<SentimentData, SentimentPrediction>(mlContext);
```

Add a comment to test the trained model's prediction in the `Predict` method by creating an instance of `SentimentData`:

```
SentimentData sampleStatement = new SentimentData
{
    SentimentText = "This was a very bad steak"
};
```

You can use that to predict the positive or negative sentiment of a single instance of the comment data. To get a prediction, use `Predict` on the data. Note that the input data is a string and the model includes the featurization. Your pipeline is in sync during training and prediction. You didn't have to write preprocessing/featurization code specifically for predictions, and the same API takes care of both batch and one-time predictions.

```
var resultprediction = predictionFunction.Predict(sampleStatement);
```

Use the model: prediction

Display `SentimentText` and corresponding sentiment prediction in order to share the results and act on them accordingly. This is called operationalization, using the returned data as part of the operational policies. Create a display for the results using the following `Console.WriteLine()` code:

```

Console.WriteLine();
Console.WriteLine("===== Prediction Test of model with a single sample and test dataset =====");
Console.WriteLine();
Console.WriteLine($"Sentiment: {sampleStatement.SentimentText} | Prediction: {(Convert.ToBoolean(resultprediction.Prediction) ? "Positive" : "Negative")}| Probability: {resultprediction.Probability}");
Console.WriteLine("===== End of Predictions =====");
Console.WriteLine();

```

Deploy and Predict with a loaded model

Create the `UseLoadedModelWithBatchItems` method, just before the `SaveModelAsFile` method, using the following code:

```

public static void UseLoadedModelWithBatchItems(MLContext mlContext)
{
}

```

The `UseLoadedModelWithBatchItems` method executes the following tasks:

- Creates batch test data.
- Predicts sentiment based on test data.
- Combines test data and predictions for reporting.
- Displays the predicted results.

Add a call to the new method from the `Main` method, right under the `UseModelWithSingleItem` method call, using the following code:

```
UseLoadedModelWithBatchItems(mlContext);
```

Add some comments to test the trained model's predictions in the `UseLoadedModelWithBatchItems` method:

```

IEnumerable<SentimentData> sentiments = new[]
{
    new SentimentData
    {
        SentimentText = "This was a horrible meal"
    },
    new SentimentData
    {
        SentimentText = "I love this spaghetti."
    }
};

```

Load the model

```

ITransformer loadedModel;
using (var stream = new FileStream(_modelPath, FileMode.Open, FileAccess.Read, FileShare.Read))
{
    loadedModel = mlContext.Model.Load(stream);
}

```

Now that you have a model, you can use that to predict the Toxic or Non Toxic sentiment of the comment data using the [Transform](#) method. To get a prediction, use [Predict](#) on new data. Note that the input data is a string and the model includes the featurization. Your pipeline is in sync during training and prediction. You didn't have to write preprocessing/featurization code specifically for predictions, and the same API takes care of both batch and one-time predictions. Add the following code to the [UseLoadedModelWithBatchItems](#) method for the predictions:

```
IDataView sentimentStreamingDataView = mlContext.Data.LoadFromEnumerable(sentiments);

IDataView predictions = loadedModel.Transform(sentimentStreamingDataView);

// Use model to predict whether comment data is Positive (1) or Negative (0).
IEnumerable<SentimentPrediction> predictedResults = mlContext.Data.CreateEnumerable<SentimentPrediction>
(predictions, reuseRowObject: false);
```

Use the loaded model for prediction

Display [SentimentText](#) and corresponding sentiment prediction in order to share the results and act on them accordingly. This is called operationalization, using the returned data as part of the operational policies. Create a header for the results using the following [Console.WriteLine\(\)](#) code:

```
Console.WriteLine();

Console.WriteLine("===== Prediction Test of loaded model with a multiple samples =====");
```

Before displaying the predicted results, combine the sentiment and prediction together to see the original comment with its predicted sentiment. The following code uses the [Zip](#) method to make that happen, so add that code next:

```
IEnumerable<(SentimentData sentiment, SentimentPrediction prediction)> sentimentsAndPredictions =
sentiments.Zip(predictedResults, (sentiment, prediction) => (sentiment, prediction));
```

Now that you've combined the [SentimentText](#) and [Sentiment](#) into a class, you can display the results using the [Console.WriteLine\(\)](#) method:

```
foreach ((SentimentData sentiment, SentimentPrediction prediction) item in sentimentsAndPredictions)
{
    Console.WriteLine($"Sentiment: {item.sentiment.SentimentText} | Prediction:
{Convert.ToBoolean(item.prediction.Prediction) ? "Positive" : "Negative"} | Probability:
{item.prediction.Probability}");

}
Console.WriteLine("===== End of predictions =====");
```

Because inferred tuple element names are a new feature in C# 7.1 and the default language version of the project is C# 7.0, you need to change the language version to C# 7.1 or higher. To do that, right-click on the project node in **Solution Explorer** and select **Properties**. Select the **Build** tab and select the **Advanced** button. In the dropdown, select **C# 7.1** (or a higher version). Select the **OK** button.

Results

Your results should be similar to the following. As the pipeline processes, it displays messages. You may see warnings, or processing messages. These have been removed from the following results for clarity.

Congratulations! You've now successfully built a machine learning model for classifying and predicting messages sentiment.

Building successful models is an iterative process. This model has initial lower quality as the tutorial uses small datasets to provide quick model training. If you aren't satisfied with the model quality, you can try to improve it by providing larger training datasets or by choosing different training algorithms with different hyper-parameters for each algorithm.

 - **Train the model**
 - **Evaluate the model**
 - Deploy Model**
 - **Use the Model to predict**

Understand the problem

You first need to understand the problem, so you can break it down to parts that can support building and training the model. Breaking down the problem allows you to predict and evaluate the results.

The problem for this tutorial is to understand what area incoming GitHub issues belong to in order to label them correctly for prioritization and scheduling.

You can break down the problem to the following parts:

- the issue title text
- the issue description text
- an area value for the model training data
- a predicted area value that you can evaluate and then use operationally

You then need to **determine** the area, which helps you with the machine learning task selection.

Select the appropriate machine learning algorithm

With this problem, you know the following facts:

Training data:

GitHub issues can be labeled in several areas (**Area**) as in the following examples:

- area-System.Numerics
- area-System.Xml
- area-Infrastructure
- area-System.Linq
- area-System.IO

Predict the **Area** of a new GitHub Issue such as in the following examples:

- Contract.Assert vs Debug.Assert
- Make fields readonly in System.Xml

The classification machine learning algorithm is best suited for this scenario.

About the classification learning algorithm

Classification is a machine learning algorithm that uses data to **determine** the category, type, or class of an item or row of data. For example, you can use classification to:

- Identify sentiment as positive or negative.
- Classify email as spam, junk, or good.
- Determine whether a patient's lab sample is cancerous.
- Categorize customers by their propensity to respond to a sales campaign.

Classification learning algorithm use cases are frequently one of the following types:

- Binary: either A or B.
- Multiclass: multiple categories that can be predicted by using a single model.

For this type of problem, use a Multiclass classification learning algorithm, since your issue category prediction can be one of multiple categories (multiclass) rather than just two (binary).

Create a console application

Create a project

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the **New Project** dialog, select the **Visual C#** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "GitHubIssueClassification" and then select the **OK** button.
2. Create a directory named *Data* in your project to save your data set files:

In **Solution Explorer**, right-click on your project and select **Add > New Folder**. Type "Data" and hit Enter.

3. Create a directory named *Models* in your project to save your model:

In **Solution Explorer**, right-click on your project and select **Add > New Folder**. Type "Models" and hit Enter.

4. Install the **Microsoft.ML NuGet Package**:

In Solution Explorer, right-click on your project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the Browse tab, search for **Microsoft.ML**, select that package in the list, and select the **Install** button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the **License Acceptance** dialog if you agree with the license terms for the packages listed.

Prepare your data

1. Download the [issues\\_train.tsv](#) and the [issues\\_test.tsv](#) data sets and save them to the *Data* folder previously created. The first dataset trains the machine learning model and the second can be used to evaluate how accurate your model is.
2. In Solution Explorer, right-click each of the \*.tsv files and select **Properties**. Under **Advanced**, change the value of **Copy to Output Directory** to **Copy if newer**.

Create classes and define paths

Add the following additional `using` statements to the top of the *Program.cs* file:

```
using System;
using System.IO;
using System.Linq;
using Microsoft.Data.DataView;
using Microsoft.ML;
using Microsoft.ML.Data;
using Microsoft.ML.Transforms;
```

Create three global fields to hold the paths to the recently downloaded files, and global variables for the `MLContext`, `DataView`, `PredictionEngine`, and `TextLoader`:

- `_trainFilePath` has the path to the dataset used to train the model.
- `_testFilePath` has the path to the dataset used to evaluate the model.
- `_modelPath` has the path where the trained model is saved.
- `_mlContext` is the `MLContext` that provides processing context.

- `_trainingDataView` is the `IDataView` used to process the training dataset.
- `_predEngine` is the `PredictionEngine<TSrc,TDst>` used for single predictions.
- `_reader` is the `TextLoader` used to load and transform the datasets.

Add the following code to the line right above the `Main` method to specify those paths and the other variables:

```
private static string _appPath => Path.GetDirectoryName(Environment.GetCommandLineArgs()[0]);
private static string _trainDataPath => Path.Combine(_appPath, "..", "..", "Data", "issues_train.tsv");
private static string _testDataPath => Path.Combine(_appPath, "..", "..", "Data", "issues_test.tsv");
private static string _modelPath => Path.Combine(_appPath, "..", "..", "Models", "model.zip");

private static MLContext _mlContext;
private static PredictionEngine<GitHubIssue, IssuePrediction> _predEngine;
private static ITransformer _trainedModel;
static IDataView _trainingDataView;
```

Create some classes for your input data and predictions. Add a new class to your project:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item** dialog box, select **Class** and change the **Name** field to `GitHubIssueData.cs`. Then, select the **Add** button.

The `GitHubIssueData.cs` file opens in the code editor. Add the following `using` statement to the top of `GitHubIssueData.cs`:

```
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code, which has two classes `GitHubIssue` and `IssuePrediction`, to the `GitHubIssueData.cs` file:

```
public class GitHubIssue
{
    [LoadColumn(0)]
    public string ID { get; set; }
    [LoadColumn(1)]
    public string Area { get; set; }
    [LoadColumn(2)]
    public string Title { get; set; }
    [LoadColumn(3)]
    public string Description { get; set; }
}

public class IssuePrediction
{
    [ColumnName("PredictedLabel")]
    public string Area;
}
```

`GitHubIssue` is the input dataset class and has the following `String` fields:

- `ID` contains a value for the GitHub issue ID
- `Area` contains a value for the `Area` label
- `Title` contains the GitHub issue title
- `Description` contains the GitHub issue description

`IssuePrediction` is the class used for prediction after the model has been trained. It has a single `string` (`Area`) and a `PredictedLabel` `ColumnName` attribute. The `Label` is used to create and train the model, and it's also used

with a second dataset to evaluate the model. The `PredictedLabel` is used during prediction and evaluation. For evaluation, an input with training data, the predicted values, and the model are used.

When building a model with ML.NET, you start by creating an `MLContext`. `MLContext` is comparable conceptually to using `DbContext` in Entity Framework. The environment provides a context for your ML job that can be used for exception tracking and logging.

Initialize variables in Main

Initialize the `_mlContext` global variable with a new instance of `MLContext` with a random seed (`seed: 0`) for repeatable/deterministic results across multiple trainings. Replace the `Console.WriteLine("Hello World!")` line with the following code in the `Main` method:

```
_mlContext = new MLContext(seed: 0);
```

Load the data

Next, initialize the `_trainingDataView` `IDataView` global variable and load the data with the `_trainDataPath` parameter.

As the input and output of `Transforms`, a `DataView` is the fundamental data pipeline type, comparable to `IEnumerable` for `LINQ`.

In ML.NET, data is similar to a `SQL view`. It is lazily evaluated, schematized, and heterogenous. The object is the first part of the pipeline, and loads the data. For this tutorial, it loads a dataset with issue titles, descriptions, and corresponding area GitHub label. The `DataView` is used to create and train the model.

Since your previously created `GitHubIssue` data model type matches the dataset schema, you can combine the initialization, mapping, and dataset loading into one line of code.

Load the data using the `MLContext.Data.LoadFromTextFile` wrapper for the [LoadFromTextFile method](#). It returns a `IDataView` which infers the dataset schema from the `GitHubIssue` data model type and uses the dataset header.

You defined the data schema previously when you created the `GitHubIssue` class. For your schema:

- the first column `ID` (GitHub Issue ID)
- the second column `Area` (the prediction for training)
- the third column `Title` (GitHub issue title) is the first **feature** used for predicting the `Area`
- the fourth column `Description` is the second feature used for predicting the `Area`

To initialize and load the `_trainingDataView` global variable in order to use it for the pipeline, add the following code after the `mlContext` initialization:

```
_trainingDataView = _mlContext.Data.LoadFromTextFile<GitHubIssue>(_trainDataPath, hasHeader: true);
```

Add the following as the next line of code in the `Main` method:

```
var pipeline = ProcessData();
```

The `ProcessData` method executes the following tasks:

- Extracts and transforms the data.
- Returns the processing pipeline.

Create the `ProcessData` method, just after the `Main` method, using the following code:

```
public static IEstimator<ITransformer> ProcessData()
{
}
```

Extract Features and transform the data

Pre-processing and cleaning data are important tasks that occur before a dataset is used effectively for machine learning. Raw data is often noisy and unreliable, and may be missing values. Using data without these modeling tasks can produce misleading results.

ML.NET's transform pipelines compose a custom `transforms` set that is applied to your data before training or testing. The transforms' primary purpose is data **featurization**. Machine learning algorithms understand **featurized** data, so the next step is to transform our textual data into a format that our ML algorithms recognize. That format is a **numeric vector**.

In the next steps, we refer to the columns by the names defined in the `GitHubIssue` class.

When the model is trained and evaluated, by default, the values in the **Label** column are considered as correct values to be predicted. As we want to predict the Area GitHub label for a `GitHubIssue`, copy the `Area` column into the **Label** column. To do that, use the `MLContext.Transforms.Conversion.MapValueToKey`, which is a wrapper for the `MapValueToKey` transformation class. The `MapValueToKey` returns an `EstimatorChain<TLastTransformer>` that will effectively be a pipeline. Name this `pipeline` as you will then append the trainer to the `EstimatorChain`. Add the next line of code:

```
var pipeline = _mlContext.Transforms.Conversion.MapValueToKey(inputColumnName: "Area", outputColumnName: "Label")
```

Featurizing assigns different numeric key values to the different values in each of the columns and is used by the machine learning algorithm. Next, call `_mlContext.Transforms.Text.FeaturizeText` which featurizes the text (`Title` and `Description`) columns into a numeric vector for each called `TitleFeaturized` and `DescriptionFeaturized`. Append the featurization for both columns to the pipeline with the following code:

```
.Append(_mlContext.Transforms.Text.FeaturizeText(inputColumnName: "Title", outputColumnName: "TitleFeaturized"))
.Append(_mlContext.Transforms.Text.FeaturizeText(inputColumnName: "Description", outputColumnName: "DescriptionFeaturized"))
```

WARNING

ML.NET Version 0.10 has changed the order of the Transform parameters. This will not error out until you build. Use the parameter names for Transforms as illustrated in the previous code snippet.

The last step in data preparation combines all of the feature columns into the **Features** column using the `Concatenate` transformation class. By default, a learning algorithm processes only features from the **Features** column. Append this transformation to the pipeline with the following code:

```
.Append(_mlContext.Transforms.Concatenate("Features", "TitleFeaturized", "DescriptionFeaturized"))
```

Next, append a `AppendCacheCheckpoint` to cache the `DataView` so when you iterate over the data multiple times

using the cache might get better performance, as with the following code:

```
.AppendCacheCheckpoint(_mlContext);
```

WARNING

Use `AppendCacheCheckpoint` for small/medium datasets to lower training time. Do NOT use it (remove `.AppendCacheCheckpoint()`) when handling very large datasets.

Return the pipeline at the end of the `ProcessData` method.

```
return pipeline;
```

This step handles preprocessing/featurization. Using additional components available in ML.NET can enable better results with your model.

Build and train the model

Add the following call to the `BuildAndTrainModel` method as the next line of code in the `Main` method:

```
var trainingPipeline = BuildAndTrainModel(_trainingDataView, pipeline);
```

The `BuildAndTrainModel` method executes the following tasks:

- Creates the training algorithm class.
- Trains the model.
- Predicts area based on training data.
- Saves the model to a `.zip` file.
- Returns the model.

Create the `BuildAndTrainModel` method, just after the `Main` method, using the following code:

```
public static IEstimator<ITransformer> BuildAndTrainModel(IDataView trainingDataView, IEstimator<ITransformer> pipeline)
{
}
```

Notice that two parameters are passed into the `BuildAndTrainModel` method; an `IDataView` for the training dataset (`trainingDataView`), and a `EstimatorChain<TLastTransformer>` for the processing pipeline created in `ProcessData` (`pipeline`).

Add the following code as the first line of the `BuildAndTrainModel` method:

Choose a learning algorithm

To add the learning algorithm, call the

`mlContext.MulticlassClassification.Trainers.StochasticDualCoordinateAscent` wrapper method which returns a `SdcaMultiClassTrainer` object. The `SdcaMultiClassTrainer` is appended to the `pipeline` and accepts the featurized `Title` and `Description` (`Features`) and the `Label` input parameters to learn from the historic data. You also need to map the label to the value to return to its original readable state. Do both of those actions with the following code:

```
var trainingPipeline =
pipeline.Append(_mlContext.MulticlassClassification.Trainers.StochasticDualCoordinateAscent(DefaultColumnNames
.Label, DefaultColumnNames.Features))
.Append(_mlContext.Transforms.Conversion.MapKeyToValue("PredictedLabel"));
```

Train the model

You train the model, [TransformerChain<TLastTransformer>](#), based on the dataset that has been loaded and transformed. Once the estimator has been defined, you train your model using the [Fit](#) while providing the already loaded training data. This method returns a model to use for predictions. `trainingPipeline.Fit()` trains the pipeline and returns a `Transformer` based on the `DataView` passed in. The experiment is not executed until the `.Fit()` method runs.

Add the following code to the `BuildAndTrainModel` method:

```
_trainedModel = trainingPipeline.Fit(trainingDataView);
```

While the `model` is a `transformer` that operates on many rows of data, a need for predictions on individual examples is a common production scenario. The [PredictionEngine<TSrc,TDst>](#) is a wrapper that is returned from the `CreatePredictionEngine` method. Let's add the following code to create the `PredictionEngine` as the next line in the `BuildAndTrainModel` Method:

```
_predEngine = _trainedModel.CreatePredictionEngine<GitHubIssue, IssuePrediction>(_mlContext);
```

Predict with the trained model

Add a GitHub issue to test the trained model's prediction in the `Predict` method by creating an instance of `GitHubIssue`:

```
GitHubIssue issue = new GitHubIssue() {
    Title = "WebSockets communication is slow in my machine",
    Description = "The WebSockets communication used under the covers by SignalR looks like is going slow in
my development machine.."
};
```

You can use that to predict the `Area` label of a single instance of the issue data. To get a prediction, use [Predict](#) on the data. The input data is a string and the model includes the featurization. Your pipeline is in sync during training and prediction. You didn't have to write preprocessing/featurization code specifically for predictions, and the same API takes care of both batch and one-time predictions.

```
var prediction = _predEngine.Predict(issue);
```

Using the model: prediction results

Display `GitHubIssue` and corresponding `Area` label prediction in order to share the results and act on them accordingly. Create a display for the results using the following [Console.WriteLine\(\)](#) code:

```
Console.WriteLine($"===== Single Prediction just-trained-model - Result: {prediction.Area}
=====");
```

Return the model trained to use for evaluation

Return the model at the end of the `BuildAndTrainModel` method.

```
return trainingPipeline;
```

Evaluate the model

Now that you've created and trained the model, you need to evaluate it with a different dataset for quality assurance and validation. In the `Evaluate` method, the model created in `BuildAndTrainModel` is passed in to be evaluated. Create the `Evaluate` method, just after `BuildAndTrainModel`, as in the following code:

```
public static void Evaluate()
{
}
```

The `Evaluate` method executes the following tasks:

- Loads the test dataset.
- Creates the multiclass evaluator.
- Evaluates the model and create metrics.
- Displays the metrics.

Add a call to the new method from the `Main` method, right under the `BuildAndTrainModel` method call, using the following code:

```
Evaluate();
```

As you did previously with the training dataset, you can combine the initialization, mapping, and test dataset loading into one line of code. You can evaluate the model using this dataset as a quality check. Add the following code to the `Evaluate` method:

```
var testDataView = _mlContext.Data.LoadFromTextFile<GitHubIssue>(_testDataPath, hasHeader: true);
```

The `MulticlassClassificationContext.Evaluate` is a wrapper for the `Evaluate` method that computes the quality metrics for the model using the specified dataset. It returns a `MultiClassClassifierMetrics` object that contains the overall metrics computed by multiclass classification evaluators. To display the metrics to determine the quality of the model, you need to get them first. Notice the use of the `Transform` method of the machine learning `_trainedModel` global variable (a transformer) to input the features and return predictions. Add the following code to the `Evaluate` method as the next line:

```
var testMetrics = _mlContext.MulticlassClassification.Evaluate(_trainedModel.Transform(test DataView));
```

The following metrics are evaluated for multiclass classification:

- Micro Accuracy - Every sample-class pair contributes equally to the accuracy metric. You want Micro Accuracy to be as close to 1 as possible.
- Macro Accuracy - Every class contributes equally to the accuracy metric. Minority classes are given equal weight as the larger classes. You want Macro Accuracy to be as close to 1 as possible.
- Log-loss - see [Log Loss](#). You want Log-loss to be as close to zero as possible.
- Log-loss reduction - Ranges from [-inf, 100], where 100 is perfect predictions and 0 indicates mean predictions. You want Log-loss reduction to be as close to zero as possible.

Displaying the metrics for model validation

Use the following code to display the metrics, share the results, and then act on them:

```
Console.WriteLine($"*****");
Console.WriteLine($"*      Metrics for Multi-class Classification model - Test Data      *");
Console.WriteLine($"*-----");
Console.WriteLine($"*      MicroAccuracy: {testMetrics.AccuracyMicro:0.###}");
Console.WriteLine($"*      MacroAccuracy: {testMetrics.AccuracyMacro:0.###}");
Console.WriteLine($"*      LogLoss: {testMetrics.LogLoss:#.###}");
Console.WriteLine($"*      LogLossReduction: {testMetrics.LogLossReduction:#.###}");
Console.WriteLine($"*****");
Console.WriteLine($"*****");
```

Save the trained and evaluated model

At this point, you have a model of type `TransformerChain<TLastTransformer>` that can be integrated into any of your existing or new .NET applications. To save your trained model to a .zip file, add the following code to call the `SaveModelAsFile` method as the next line in `BuildAndTrainModel`:

```
SaveModelAsFile(_mlContext, _trainedModel);
```

Save the model as a .zip file

Create the `SaveModelAsFile` method, just after the `Evaluate` method, using the following code:

```
private static void SaveModelAsFile(MLContext mlContext, ITransformer model)
{
}
```

The `SaveModelAsFile` method executes the following tasks:

- Saves the model as a .zip file.

Next, create a method to save the model so that it can be reused and consumed in other applications. The `ITransformer` has a `SaveTo(IHostEnvironment, Stream)` method that takes in the `_modelPath` global field, and a `Stream`. To save the model as a zip file, you'll create the `FileStream` immediately before calling the `SaveTo` method. Add the following code to the `SaveModelAsFile` method as the next line:

```
using (var fs = new FileStream(_modelPath, FileMode.Create, FileAccess.Write, FileShare.Write))
    mlContext.Model.Save(model, fs);
```

You could also display where the file was written by writing a console message with the `_modelPath`, using the following code:

```
Console.WriteLine("The model is saved to {0}", _modelPath);
```

Deploy and Predict with a loaded model

Add a call to the new method from the `Main` method, right under the `Evaluate` method call, using the following code:

```
PredictIssue();
```

Create the `PredictIssue` method, just after the `Evaluate` method (and just before the `SaveModelAsFile` method), using the following code:

```
private static void PredictIssue()
{
}
```

The `PredictIssue` method executes the following tasks:

- Creates a single issue of test data.
- Predicts Area based on test data.
- Combines test data and predictions for reporting.
- Displays the predicted results.

First, load the model that you saved previously with the following code:

```
ITransformer loadedModel;
using (var stream = new FileStream(_modelPath, FileMode.Open, FileAccess.Read, FileShare.Read))
{
    loadedModel = _mlContext.Model.Load(stream);
}
```

Add a GitHub issue to test the trained model's prediction in the `Predict` method by creating an instance of `GitHubIssue`:

```
GitHubIssue singleIssue = new GitHubIssue() { Title = "Entity Framework crashes", Description = "When connecting to the database, EF is crashing" };
```

```
_predEngine = loadedModel.CreatePredictionEngine<GitHubIssue, IssuePrediction>(_mlContext);
```

Now that you have a model, you can use that to predict the Area GitHub label of a single instance of the GitHub issue data. To get a prediction, use `Predict` on the data. The input data is a string and the model includes the featurization. Your pipeline is in sync during training and prediction. You didn't have to write preprocessing/featurization code specifically for predictions, and the same API takes care of both batch and one-time predictions. Add the following code to the `PredictIssue` method for the predictions:

```
var prediction = _predEngine.Predict(singleIssue);
```

Using the loaded model for prediction

Display `Area` in order to categorize the issue and act on it accordingly. Create a display for the results using the following `Console.WriteLine()` code:

```
Console.WriteLine($"===== Single Prediction - Result: {prediction.Area} =====");
```

Results

Your results should be similar to the following. As the pipeline processes, it displays messages. You may see

warnings, or processing messages. These messages have been removed from the following results for clarity.

```

[Taxi Fare Predictor](#)

Tutorial: Predict prices using a regression learner with ML.NET

3/21/2019 • 13 minutes to read • [Edit Online](#)

This tutorial illustrates how to use ML.NET to build a [regression model](#) for predicting prices, specifically, New York City taxi fares.

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, see the [ML.NET introduction](#).

This tutorial and related sample are currently using **ML.NET version 0.11**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#).

In this tutorial, you learn how to:

- Understand the problem
- Select the appropriate machine learning task
- Prepare and understand the data
- Create a learning pipeline
- Load and transform the data
- Choose a learning algorithm
- Train the model
- Evaluate the model
- Use the model for predictions

Prerequisites

- [Visual Studio 2017 15.6 or later](#) with the ".NET Core cross-platform development" workload installed.

Understand the problem

This problem is about predicting the fare of a taxi trip in New York City. At first glance, it may seem to depend simply on the distance traveled. However, taxi vendors in New York charge varying amounts for other factors such as additional passengers or paying with a credit card instead of cash.

Select the appropriate machine learning task

You want to predict the price value, which is a real value, based on the other factors in the data set. To do that you choose a [regression](#) machine learning task.

Create a console application

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the **New Project** dialog, select the **Visual C#** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "TaxiFarePrediction" and then select the **OK** button.
2. Create a directory named *Data* in your project to store the data set and model files:

In **Solution Explorer**, right-click the project and select **Add > New Folder**. Type "Data" and hit Enter.

3. Install the **Microsoft.ML** NuGet Package:

In **Solution Explorer**, right-click the project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the **Browse** tab, search for **Microsoft.ML**, select that package in the list, and select the **Install** button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the **License Acceptance** dialog if you agree with the license terms for the packages listed.

Prepare and understand the data

1. Download the [taxi-fare-train.csv](#) and the [taxi-fare-test.csv](#) data sets and save them to the *Data* folder you've created at the previous step. We use these data sets to train the machine learning model and then evaluate how accurate the model is. These data sets are originally from the [NYC TLC Taxi Trip data set](#).
2. In **Solution Explorer**, right-click each of the \*.csv files and select **Properties**. Under **Advanced**, change the value of **Copy to Output Directory** to **Copy if newer**.
3. Open the **taxi-fare-train.csv** data set and look at column headers in the first row. Take a look at each of the columns. Understand the data and decide which columns are **features** and which one is the **label**.

The **label** is the identifier of the column you want to predict. The identified **features** are used to predict the label.

The provided data set contains the following columns:

- **vendor\_id**: The ID of the taxi vendor is a feature.
- **rate\_code**: The rate type of the taxi trip is a feature.
- **passenger\_count**: The number of passengers on the trip is a feature.
- **trip\_time\_in\_secs**: The amount of time the trip took. You want to predict the fare of the trip before the trip is completed. At that moment you don't know how long the trip would take. Thus, the trip time is not a feature and you'll exclude this column from the model.
- **trip\_distance**: The distance of the trip is a feature.
- **payment\_type**: The payment method (cash or credit card) is a feature.
- **fare\_amount**: The total taxi fare paid is the label.

Create data classes

Create classes for the input data and the predictions:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *TaxiTrip.cs*. Then, select the **Add** button.
3. Add the following `using` directives to the new file:

```
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code, which has two classes `TaxiTrip` and `TaxiTripFarePrediction`, to the *TaxiTrip.cs* file:

```

public class TaxiTrip
{
    [LoadColumn(0)]
    public string VendorId;

    [LoadColumn(1)]
    public string RateCode;

    [LoadColumn(2)]
    public float PassengerCount;

    [LoadColumn(3)]
    public float TripTime;

    [LoadColumn(4)]
    public float TripDistance;

    [LoadColumn(5)]
    public string PaymentType;

    [LoadColumn(6)]
    public float FareAmount;
}

public class TaxiTripFarePrediction
{
    [ColumnName("Score")]
    public float FareAmount;
}

```

`TaxiTrip` is the input data class and has definitions for each of the data set columns. Use the `LoadColumnAttribute` attribute to specify the indices of the source columns in the data set.

The `TaxiTripFarePrediction` class represents predicted results. It has a single float field, `FareAmount`, with a `Score ColumnNameAttribute` attribute applied. In case of the regression task the **Score** column contains predicted label values.

NOTE

Use the `float` type to represent floating-point values in the input and prediction data classes.

Define data and model paths

Add the following additional `using` statements to the top of the *Program.cs* file:

```

using System;
using System.IO;
using Microsoft.Data.DataView;
using Microsoft.ML;
using Microsoft.ML.Data;

```

You need to create three fields to hold the paths to the files with data sets and the file to save the model:

- `_trainDataPath` contains the path to the file with the data set used to train the model.
- `_testDataPath` contains the path to the file with the data set used to evaluate the model.
- `_modelPath` contains the path to the file where the trained model is stored.

Add the following code right above the `Main` method to specify those paths and for the `_textLoader` variable:

```
static readonly string _trainDataPath = Path.Combine(Environment.CurrentDirectory, "Data", "taxi-fare-train.csv");
static readonly string _testDataPath = Path.Combine(Environment.CurrentDirectory, "Data", "taxi-fare-test.csv");
static readonly string _modelPath = Path.Combine(Environment.CurrentDirectory, "Data", "Model.zip");
```

When building a model with ML.NET you start by creating an ML Context. This is comparable conceptually to using `DbContext` in Entity Framework. The environment provides a context for your machine learning job that can be used for exception tracking and logging.

Initialize variables in Main

Create a variable called `mlContext` and initialize it with a new instance of `MLContext`. Replace the `Console.WriteLine("Hello World!")` line with the following code in the `Main` method:

```
MLContext mlContext = new MLContext(seed: 0);
```

Add the following as the next line of code in the `Main` method to call the `Train` method:

```
var model = Train(mlContext, _trainDataPath);
```

The `Train` method executes the following tasks:

- Loads the data.
- Extracts and transforms the data.
- Trains the model.
- Saves the model as .zip file.
- Returns the model.

The `Train` method trains the model. Create that method just below `Main`, using the following code:

```
public static ITransformer Train(MLContext mlContext, string dataPath)
{
}
```

We are passing two parameters into the `Train` method; an `MLContext` for the context (`mlContext`), and a string for the dataset path (`dataPath`). We're going to reuse this method for loading datasets.

Load and transform data

Load the data using the `MLContext.Data.LoadFromFile` wrapper for the [LoadFromFile method](#). It returns a `IDataView`.

As the input and output of `Transforms`, a `DataView` is the fundamental data pipeline type, comparable to `IEnumerable` for `LINQ`.

In ML.NET, data is similar to a SQL view. It is lazily evaluated, schematized, and heterogenous. The object is the first part of the pipeline, and loads the data. For this tutorial, it loads a dataset with taxi trip pricing information. This is used to create the model, and train it.

Add the following code as the first line of the `Train` method:

```
IDataView dataView = mlContext.Data.LoadFromTextFile<TaxiTrip>(dataPath, hasHeader: true, separatorChar: ',');
```

In the next steps we refer to the columns by the names defined in the `TaxiTrip` class.

When the model is trained and evaluated, by default, the values in the **Label** column are considered as correct values to be predicted. As we want to predict the taxi trip fare, copy the `FareAmount` column into the **Label** column. To do that, use the `CopyColumnsEstimator` transformation class, and add the following code:

```
var pipeline = mlContext.Transforms.CopyColumns(outputColumnName: "Label", inputColumnName:"FareAmount")
```

The algorithm that trains the model requires **numeric** features, so you have to transform the categorical data (`VendorId`, `RateCode`, and `PaymentType`) values into numbers (`VendorIdEncoded`, `RateCodeEncoded`, and `PaymentTypeEncoded`). To do that, use the `Microsoft.ML.Transforms.OneHotEncodingTransformer` transformation class, which assigns different numeric key values to the different values in each of the columns, and add the following code:

```
.Append(mlContext.Transforms.Categorical.OneHotEncoding(outputColumnName: "VendorIdEncoded",
    inputColumnName:"VendorId"))
.Append(mlContext.Transforms.Categorical.OneHotEncoding(outputColumnName: "RateCodeEncoded", inputColumnName:
    "RateCode"))
.Append(mlContext.Transforms.Categorical.OneHotEncoding(outputColumnName: "PaymentTypeEncoded",
    inputColumnName: "PaymentType"))
```

The last step in data preparation combines all of the feature columns into the **Features** column using the `mlContext.Transforms.Concatenate` transformation class. By default, a learning algorithm processes only features from the **Features** column. Add the following code:

```
.Append(mlContext.Transforms.Concatenate("Features", "VendorIdEncoded", "RateCodeEncoded", "PassengerCount",
    "TripTime", "TripDistance", "PaymentTypeEncoded"))
```

Choose a learning algorithm

After adding the data to the pipeline and transforming it into the correct input format, we select a learning algorithm (**learner**). The learner trains the model. We chose a **regression** task for this problem, so we use a `FastTreeRegressionTrainer` learner, which is one of the regression learners provided by ML.NET.

The `FastTreeRegressionTrainer` training algorithm utilizes gradient boosting. Gradient boosting is a machine learning technique for regression problems. It builds each regression tree in a step-wise fashion. It uses a pre-defined loss function to measure the error in each step and correct for it in the next. The result is a prediction model that is actually an ensemble of weaker prediction models. For more information about gradient boosting, see [Boosted Decision Tree Regression](#).

Add the following code into the `Train` method to add the `FastTreeRegressionTrainer` to the data processing code added in the previous step:

```
.Append(mlContext.Regression.Trainers.FastTree());
```

Train the model

The final step is to train the model. We train the model, `TransformerChain`, based on the dataset that has been loaded and transformed. Once the estimator has been defined, we train the model using the `Fit` while providing

the already loaded training data. This returns a model to use for predictions. `pipeline.Fit()` trains the pipeline and returns a `Transformer` based on the `DataView` passed in. The experiment is not executed until this happens.

```
var model = pipeline.Fit(dataView);
```

Save the model

At this point, you have a model of type `TransformerChain` that can be integrated into any of your existing or new .NET applications. To save the model to a .zip file, add the following code at the end of the `Train` method:

```
SaveModelAsFile(mlContext, model);
return model;
```

Save the model as a .zip file

Create the `SaveModelAsFile` method, just after the `Train` method, using the following code:

```
private static void SaveModelAsFile(MLContext mlContext, ITransformer model)
{
}
```

The `SaveModelAsFile` method executes the following tasks:

- Saves the model as a .zip file.

We need to create a method to save the model so that it can be reused and consumed in other applications. The `ITransformer` has a `SaveTo(IHostEnvironment, Stream)` method that takes in the `_modelPath` global field, and a `Stream`. Since we want to save this as a zip file, we'll create the `FileStream` immediately before calling the `SaveTo` method. Add the following code to the `SaveModelAsFile` method as the next line:

```
using (var fileStream = new FileStream(_modelPath, FileMode.Create, FileAccess.Write, FileShare.Write))
    mlContext.Model.Save(model, fileStream);
```

We could also display where the file was written by writing a console message with the `_modelPath`, using the following code:

```
Console.WriteLine("The model is saved to {0}", _modelPath);
```

Evaluate the model

Evaluation is the process of checking how well the model predicts label values. It's important that the model makes good predictions on data that was not used to train the model. One way to do this is to split the data into training and test data sets, as it's done in this tutorial. Now that you've trained the model on the training data, you can see how well it performs on the test data.

The `Evaluate` method evaluates the model. To create that method, add the following code below the `Train` method:

```
private static void Evaluate(MLContext mlContext, ITransformer model)
{
}
```

The `Evaluate` method executes the following tasks:

- Loads the test dataset.
- Creates the regression evaluator.
- Evaluates the model and creates metrics.
- Displays the metrics.

Add a call to the new method from the `Main` method, right under the `Train` method call, using the following code:

```
Evaluate(mlContext, model);
```

Load the test dataset using the `MLContext.Data.LoadFromTextFile` wrapper. You can evaluate the model using this dataset as a quality check. Add the following code to the `Evaluate` method:

```
IDataView dataView = mlContext.Data.LoadFromTextFile<TaxiTrip>(_testDataPath, hasHeader: true, separatorChar: ',');
```

Next, use the machine learning `model` parameter (a transformer) to input the features and return predictions. Add the following code to the `Evaluate` method as the next line:

```
var predictions = model.Transform(dataView);
```

The `RegressionContext.Evaluate` method computes the quality metrics for the `PredictionModel` using the specified dataset. It returns a `RegressionMetrics` object that contains the overall metrics computed by regression evaluators. To display these to determine the quality of the model, you need to get the metrics first. Add the following code as the next line in the `Evaluate` method:

```
var metrics = mlContext.Regression.Evaluate(predictions, "Label", "Score");
```

Add the following code to evaluate the model and produce the evaluation metrics:

```
Console.WriteLine();
Console.WriteLine($"*****");
Console.WriteLine($"*      Model quality metrics evaluation      ");
Console.WriteLine($"*-----");
```

[RSquared](#) is another evaluation metric of the regression models. RSquared takes values between 0 and 1. The closer its value is to 1, the better the model is. Add the following code into the `Evaluate` method to display the RSquared value:

```
Console.WriteLine($"*      R2 Score:      {metrics.RSquared:0.##}");
```

[RMS](#) is one of the evaluation metrics of the regression model. The lower it is, the better the model is. Add the following code into the `Evaluate` method to display the RMS value:

```
Console.WriteLine($"*      RMS loss:      {metrics.Rms:#.##}");
```

Use the model for predictions

Predict the test data outcome with the model and a single comment

Create the `TestSinglePrediction` method, just after the `Evaluate` method, using the following code:

```
private static void TestSinglePrediction(MLContext mlContext)
{
}
```

The `TestSinglePrediction` method executes the following tasks:

- Creates a single comment of test data.
- Predicts fare amount based on test data.
- Combines test data and predictions for reporting.
- Displays the predicted results.

Add a call to the new method from the `Main` method, right under the `Evaluate` method call, using the following code:

```
TestSinglePrediction(mlContext);
```

Since we want to load the model from the zip file we saved, we'll create the `FileStream` immediately before calling the `Load` method. Add the following code to the `TestSinglePrediction` method as the next line:

```
ITransformer loadedModel;
using (var stream = new FileStream(_modelPath, FileMode.Open, FileAccess.Read, FileShare.Read))
{
    loadedModel = mlContext.Model.Load(stream);
}
```

While the `model` is a `transformer` that operates on many rows of data, a very common production scenario is a need for predictions on individual examples. The `PredictionEngine<TSrc,TDst>` is a wrapper that is returned from the `CreatePredictionEngine` method. Let's add the following code to create the `PredictionEngine` as the next line in the `TestSinglePrediction` Method:

```
var predictionFunction = loadedModel.CreatePredictionEngine<TaxiTrip, TaxiTripFarePrediction>(mlContext);
```

This tutorial uses one test trip within this class. Later you can add other scenarios to experiment with the model.

Add a trip to test the trained model's prediction of cost in the `TestSinglePrediction` method by creating an instance of `TaxiTrip`:

```
var taxiTripSample = new TaxiTrip()
{
    VendorId = "VTS",
    RateCode = "1",
    PassengerCount = 1,
    TripTime = 1140,
    TripDistance = 3.75f,
    PaymentType = "CRD",
    FareAmount = 0 // To predict. Actual/Observed = 15.5
};
```

We can use that to predict the fare based on a single instance of the taxi trip data. To get a prediction, use [Predict](#) on the data. Note that the input data is a string and the model includes the featurization. Your pipeline is in sync during training and prediction. You didn't have to write preprocessing/featurization code specifically for predictions, and the same API takes care of both batch and one-time predictions.

```
var prediction = predictionFunction.Predict(taxiTripSample);
```

To display the predicted fare of the specified trip, add the following code into the [TestSinglePrediction](#) method:

```
Console.WriteLine($"*****");
Console.WriteLine($"Predicted fare: {prediction.FareAmount:0.###}, actual fare: 15.5");
Console.WriteLine($"*****");
```

Run the program to see the predicted taxi fare for your test case.

Congratulations! You've now successfully built a machine learning model for predicting taxi trip fares, evaluated its accuracy, and used it to make predictions. You can find the source code for this tutorial at the [dotnet/samples](#) GitHub repository.

Tutorial: Cluster iris flowers using a clustering learner with ML.NET

3/19/2019 • 7 minutes to read • [Edit Online](#)

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, see the [ML.NET introduction](#).

This tutorial and related sample are currently using **ML.NET version 0.11**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#).

This tutorial illustrates how to use ML.NET to build a [clustering model](#) for the [iris flower data set](#).

In this tutorial, you learn how to:

- Understand the problem
- Select the appropriate machine learning task
- Prepare the data
- Load and transform the data
- Choose a learning algorithm
- Train the model
- Use the model for predictions

Prerequisites

- [Visual Studio 2017 15.6 or later](#) with the ".NET Core cross-platform development" workload installed.

Understand the problem

This problem is about dividing the set of iris flowers in different groups based on the flower features. Those features are the length and width of a sepal and the length and width of a petal. For this tutorial, assume that the type of each flower is unknown. You want to learn the structure of a data set from the features and predict how a data instance fits this structure.

Select the appropriate machine learning task

As you don't know to which group each flower belongs to, you choose the [unsupervised machine learning](#) task. To divide a data set in groups in such a way that elements in the same group are more similar to each other than to those in other groups, use a [clustering](#) machine learning task.

Create a console application

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the **New Project** dialog, select the **Visual C#** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "IrisFlowerClustering" and then select the **OK** button.
2. Create a directory named *Data* in your project to store the data set and model files:

In **Solution Explorer**, right-click the project and select **Add > New Folder**. Type "Data" and hit Enter.

3. Install the **Microsoft.ML** NuGet package:

In **Solution Explorer**, right-click the project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the **Browse** tab, search for **Microsoft.ML**, select that package in the list, and select the **Install** button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the **License Acceptance** dialog if you agree with the license terms for the packages listed.

Prepare the data

1. Download the [iris.data](#) data set and save it to the *Data* folder you've created at the previous step. For more information about the iris data set, see the [Iris flower data set](#) Wikipedia page and the [Iris Data Set](#) page, which is the source of the data set.
2. In **Solution Explorer**, right-click the *iris.data* file and select **Properties**. Under **Advanced**, change the value of **Copy to Output Directory** to **Copy if newer**.

The *iris.data* file contains five columns that represent:

- sepal length in centimetres
- sepal width in centimetres
- petal length in centimetres
- petal width in centimetres
- type of iris flower

For the sake of the clustering example, this tutorial ignores the last column.

Create data classes

Create classes for the input data and the predictions:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *IrisData.cs*. Then, select the **Add** button.
3. Add the following `using` directive to the new file:

```
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code, which defines the classes `IrisData` and `ClusterPrediction`, to the *IrisData.cs* file:

```

public class IrisData
{
    [LoadColumn(0)]
    public float SepalLength;

    [LoadColumn(1)]
    public float SepalWidth;

    [LoadColumn(2)]
    public float PetalLength;

    [LoadColumn(3)]
    public float PetalWidth;
}

public class ClusterPrediction
{
    [ColumnName("PredictedLabel")]
    public uint PredictedClusterId;

    [ColumnName("Score")]
    public float[] Distances;
}

```

`IrisData` is the input data class and has definitions for each feature from the data set. Use the `LoadColumn` attribute to specify the indices of the source columns in the data set file.

The `ClusterPrediction` class represents the output of the clustering model applied to an `IrisData` instance. Use the `ColumnName` attribute to bind the `PredictedClusterId` and `Distances` fields to the **PredictedLabel** and **Score** columns respectively. In case of the clustering task those columns have the following meaning:

- **PredictedLabel** column contains the ID of the predicted cluster.
- **Score** column contains an array with squared Euclidean distances to the cluster centroids. The array length is equal to the number of clusters.

NOTE

Use the `float` type to represent floating-point values in the input and prediction data classes.

Define data and model paths

Go back to the `Program.cs` file and add two fields to hold the paths to the data set file and to the file to save the model:

- `_dataPath` contains the path to the file with the data set used to train the model.
- `_modelPath` contains the path to the file where the trained model is stored.

Add the following code right above the `Main` method to specify those paths:

```

static readonly string _dataPath = Path.Combine(Environment.CurrentDirectory, "Data", "iris.data");
static readonly string _modelPath = Path.Combine(Environment.CurrentDirectory, "Data",
    "IrisClusteringModel.zip");

```

To make the preceding code compile, add the following `using` directives at the top of the `Program.cs` file:

```
using System;
using System.IO;
```

Create ML context

Add the following additional `using` directives to the top of the `Program.cs` file:

```
using Microsoft.Data.DataView;
using Microsoft.ML;
using Microsoft.ML.Data;
```

In the `Main` method, replace the `Console.WriteLine("Hello World!");` line with the following code:

```
var mlContext = new MLContext(seed: 0);
```

The [Microsoft.ML.MLContext](#) class represents the machine learning environment and provides mechanisms for logging and entry points for data loading, model training, prediction, and other tasks. This is comparable conceptually to using `DbContext` in Entity Framework.

Setup data loading

Add the following code to the `Main` method to setup the way to load data:

```
MLContext.Data.LoadFromTextFile<IrisData>(irisPath, separator: ",")
```

Load the data using the generic `MLContext.Data.LoadFromTextFile` wrapper for the [LoadFromTextFile method](#). It returns a `IDataView` which infers the dataset schema from the `IrisData` data model type, uses the dataset header and is separated by a comma.

Create a learning pipeline

For this tutorial, the learning pipeline of the clustering task comprises two following steps:

- concatenate loaded columns into one **Features** column, which is used by a clustering trainer;
- use a [KMeansPlusPlusTrainer](#) trainer to train the model using the k-means++ clustering algorithm.

Add the following code to the `Main` method:

```
string featuresColumnName = "Features";
var pipeline = mlContext.Transforms
    .Concatenate(featuresColumnName, "SepalLength", "SepalWidth", "PetalLength", "PetalWidth")
    .Append(mlContext.Clustering.Trainers.KMeans(featuresColumnName, clustersCount: 3));
```

The code specifies that the data set should be split in three clusters.

Train the model

The steps added in the preceding sections prepared the pipeline for training, however, none have been executed.

Add the following line to the `Main` method to perform data loading and model training:

```
var model = pipeline.Fit(dataView);
```

Save the model

At this point, you have a model that can be integrated into any of your existing or new .NET applications. To save your model to a .zip file, add the following code to the `Main` method:

```
using (var fileStream = new FileStream(_modelPath, FileMode.Create, FileAccess.Write, FileShare.Write))
{
    mlContext.Model.Save(model, fileStream);
}
```

Use the model for predictions

To make predictions, use the `PredictionEngine<TSrc,TDst>` class that takes instances of the input type through the transformer pipeline and produces instances of the output type. Add the following line to the `Main` method to create an instance of that class:

```
var predictor = model.CreatePredictionEngine<IrisData, ClusterPrediction>(mlContext);
```

Create the `TestIrisData` class to house test data instances:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item** dialog box, select **Class** and change the **Name** field to `TestIrisData.cs`. Then, select the **Add** button.
3. Modify the class to be static like in the following example:

```
static class TestIrisData
```

This tutorial introduces one iris data instance within this class. You can add other scenarios to experiment with the model. Add the following code into the `TestIrisData` class:

```
internal static readonly IrisData Setosa = new IrisData
{
    SepalLength = 5.1f,
    SepalWidth = 3.5f,
    PetalLength = 1.4f,
    PetalWidth = 0.2f
};
```

To find out the cluster to which the specified item belongs to, go back to the `Program.cs` file and add the following code into the `Main` method:

```
var prediction = predictor.Predict(TestIrisData.Setosa);
Console.WriteLine($"Cluster: {prediction.PredictedClusterId}");
Console.WriteLine($"Distances: {string.Join(" ", prediction.Distances)}");
```

Run the program to see which cluster contains the specified data instance and squared distances from that instance to the cluster centroids. Your results should be similar to the following:

```
Cluster: 2
Distances: 11.69127 0.02159119 25.59896
```

Congratulations! You've now successfully built a machine learning model for iris clustering and used it to make

predictions. You can find the source code for this tutorial at the [dotnet/samples](#) GitHub repository.

Tutorial: Create a Movie Recommender with ML.NET

3/25/2019 • 16 minutes to read • [Edit Online](#)

This sample tutorial illustrates using ML.NET to build a movie recommender via a .NET Core console application using C# in Visual Studio 2017.

In this tutorial, you learn how to:

- Select a machine learning algorithm
- Prepare and load your data
- Build and train a model
- Evaluate a model
- Deploy and consume a model

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit [the ML.NET introduction](#).

This tutorial and related sample are currently using **ML.NET version 0.11**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#).

You can find the source code for this tutorial at the [dotnet/samples](#) repository.

Machine learning workflow

You will use the following steps to accomplish your task, as well as any other ML.NET task:

1. [Load your data](#)
2. [Build and train your model](#)
3. [Evaluate your model](#)
4. [Use your model](#)

Prerequisites

- [Visual Studio 2017 15.6 or later](#) with the ".NET Core cross-platform development" workload installed.

Select the appropriate machine learning task

There are several ways to approach recommendation problems, such as recommending a list of movies or recommending a list of related products, but in this case you will predict what rating (1-5) a user will give to a particular movie and recommend that movie if it's higher than a defined threshold (the higher the rating, the higher the likelihood of a user liking a particular movie).

Create a console application

Create a project

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the **New Project** dialog, select the **Visual C#** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "MovieRecommender" and then select the **OK** button.

2. Create a directory named *Data* in your project to store the data set:

In **Solution Explorer**, right-click the project and select **Add > New Folder**. Type "Data" and hit Enter.

3. Install the **Microsoft.ML** and **Microsoft.ML.Recommender** NuGet Packages:

In **Solution Explorer**, right-click the project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the **Browse** tab, search for **Microsoft.ML**, select that package in the list, and select the **Install** button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the **License Acceptance** dialog if you agree with the license terms for the packages listed. Repeat these steps for **Microsoft.ML.Recommender**.

NOTE

This tutorial uses **Microsoft.ML v0.11.0** and **Microsoft.ML.Recommender v0.11.0**.

4. Add the following `using` statements at the top of your *Program.cs* file:

```
using System;
using System.IO;
using Microsoft.ML;
using Microsoft.ML.Trainers;
using Microsoft.ML.Data;
using Microsoft.Data.DataView;
```

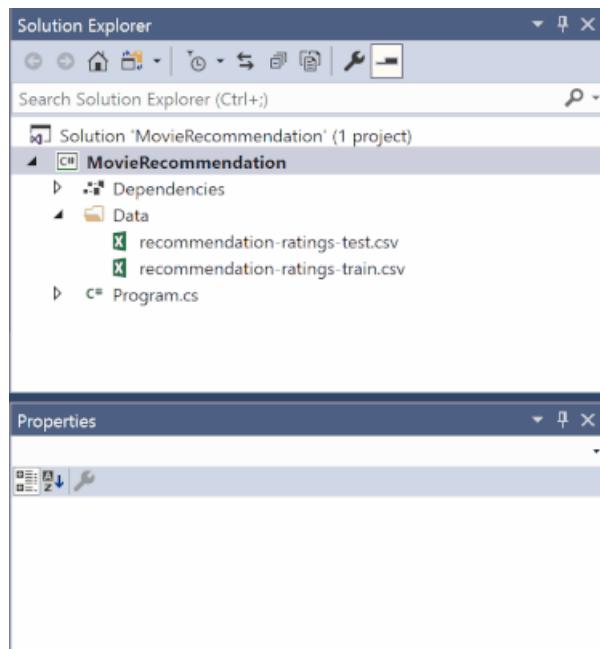

Download your data

1. Download the two datasets and save them to the *Data* folder you previously created:

- Right click on *recommendation-ratings-train.csv* and select "Save Link (or Target) As..."
- Right click on *recommendation-ratings-test.csv* and select "Save Link (or Target) As..."

Make sure you either save the \*.csv files to the *Data* folder, or after you save it elsewhere, move the \*.csv files to the *Data* folder.

2. In Solution Explorer, right-click each of the \*.csv files and select **Properties**. Under **Advanced**, change the value of **Copy to Output Directory** to **Copy if newer**.

Load your data

The first step in the ML.NET process is to prepare and load your model training and testing data.

The recommendation ratings data is split into `Train` and `Test` datasets. The `Train` data is used to fit your model. The `Test` data is used to make predictions with your trained model and evaluate model performance. It's common to have an 80/20 split with `Train` and `Test` data.

Below is a preview of the data from your \*.csv files:

userId	movieId	rating	timestamp
1	1	4	964982703
1	3	4	964981247
1	6	4	964982224
1	47	5	964983815
1	50	5	964982931
1	70	3	964982400
1	101	5	964980868
1	110	4	964982176
1	151	5	964984041

In the \*.csv files, there are four columns:

- `userId`
- `movieId`
- `rating`
- `timestamp`

In machine learning, the columns that are used to make a prediction are called **Features**, and the column with the returned prediction is called the **Label**.

You want to predict movie ratings, so the rating column is the `Label`. The other three columns, `userId`, `movieId`, and `timestamp` are all **Features** used to predict the `Label`.

FEATURES	LABEL
<code>userId</code>	<code>rating</code>
<code>movieId</code>	
<code>timestamp</code>	

It's up to you to decide which **Features** are used to predict the `Label`. You can also use methods like [Feature Permutation Importance](#) to help with selecting the best **Features**.

In this case, you should eliminate the `timestamp` column as a **Feature** because the timestamp does not really affect how a user rates a given movie and thus would not contribute to making a more accurate prediction:

FEATURES	LABEL
<code>userId</code>	<code>rating</code>
<code>movieId</code>	

Next you must define your data structure for the input class.

Add a new class to your project:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item dialog box**, select **Class** and change the **Name** field to *MovieRatingData.cs*. Then, select the **Add** button.

The *MovieRatingData.cs* file opens in the code editor. Add the following `using` statement to the top of *MovieRatingData.cs*:

```
using Microsoft.ML.Data;
```

Create a class called `MovieRating` by removing the existing class definition and adding the following code in *MovieRatingData.cs*:

```
public class MovieRating
{
    [LoadColumn(0)]
    public float userId;
    [LoadColumn(1)]
    public float movieId;
    [LoadColumn(2)]
    public float Label;
}
```

`MovieRating` specifies an input data class. The `LoadColumn` attribute specifies which columns (by column index) in the dataset should be loaded. The `userId` and `movieId` columns are your `Features` (the inputs you will give the model to predict the `Label`), and the rating column is the `Label` that you will predict (the output of the model).

Create another class, `MovieRatingPrediction`, to represent predicted results by adding the following code after the `MovieRating` class in *MovieRatingData.cs*:

```
public class MovieRatingPrediction
{
    public float Label;
    public float Score;
}
```

In *Program.cs*, replace the `Console.WriteLine("Hello World!")` with the following code inside `Main()`:

```
MLContext mlContext = new MLContext();
```

The `MLContext` class is a starting point for all ML.NET operations, and initializing `mlContext` creates a new ML.NET environment that can be shared across the model creation workflow objects. It's similar, conceptually, to `DbContext` in Entity Framework.

After `Main()`, create a method called `LoadData()`:

```
public static (IDataView training, IDataView test) LoadData(MLContext mlContext)
{
}
```

NOTE

This method will give you an error until you add a return statement in the following steps.

Initialize your data path variables, load the data from the \*.csv files, and return the `Train` and `Test` data as `IDataView` objects by adding the following as the next line of code in `LoadData()`:

```
var trainingDataPath = Path.Combine(Environment.CurrentDirectory, "Data", "recommendation-ratings-train.csv");
var testDataPath = Path.Combine(Environment.CurrentDirectory, "Data", "recommendation-ratings-test.csv");

IDataView trainingDataView = mlContext.Data.LoadFromTextFile<MovieRating>(trainingDataPath, hasHeader: true,
separatorChar: ',');
IDataView testDataView = mlContext.Data.LoadFromTextFile<MovieRating>(testDataPath, hasHeader: true,
separatorChar: ',');

return (trainingDataView, testDataView);
```

Data in ML.NET is represented as an [IDataView class](#). `IDataView` is a flexible, efficient way of describing tabular data (numeric and text). Data can be loaded from a text file or in real time (for example, SQL database or log files) to an `IDataView` object.

The `LoadFromTextFile()` defines the data schema and reads in the file. It takes in the data path variables and returns an `IDataView`. In this case, you provide the path for your `Test` and `Train` files and indicate both the text file header (so it can use the column names properly) and the comma character data separator (the default separator is a tab).

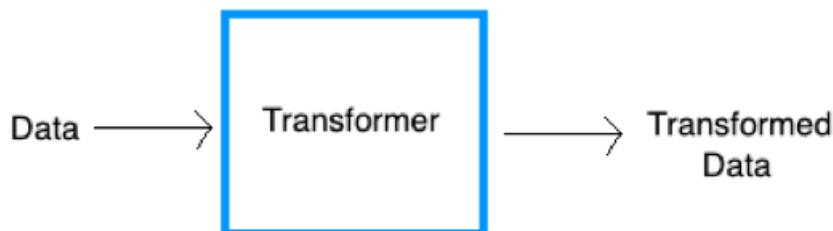

Add the following as the next two lines of code in the `Main()` method to call your `LoadData()` method and return the `Train` and `Test` data:

```
IDataView trainingDataView = LoadData(mlContext).training;
IDataView testDataView = LoadData(mlContext).test;
```

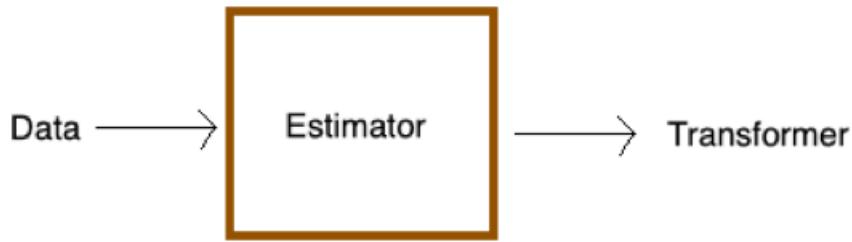

Build and train your model

There are three major concepts in ML.NET: [Data](#), [Transformers](#), and [Estimators](#).

Machine learning training algorithms require data in a certain format. `Transformers` are used to transform tabular data to a compatible format.

You create `Transformers` in ML.NET by creating `Estimators`. `Estimators` take in data and return `Transformers`.

The recommendation training algorithm you will use for training your model is an example of an `Estimator`.

Build an `Estimator` with the following steps:

Create the `BuildAndTrainModel()` method, just after the `LoadData()` method, using the following code:

```

public static ITransformer BuildAndTrainModel(MLContext mlContext, IDataView trainingDataView)
{
}

```

NOTE

This method will give you an error until you add a return statement in the following steps.

Define the data transformations by adding the following code to `BuildAndTrainModel()`:

```

IEstimator<ITransformer> estimator = mlContext.Transforms.Conversion.MapValueToKey(outputColumnName:
    "userIdEncoded", inputColumnName: "userId")
    .Append(mlContext.Transforms.Conversion.MapValueToKey(outputColumnName: "movieIdEncoded", inputColumnName:
    "movieId"));

```

Since `userId` and `movieId` represent users and movie titles, not real values, you use the `MapValueToKey()` method to transform each `userId` and each `movieId` into a numeric key type `Feature` column (a format accepted by recommendation algorithms) and add them as new dataset columns:

USERID	MOVIEID	LABEL	USERIDENCODED	MOVIEIDENCODED
1	1	4	userKey1	movieKey1
1	3	4	userKey1	movieKey2
1	6	4	userKey1	movieKey3

Choose the machine learning algorithm and append it to the data transformation definitions by adding the following as the next line of code in `BuildAndTrainModel()`:

```

var options = new MatrixFactorizationTrainer.Options
{
    MatrixColumnIndexColumnName = "userIdEncoded",
    MatrixRowIndexColumnName = "movieIdEncoded",
    LabelColumnName = "Label",
    NumberOfIterations = 20,
    ApproximationRank = 100
};

var trainerEstimator = estimator.Append(mlContext.Recommendation().Trainers.MatrixFactorization(options));

```

The [MatrixFactorizationTrainer](#) is your recommendation training algorithm. [Matrix Factorization](#) is a common approach to recommendation when you have data on how users have rated products in the past, which is the case for the datasets in this tutorial. There are other recommendation algorithms for when you have different data available (see the [Other recommendation algorithms](#) section below to learn more).

In this case, the [Matrix Factorization](#) algorithm uses a method called "collaborative filtering", which assumes that if User 1 has the same opinion as User 2 on a certain issue, then User 1 is more likely to feel the same way as User 2 about a different issue.

For instance, if User 1 and User 2 rate movies similarly, then User 2 is more likely to enjoy a movie that User 1 has watched and rated highly:

	INCREDIBLES 2 (2018)	THE AVENGERS (2012)	GUARDIANS OF THE GALAXY (2014)
User 1	Watched and liked movie	Watched and liked movie	Watched and liked movie
User 2	Watched and liked movie	Watched and liked movie	Has not watched -- RECOMMEND movie

The [Matrix Factorization](#) trainer has several [Options](#), which you can read more about in the [Algorithm hyperparameters](#) section below.

Fit the model to the [Train](#) data and return the trained model by adding the following as the next line of code in the [BuildAndTrainModel\(\)](#) method:

```

Console.WriteLine("===== Training the model =====");
ITransformer model = trainerEstimator.Fit(trainingDataView);

return model;

```

The [Fit\(\)](#) method trains your model with the provided training dataset. Technically, it executes the [Estimator](#) definitions by transforming the data and applying the training, and it returns back the trained model, which is a [Transformer](#).

Add the following as the next line of code in the [Main\(\)](#) method to call your [BuildAndTrainModel\(\)](#) method and return the trained model:

```
ITransformer model = BuildAndTrainModel(mlContext, trainingDataView);
```

Evaluate your model

Once you have trained your model, use your test data to evaluate how your model is performing.

Create the [EvaluateModel\(\)](#) method, just after the [BuildAndTrainModel\(\)](#) method, using the following code:

```
public static void EvaluateModel(MLContext mlContext, IDataView testDataView, ITransformer model)
{
}
```

Transform the `Test` data by adding the following code to `EvaluateModel()`:

```
Console.WriteLine("===== Evaluating the model =====");
var prediction = model.Transform(testDataView);
```

The `Transform()` method makes predictions for multiple provided input rows of a test dataset.

Evaluate the model by adding the following as the next line of code in the `EvaluateModel()` method:

```
var metrics = mlContext.Regression.Evaluate(prediction, label: DefaultColumnNames.Label, score:
DefaultColumnNames.Score);
```

Once you have the prediction set, the `Evaluate()` method assesses the model, which compares the predicted values with the actual `Labels` in the test dataset and returns metrics on how the model is performing.

Print your evaluation metrics to the console by adding the following as the next line of code in the `EvaluateModel()` method:

```
Console.WriteLine("Rms: " + metrics.Rms.ToString());
Console.WriteLine("RSquared: " + metrics.RSquared.ToString());
```

Add the following as the next line of code in the `Main()` method to call your `EvaluateModel()` method:

```
EvaluateModel(mlContext, testDataView, model);
```

The output so far should look similar to the following text:

```

===== Training the model =====

RSquared: 0.412556298844873

```

In this output, there are 20 iterations. In each iteration, the measure of error decreases and converges closer and closer to 0.

The `root of mean squared error` (RMS or RMSE) is frequently used to measure the differences between values predicted by a model and the values observed in a test dataset. Technically it's the square root of the average of the squares of the errors. You want your RMSE score to be as close to 1 as possible.

`R Squared` is the variation percentage in the predicted values explained by your model. It's a value between 0 and 1, and the closer the value is to 0, the better the model is.

Use your model

Now you can use your trained model to make predictions on new data.

Create the `UseModelForSinglePrediction()` method, just after the `EvaluateModel()` method, using the following code:

```

public static void UseModelForSinglePrediction(MLContext mlContext, ITransformer model)
{
}

```

Use the `PredictionEngine` to predict the rating by adding the following code to `UseModelForSinglePrediction()`:

```

Console.WriteLine("===== Making a prediction =====");
var predictionEngine = model.CreatePredictionEngine<MovieRating, MovieRatingPrediction>(mlContext);

```

The `PredictionEngine class` is a convenience API, which allows you to pass a single instance of data and then perform a prediction on this single instance of data.

Create an instance of `MovieRating` called `testInput` and pass it to the Prediction Engine by adding the following as the next lines of code in the `UseModelForSinglePrediction()` method:

```
var testInput = new MovieRating { userId = 6, movieId = 10 };

var movieRatingPrediction = predictionEngine.Predict(testInput);
```

The `Predict()` function makes a prediction on a single column of data.

You can then use the `Score`, or the predicted rating, to determine whether you want to recommend the movie with `movieId` 10 to user 6. The higher the `Score`, the higher the likelihood of a user liking a particular movie. In this case, let's say that you recommend movies with a predicted rating of > 3.5.

To print the results, add the following as the next lines of code in the `UseModelForSinglePrediction()` method:

```
if (Math.Round(movieRatingPrediction.Score, 1) > 3.5)
{
    Console.WriteLine("Movie " + testInput.movieId + " is recommended for user " + testInput.userId);
}
else
{
    Console.WriteLine("Movie " + testInput.movieId + " is not recommended for user " + testInput.userId);
}
```

Add the following as the next line of code in the `Main()` method to call your `useModelForSinglePrediction()` method:

```
useModelForSinglePrediction(mlContext, model);
```

The output of this method should look similar to the following text:

```
===== Making a prediction =====
Movie 10 is recommended for user 6
```

Save your model

To use your model to make predictions in end-user applications, you must first save the model.

Create the `SaveModel()` method, just after the `useModelForSinglePrediction()` method, using the following code:

```
public static void SaveModel(MLContext mlContext, ITransformer model)
{
}
```

Save your trained model by adding the following code in the `SaveModel()` method:

```
var modelPath = Path.Combine(Environment.CurrentDirectory, "Data", "MovieRecommenderModel.zip");

Console.WriteLine("===== Saving the model to a file =====");
using (var fs = new FileStream(modelPath, FileMode.Create, FileAccess.Write, FileShare.Write))
    mlContext.Model.Save(model, fs);
```

This method saves your trained model to a .zip file (in the "Data" folder), which can then be used in other .NET applications to make predictions.

Add the following as the next line of code in the `Main()` method to call your `saveModel()` method:

```
SaveModel(mlContext, model);
```

Use your saved model

Once you have saved your trained model, you can consume the model in different environments (see the ["How-to guide"](#) to learn how to operationalize a trained machine learning model in apps).

Results

After following the steps above, run your console app (Ctrl + F5). Your results from the single prediction above should be similar to the following. You may see warnings or processing messages, but these messages have been removed from the following results for clarity.

```

Congratulations! You've now successfully built a machine learning model for recommending movies. You can find the source code for this tutorial at the [dotnet/samples](#) repository.

Improve your model

There are several ways that you can improve the performance of your model so that you can get more accurate predictions.

Data

Adding more training data that has enough samples for each user and movie id can help improve the quality of the recommendation model.

[Cross validation](#) is a technique for evaluating models that randomly splits up data into subsets (instead of extracting out test data from the dataset like you did in this tutorial) and takes some of the groups as train data and some of the groups as test data. This method outperforms making a train-test split in terms of model quality.

Features

In this tutorial, you only use the three `Features` (`user id`, `movie id`, and `rating`) that are provided by the dataset.

While this is a good start, in reality you might want to add other attributes or `Features` (for example, age, gender, geo-location, etc.) if they are included in the dataset. Adding more relevant `Features` can help improve the performance of your recommendation model.

If you are unsure about which `Features` might be the most relevant for your machine learning task, you can also make use of Feature Contribution Calculation (FCC) and [Feature Permutation Importance](#), which ML.NET provides to discover the most influential `Features`.

Algorithm hyperparameters

While ML.NET provides good default training algorithms, you can further fine-tune performance by changing the algorithm's [hyperparameters](#).

For `Matrix Factorization`, you can experiment with hyperparameters such as `NumberOfIterations` and `ApproximationRank` to see if that gives you better results.

For instance, in this tutorial the algorithm options are:

```
var options = new MatrixFactorizationTrainer.Options
{
    MatrixColumnIndexColumnName = "userIdEncoded",
    MatrixRowIndexColumnName = "movieIdEncoded",
    LabelColumnName = "Label",
    NumberOfIterations = 20,
    ApproximationRank = 100
};
```

Other Recommendation Algorithms

The matrix factorization algorithm with collaborative filtering is only one approach for performing movie recommendations. In many cases, you may not have the ratings data available and only have movie history available from users. In other cases, you may have more than just the user's rating data.

ALGORITHM	SCENARIO	SAMPLE
One Class Matrix Factorization	Use this when you only have <code>userId</code> and <code>movieId</code> . This style of recommendation is based upon the co-purchase scenario, or products frequently bought together, which means it will recommend to customers a set of products based upon their own purchase order history.	> Try it out
Field Aware Factorization Machines	Use this to make recommendations when you have more <code>Features</code> beyond <code>userId</code> , <code>productId</code> , and <code>rating</code> (such as product description or product price). This method also uses a collaborative filtering approach.	> Try it out

New user scenario

One common problem in collaborative filtering is the cold start problem, which is when you have a new user with no previous data to draw inferences from. This problem is often solved by asking new users to create a profile and, for instance, rate movies they have seen in the past. While this method puts some burden on the user, it provides some starting data for new users with no rating history.

You need to convert any non float data to `float` data types since all ML.NET `learners` expect features as a `float vector`.

If the dataset contains `categorical` data (for example, 'enum'), ML.NET offers several ways of converting it to features:

- One-hot encoding
- Hash-based one-hot encoding
- Binary encoding (convert category index into a bit sequence and use bits as features)

A `one-hot encoding` can be wasteful if some categories are very high-cardinality (lots of different values, with a small set commonly occurring). In that case, reduce the number of slots to encode with count-based feature selection.

Include categorical featurization directly in the ML.NET learning pipeline to ensure that the categorical transformation:

- is only 'trained' on the training data, and not on your test data,
- is correctly applied to new incoming data, without extra pre-processing at prediction time.

The following example illustrates categorical handling for the [adult census dataset](#):

```

Apply feature engineering for machine learning model training on textual data with ML.NET

You need to convert any non float data to `float` data types since all ML.NET `learners` expect features as a `float vector`.

To learn on textual data, you need to extract text features. ML.NET has some basic text feature extraction mechanisms:

- `Text normalization` (removing punctuation, diacritics, switching to lowercase etc.)
- `Separator-based tokenization`.
- `Stopword removal`.
- `Ngram` and `skip-gram` extraction.
- `TF-IDF rescaling`.
- `Bag of words` conversion.

The following example demonstrates ML.NET text feature extraction mechanisms using the [Wikipedia detox dataset](#):

Load data with many columns from a CSV file for machine learning processing - ML.NET

`TextLoader` is used to load data from text files. You need to specify the data columns, their types, and their location in the text file.

When the input file contains many columns of the same type and always used together, read them as a *vector column*. This strategy results in a clean data schema and avoids unnecessary performance costs, as shown in the following example:

Example file:

```
-2.75;0.77;-0.61;0.14;1.39;0.38;-0.53;-0.50;-2.13;-0.39;0.46;140.66  
-0.61;-0.37;-0.12;0.55;-1.00;0.84;-0.02;1.30;-0.24;-0.50;-2.12;148.12  
-0.85;-0.91;1.81;0.02;-0.78;-1.41;-1.09;-0.65;0.90;-0.37;-0.22;402.20  
0.28;1.05;-0.24;0.30;-0.99;0.19;0.32;-0.95;-1.19;-0.63;0.75;443.51
```

Reading this file using `TextLoader`:

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,  
// as a catalog of available operations and as the source of randomness.  
var mlContext = new MLContext();  
  
// Create the reader: define the data columns and where to find them in the text file.  
var reader = mlContext.Data.CreateTextLoader(  
    columns: new TextLoader.Column[]  
    {  
        // We read the first 10 values as a single float vector.  
        new TextLoader.Column("FeatureVector", DataKind.R4, 0, 9),  
        // Separately, read the target variable.  
        new TextLoader.Column("Target", DataKind.R4, 10)  
    },  
    // Default separator is tab, but we need a semicolon.  
    separatorChar: ';',  
    hasHeader: true  
);  
  
// Now read the file (remember though, readers are lazy, so the actual reading will happen when the data is  
// accessed).  
var data = reader.Read(dataPath);
```

Load data from multiple files for machine learning processing - ML.NET

Use the `TextLoader`, and specify an array of files to the `Read` method. The files must have the same schema (same number and type of columns):

- [Example file1](#)
- [Example file2](#)

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Create the reader: define the data columns and where to find them in the text file.
var reader = mlContext.Data.CreateTextLoader(
    columns: new TextLoader.Column[]
    {
        // A boolean column depicting the 'target label'.
        new TextLoader.Column("IsOver50k", DataKind.BL, 0),
        // Three text columns.
        new TextLoader.Column("WorkClass", DataKind.TX, 1),
        new TextLoader.Column("Education", DataKind.TX, 2),
        new TextLoader.Column("MaritalStatus", DataKind.TX, 3)
    },
    hasHeader: true
);

// Now read the files (remember though, readers are lazy, so the actual reading will happen when the data is

`TextLoader` is used to load data from text files. You need to specify the data columns, their types, and their location in the text file.

Note that it's perfectly acceptable to read some columns of a file, or read the same column multiple times.

Example file:

```
Label Workclass education marital-status
0 Private 11th Never-married
0 Private HS-grad Married-civ-spouse
1 Local-gov Assoc-acdm Married-civ-spouse
1 Private Some-college Married-civ-spouse
```

To load the data from a text file:

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Create the reader: define the data columns and where to find them in the text file.
var reader = mlContext.Data.CreateTextLoader(
    columns: new TextLoader.Column[]
    {
        // A boolean column depicting the 'target label'.
        new TextLoader.Column("IsOver50k", DataKind.BL, 0),
        // Three text columns.
        new TextLoader.Column("WorkClass", DataKind.TX, 1),
        new TextLoader.Column("Education", DataKind.TX, 2),
        new TextLoader.Column("MaritalStatus", DataKind.TX, 3)
    },
    hasHeader: true
);

// Now read the file (remember though, readers are lazy, so the actual reading will happen when the data is
// accessed).
var data = reader.Read(dataPath);

Preprocess training data with normalizers to use in data processing - ML.NET

ML.NET exposes a number of [parametric and non-parametric algorithms](#).

It's **not** as important which normalizer you choose as it is to **use** a normalizer when training linear or other parametric models.

Always include the normalizer directly in the ML.NET learning pipeline, so it:

- is only trained on the training data, and not on your test data,
- is correctly applied to all the new incoming data, without the need for extra pre-processing at prediction time.

Here's a snippet of code that demonstrates normalization in learning pipelines. It assumes the Iris dataset:

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Define the reader: specify the data columns and where to find them in the text file.
var reader = mlContext.Data.CreateTextLoader(
    columns: new TextLoader.Column[]
{
    // The four features of the Iris dataset will be grouped together as one Features column.
    new TextLoader.Column("Features", DataKind.R4, 0, 3),
    // Label: kind of iris.
    new TextLoader.Column("Label", DataKind.TX, 4)
},
// Default separator is tab, but the dataset has comma.
separatorChar: ',',
// First line of the file is a header, not a data row.
hasHeader: true
);

// Read the training data.
var trainData = reader.Read(dataPath);

// Apply all kinds of standard ML.NET normalization to the raw features.
var pipeline =
    mlContext.Transforms.Normalize(
        new NormalizingEstimator.MinMaxColumn(inputColumnName:"Features",
outputColumnName:"MinMaxNormalized", fixZero: true),
        new NormalizingEstimator.MeanVarColumn(inputColumnName: "Features", outputColumnName:
"MeanVarNormalized", fixZero: true),
        new NormalizingEstimator.BinningColumn(inputColumnName: "Features", outputColumnName:
"BinNormalized", numBins: 256));

// Let's train our pipeline of normalizers, and then apply it to the same data.
var normalizedData = pipeline.Fit(trainData).Transform(trainData);

// Inspect one column of the resulting dataset.
var meanVarValues = normalizedData.GetColumn<float[]>(mlContext, "MeanVarNormalized").ToArray();
```

Train a machine learning model with data that's not in a text file - ML.NET

3/19/2019 • 2 minutes to read • [Edit Online](#)

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit the [ML.NET introduction](#).

This how-to and related sample are currently using **ML.NET version 0.11**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#).

The commonly demonstrated use case for ML.NET is use the `TextLoader` to read the training data from a file. However, in real-time training scenarios the data can be elsewhere, such as:

- in SQL tables
- JSON/XML
- extracted from log files
- generated on the fly

Use [schema comprehension](#) to bring an existing C# `IEnumerable` into ML.NET as a `DataView`.

For this example, you'll build the customer churn prediction model, and extract the following features from your production system:

- Customer ID (ignored by the model)
- Whether the customer has churned (the target 'label')
- The 'demographic category' (one string, like 'young adult' etc.)
- The number of visits from the last 5 days.

```
private class CustomerChurnInfo
{
    public string CustomerID { get; set; }
    public bool HasChurned { get; set; }
    public string DemographicCategory { get; set; }
    // Visits during last 5 days, latest to newest.
    [VectorType(5)]
    public float[] LastVisits { get; set; }
}
```

Load this data into the `DataView` and train the model, using the following code:

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Step one: read the data as an IDataView.
// Let's assume that 'GetChurnData()' fetches and returns the training data from somewhere.
IEnumerable<CustomerChurnInfo> churnData = GetChurnInfo();

// Turn the data into the ML.NET data view.
// We can use Create DataView or CreateStreaming DataView, depending on whether 'churnData' is an IList,
// or merely an IEnumerable.
var trainData = mlContext.Data.LoadFromEnumerable(churnData);

// Build the learning pipeline.
// In our case, we will one-hot encode the demographic category, and concatenate that with the number of
visits.
// We apply our FastTree binary classifier to predict the 'HasChurned' label.

var pipeline = mlContext.Transforms.Categorical.OneHotEncoding("DemographicCategory")
    .Append(mlContext.Transforms.Concatenate("Features", "DemographicCategory", "LastVisits"))
    .Append(mlContext.BinaryClassification.Trainers.FastTree("HasChurned", "Features", numTrees: 20));

var model = pipeline.Fit(trainData);
```

Train a machine learning model using cross-validation - ML.NET

[Cross-validation](#) is a useful technique for ML applications. It helps estimate the variance of the model quality from one run to another and also eliminates the need to extract a separate test set for evaluation.

ML.NET automatically applies featurization correctly (as long as all of the preprocessing resides in one learning pipeline) then use the 'stratification column' concept to make sure that related examples don't get separated.

Here's a training example on an Iris dataset using randomized 90/10 train-test split, and a 5-fold cross-validation:

```

// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Step one: read the data as an IDataView.
// First, we define the reader: specify the data columns and where to find them in the text file.
var reader = mlContext.Data.CreateTextLoader(
    columns: new TextLoader.Column[]
    {
        // The four features of the Iris dataset will be grouped together as one Features column.
        new TextLoader.Column("SepalLength", DataKind.R4, 0),
        new TextLoader.Column("SepalWidth", DataKind.R4, 1),
        new TextLoader.Column("PetalLength", DataKind.R4, 2),
        new TextLoader.Column("PetalWidth", DataKind.R4, 3),
        // Label: kind of iris.
        new TextLoader.Column("Label", DataKind.TX, 4)
    },
    // Default separator is tab, but the dataset has semicolon.
    separatorChar: ',',
    // First line of the file is a header, not a data row.
    hasHeader: true
);

// Read the data.
var data = reader.Read(dataPath);

// Build the training pipeline.
var dynamicPipeline =
    // Concatenate all the features together into one column 'Features'.
    mlContext.Transforms.Concatenate("Features", "SepalLength", "SepalWidth", "PetalLength", "PetalWidth")
    // Note that the label is text, so it needs to be converted to key.
    .Append(mlContext.Transforms.Conversion.MapValueToKey("Label"), TransformerScope.TrainTest)
    // Use the multi-class SDCA model to predict the label using features.
    .Append(mlContext.MulticlassClassification.Trainers.StochasticDualCoordinateAscent());

// Split the data 90:10 into train and test sets, train and evaluate.
var (trainData, testData) = mlContext.MulticlassClassification.TrainTestSplit(data, testFraction: 0.1);

// Train the model.
var model = dynamicPipeline.Fit(trainData);
// Compute quality metrics on the test set.
var metrics = mlContext.MulticlassClassification.Evaluate(model.Transform(testData));
Console.WriteLine(metrics.AccuracyMicro);

// Now run the 5-fold cross-validation experiment, using the same pipeline.
var cvResults = mlContext.MulticlassClassification.CrossValidate(data, dynamicPipeline, numFolds: 5);

// The results object is an array of 5 elements. For each of the 5 folds, we have metrics, model and scored
test data.
// Let's compute the average micro-accuracy.
var microAccuracies = cvResults.Select(r => r.metrics.AccuracyMicro);
Console.WriteLine(microAccuracies.Average());

Inspect intermediate data values during ML.NET pipeline processing

During the experiment, you may want to observe and validate the data processing results at a given point. This isn't easy since ML.NET operations are lazy, constructing objects that are 'promises' of data.

The `GetColumn<T>` extension method lets you inspect the intermediate data. It returns the contents of one data column as an `IEnumerable`.

The following example shows how to use the `GetColumn<T>` extension method:

Example file:

```
Label Workclass education marital-status
0 Private 11th Never-married
0 Private HS-grad Married-civ-spouse
1 Local-gov Assoc-acdm Married-civ-spouse
1 Private Some-college Married-civ-spouse
```

Our class is defined as follows:

```
public class InspectedRow
{
    [LoadColumn(0)]
    public bool IsOver50K { get; set; }
    [LoadColumn(1)]
    public string WorkClass { get; set; }
    [LoadColumn(2)]
    public string Education { get; set; }
    [LoadColumn(3)]
    public string MaritalStatus { get; set; }
}
```

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Read the data into a data view.
var data = mlContext.Data.ReadFromTextFile<InspectedRow>(dataPath, hasHeader: true);

// Start creating our processing pipeline. For now, let's just concatenate all the text columns
// together into one.
var pipeline = mlContext.Transforms.Concatenate("AllFeatures", "WorkClass", "Education", "MaritalStatus");

// Fit our data pipeline and transform data with it.
var transformedData = pipeline.Fit(data).Transform(data);

// Extract the 'AllFeatures' column.
// This will give the entire dataset: make sure to only take several row
// in case the dataset is huge. The is similar to the static API, except
// you have to specify the column name and type.
var featureColumns =
    transformedData
        .GetColumn<string[]>(mlContext, "AllFeatures")
        .Take(20)
        .ToArray();
```

Train a regression model to predict a value using ML.NET

Generally, there are three steps for model training in ML.NET:

1. Get the training data in a form of an `IDataView`
2. Build the 'learning pipeline' as a sequence of elementary 'operators' (estimators).
3. Call `Fit` on the pipeline to obtain the trained model.

In this [Example file](#), the predicted label (`target`) is the last column (12th) and all the rest are features:

```
feature_0;feature_1;feature_2;feature_3;feature_4;feature_5;feature_6;feature_7;feature_8;feature_9;feature_10
;target
-2.75;0.77;-0.61;0.14;1.39;0.38;-0.53;-0.50;-2.13;-0.39;0.46;140.66
-0.61;-0.37;-0.12;0.55;-1.00;0.84;-0.02;1.30;-0.24;-0.50;-2.12;148.12
-0.85;-0.91;1.81;0.02;-0.78;-1.41;-1.09;-0.65;0.90;-0.37;-0.22;402.20
```

```

// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Step one: read the data as an IDataView.

// First, we define the reader: specify the data columns and where to find them in the text file.
var reader = mlContext.Data.CreateTextLoader(
    columns: new TextLoader.Column[]
    {
        // We read the first 11 values as a single float vector.
        new TextLoader.Column("FeatureVector", DataKind.R4, 0, 10),
        // Separately, read the target variable.
        new TextLoader.Column("Target", DataKind.R4, 11)
    },
    // Default separator is tab, but the dataset has semicolon.
    separatorChar: ';',
    // First line of the file is a header, not a data row.
    hasHeader: true
);

// Now read the file (remember though, readers are lazy, so the actual reading will happen when the data is
// accessed).
var trainData = reader.Read(dataPath);

// Step two: define the learning pipeline.

// We 'start' the pipeline with the output of the reader.
var pipeline =
    // First 'normalize' the data (rescale to be
    // between -1 and 1 for all examples)
    mlContext.Transforms.Normalize("FeatureVector")
    // Cache data in memory so that SDCA trainer will be able to randomly access training examples without
    // reading data from disk multiple times. Data will be cached at its first use in any downstream step.
    // Notice that unused part in the data may not be cached.
    .AppendCacheCheckpoint(mlContext)
    // First 'normalize' the data (rescale to be
    // between -1 and 1 for all examples)
    .Append(mlContext.Regression.Trainers.StochasticDualCoordinateAscent("Target", "FeatureVector"));

// Step three. Fit the pipeline to the training data.
var model = pipeline.Fit(trainData);

Determine the feature importance of models with Permutation Feature Importance in ML.NET

When creating machine learning models, it is often not enough to simply make predictions. Often, machine learning developers, decision makers, and those affected by the models need to understand how machine learning models make decisions and which features contribute to their performance. [Permutation Feature Importance](#) (PFI) is a model explainability tool that is used internally at Microsoft to help machine learning developers better understand the feature importance of models.

PFI is a technique to determine **global feature importance** in a trained machine learning model, motivated by Breiman in the ["Random Forests" paper, section 10](#). PFI measures feature importance by asking the question, "What would the effect on the model be if the values for a feature were set to a random\* value?". The advantage of the PFI method is that it is model agnostic — it works with any model that can be evaluated — and it can use any dataset, not just the training set, to compute feature importance. You can use PFI like so to produce feature importances like this graph:

```
// Compute the feature importance using PFI
var permutationMetrics = mlContext.Regression.PermutationFeatureImportance(model.LastTransformer,
model.Transform(data), "MedianHomeValue");

// Get the feature names from the training set
var featureNames =
    data.Schema.AsEnumerable()
    .Select(column => column.Name) // Get the column names
    .Where(name => name != "MedianHomeValue") // Drop the Label
    .ToArray();

// Write out the feature names and their importance to the model's Mean R-squared value
for (int i = 0; i < featureNames.Length;i++)
{
    Console.WriteLine($"{featureNames[i]}\t{permutationMetrics[i].RSquared.Mean:G4}");
}
```

For a sample using PFI to analyze the feature importance of a model, see [the dotnet/machinelearning GitHub repository](#).

/\* Well, not random exactly, but permuted across the set of examples.

Use the PredictionEngine to make one prediction at a time - ML.NET

Since any ML.NET model is a transformer, you use `model.Transform` to apply the model to the `DataView` to make predictions.

A more typical case, though, is when there is no 'dataset' that you want to predict on, but instead you receive one example at a time. For instance, you run the model as part of your ASP.NET website, and need to make a prediction for an incoming HTTP request.

The `PredictionEngine` runs one example at a time through the prediction pipeline.

Here is the full example using a prebuilt Iris prediction dataset model:

```

// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Step one: read the data as an IDataView.
// First, we define the reader: specify the data columns and where to find them in the text file.
var reader = mlContext.Data.CreateTextLoader(
    columns: new TextLoader.Column[]
    {
        // The four features of the Iris dataset will be grouped together as one Features column.
        new TextLoader.Column("SepalLength", DataKind.R4, 0),
        new TextLoader.Column("SepalWidth", DataKind.R4, 1),
        new TextLoader.Column("PetalLength", DataKind.R4, 2),
        new TextLoader.Column("PetalWidth", DataKind.R4, 3),
        // Label: kind of iris.
        new TextLoader.Column("Label", DataKind.TX, 4)
    },
    separatorChar: ',',
    hasHeader: true
);

// Retrieve the training data.
var trainData = reader.Read(irisDataPath);

// Build the training pipeline.
var pipeline =
    // Concatenate all the features together into one column 'Features'.
    mlContext.Transforms.Concatenate("Features", "SepalLength", "SepalWidth", "PetalLength", "PetalWidth")
    // Note that the label is text, so it needs to be converted to key.
    .Append(mlContext.Transforms.Categorical.MapValueToKey("Label"), TransformerScope.TrainTest)
    // Use the multi-class SDCA model to predict the label using features.
    .Append(mlContext.MulticlassClassification.Trainers.StochasticDualCoordinateAscent())
    // Apply the inverse conversion from 'PredictedLabel' column back to string value.
    .Append(mlContext.Transforms.Conversion.MapKeyToValue(("Data", "PredictedLabel")));

// Train the model.
var model = pipeline.Fit(trainData);

```

To use [schema comprehension](#) for prediction, define a pair of classes like the following:

```

private class IrisInput
{
    // Unfortunately, we still need the dummy 'Label' column to be present.
    [ColumnName("Label")]
    public string IgnoredLabel { get; set; }
    public float SepalLength { get; set; }
    public float SepalWidth { get; set; }
    public float PetalLength { get; set; }
    public float PetalWidth { get; set; }
}

private class IrisPrediction
{
    [ColumnName("Data")]
    public string PredictedClass { get; set; }
}

```

The prediction code now looks as follows:

```
// Create a new context for ML.NET operations. It can be used for exception tracking and logging,
// as a catalog of available operations and as the source of randomness.
var mlContext = new MLContext();

// Use the model for one-time prediction.
// Make the prediction function object. Note that, on average, this call takes around 200x longer
// than one prediction, so you might want to cache and reuse the prediction engine, instead of
// creating one per prediction.
var predictionEngine = model.CreatePredictionEngine<IrisInput, IrisPrediction>(mlContext);

// Obtain the prediction. Remember that 'Predict' is not reentrant. If you want to use multiple threads
// for simultaneous prediction, make sure each thread is using its own PredictionEngine.
var prediction = predictionEngine.Predict(new IrisInput
{
    SepalLength = 4.1f,
    SepalWidth = 0.1f,
    PetalLength = 3.2f,
    PetalWidth = 1.4f
});
```

Operationalize a trained machine learning model in apps - ML.NET

3/8/2019 • 2 minutes to read • [Edit Online](#)

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit [the ML.NET introduction](#).

This how-to and related sample are currently using **ML.NET version 0.10**. For more information, see the release notes at the [dotnet/machinelearning github repo](#)

When the model metrics look good to you, it's time to 'operationalize' the model. The `model` object you built can be consumed, persisted, and reused in different environments, applying the same steps that it 'learned' during training.

To save the model to a file, and reload it (potentially in a different context), use the following example:

```
using (var stream = File.Create(modelPath))
{
    // Saving and loading happens to 'dynamic' models.
    mlContext.Model.Save(model, stream);
}

// Potentially, the lines below can be in a different process altogether.

// When you load the model, it's a transformer.
ITransformer loadedModel;
using (var stream = File.OpenRead(modelPath))
    loadedModel = mlContext.Model.Load(stream);
```

How-To: Use ML.NET Model in Azure Functions

3/12/2019 • 4 minutes to read • [Edit Online](#)

This how-to shows how individual predictions can be made using a pre-built ML.NET machine learning model through the internet in a serverless environment such as Azure Functions.

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit [the ML.NET introduction](#).

This how-to and related sample are currently using **ML.NET version 0.10**. For more information, see the release notes at the [dotnet/machinelearning github repo](#).

Prerequisites

- [Visual Studio 2017 15.6 or later](#) with the ".NET Core cross-platform development" workload and "Azure development" installed.
- [Azure Functions Tools](#)
- Powershell
- Pre-trained model.
 - Use the [ML.NET Sentiment Analysis tutorial](#) to build your own model.
 - Download this [pre-trained sentiment analysis machine learning model](#)

Create Azure Functions Project

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the **New Project** dialog, select the **Visual C#** node followed by the **Cloud** node. Then select the **Azure Functions** project template. In the **Name** text box, type "SentimentAnalysisFunctionsApp" and then select the **OK** button.
2. In the **New Project** dialog, open the dropdown above the project options and select **Azure Functions v2 (.NET Core)**. Then, select the **Http trigger** project and then select the **OK** button.
3. Create a directory named *MLModels* in your project to save your model:

In **Solution Explorer**, right-click on your project and select **Add > New Folder**. Type "MLModels" and hit Enter.

4. Install the **Microsoft.ML NuGet Package**:

In Solution Explorer, right-click on your project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the Browse tab, search for **Microsoft.ML**, select that package in the list, and select the **Install** button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the **License Acceptance** dialog if you agree with the license terms for the packages listed.

Add Pre-built Model To Project

1. Copy your pre-built model to the *MLModels* folder.
2. In Solution Explorer, right-click your pre-built model file and select **Properties**. Under **Advanced**, change the

value of **Copy to Output Directory** to **Copy if newer**.

Create Function to Analyze Sentiment

Create a class to predict sentiment. Add a new class to your project:

1. In **Solution Explorer**, right-click the project, and then select **Add > New Item**.
2. In the **Add New Item** dialog box, select **Azure Function** and change the **Name** field to *AnalyzeSentiment.cs*. Then, select the **Add** button.
3. In the **New Azure Function** dialog box, select **Http Trigger**. Then, select the **OK** button.

The *AnalyzeSentiment.cs* file opens in the code editor. Add the following `using` statement to the top of *GitHubIssueData.cs*:

```
using System;
using System.IO;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Azure.WebJobs;
using Microsoft.Azure.WebJobs.Extensions.Http;
using Microsoft.AspNetCore.Http;
using Microsoft.Extensions.Logging;
using Newtonsoft.Json;
using Microsoft.ML;
using Microsoft.ML.Core.Data;
using Microsoft.ML.Data;
using MLNETServerless.DataModels;
```

Create Data Models

You need to create some classes for your input data and predictions. Add a new class to your project:

1. Create a directory named *DataModels* in your project to save your data models: In Solution Explorer, right-click on your project and select **Add > New Folder**. Type "DataModels" and hit Enter.
2. In Solution Explorer, right-click the *DataModels* directory, and then select **Add > New Item**.
3. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *SentimentData.cs*. Then, select the **Add** button. The *SentimentData.cs* file opens in the code editor. Add the following `using` statement to the top of *SentimentData.cs*:

```
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code to the *SentimentData.cs* file:

```
public class SentimentData
{
    [LoadColumn(0)]
    public bool Label { get; set; }
    [LoadColumn(1)]
    public string Text { get; set; }
}
```

4. In Solution Explorer, right-click the *DataModels* directory, and then select **Add > New Item**.
5. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *SentimentPrediction.cs*. Then, select the **Add** button. The *SentimentPrediction.cs* file opens in the code editor. Add the following `using` statement to the top of *SentimentPrediction.cs*:

```
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code to the *SentimentPrediction.cs* file:

```
public class SentimentPrediction
{
    [ColumnName("PredictedLabel")]
    public bool Prediction { get; set; }
}
```

Add Prediction Logic

Replace the existing implementation of *Run* method in *AnalyzeSentiment* class with the following code:

```
public static async Task<IActionResult> Run(
    [HttpTrigger(AuthorizationLevel.Function, "post", Route = null)] HttpRequest req,
    ILogger log)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    //Create Context
    MLContext mlContext = new MLContext();

    //Load Model
    using (var fs = File.OpenRead("MLModels/sentiment_model.zip"))
    {
        model = mlContext.Model.Load(fs);
    }

    //Parse HTTP Request Body
    string requestBody = await new StreamReader(req.Body).ReadToEndAsync();
    SentimentData data = JsonConvert.DeserializeObject<SentimentData>(requestBody);

    //Create Prediction Engine
    PredictionEngine<SentimentData, SentimentPrediction> predictionEngine =
    model.CreatePredictionEngine<SentimentData, SentimentPrediction>(mlContext);

    //Make Prediction
    SentimentPrediction prediction = predictionEngine.Predict(data);

    //Convert prediction to string
    string isToxic = Convert.ToBoolean(prediction.Prediction) ? "Toxic" : "Not Toxic";

    //Return Prediction
    return (ActionResult)new OkObjectResult(isToxic);
}
```

Test Locally

Now that everything is set up, it's time to test the application:

1. Run the application
2. Open PowerShell and enter the code into the prompt where PORT is the port your application is running on.
Typically the port is 7071.

```
Invoke-RestMethod "http://localhost:<PORT>/api/AnalyzeSentiment" -Method Post -Body (@{Text="This is a very
rude movie"} | ConvertTo-Json) -ContentType "application/json"
```

If successful, the output should look similar to the text below:

```
Toxic
```

Congratulations! You have successfully served your model to make predictions over the internet using an Azure Function.

How-To: Serve Machine Learning Model Through ASP.NET Core Web API

3/21/2019 • 5 minutes to read • [Edit Online](#)

This how-to shows how to serve a pre-built ML.NET machine learning model to the web using an ASP.NET Core Web API. By doing so it allows for users to access the API for prediction purposes via standard HTTP methods.

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit [the ML.NET introduction](#).

This how-to and related sample are currently using **ML.NET version 0.10**. For more information, see the release notes at the [dotnet/machinelearning github repo](#).

Prerequisites

- [Visual Studio 2017 15.6 or later](#) with the ".NET Core cross-platform development" workload installed.
- Powershell.
- Pre-trained model.
 - Use the [ML.NET Sentiment Analysis tutorial](#) to build your own model.
 - Download this [pre-trained sentiment analysis machine learning model](#)

Create ASP.NET Core Web API Project

1. Open Visual Studio 2017. Select **File > New > Project** from the menu bar. In the New Project dialog, select the **Visual C#** node followed by the **Web** node. Then select the **ASP.NET Core Web Application** project template. In the **Name** text box, type "SentimentAnalysisWebAPI" and then select the **OK** button.
2. In the window that displays the different types of ASP.NET Core Projects, select **API** and then select the **OK** button.
3. Create a directory named *MLModels* in your project to save your pre-built machine learning model files:
In Solution Explorer, right-click on your project and select Add > New Folder. Type "MLModels" and hit Enter.

4. Install the **Microsoft.ML NuGet Package**:
In Solution Explorer, right-click on your project and select **Manage NuGet Packages**. Choose "nuget.org" as the Package source, select the Browse tab, search for **Microsoft.ML**, select that package in the list, and select the Install button. Select the **OK** button on the **Preview Changes** dialog and then select the **I Accept** button on the License Acceptance dialog if you agree with the license terms for the packages listed.

Add Model to ASP.NET Core Web API Project

1. Copy your pre-built model to the *MLModels* directory
2. In Solution Explorer, right-click the model zip file and select Properties. Under Advanced, change the value of Copy to Output Directory to Copy if newer.

Build Data Models

You need to create some classes for your input data and predictions. Add a new class to your project:

1. Create a directory named *DataModels* in your project to save your data models:

In Solution Explorer, right-click on your project and select Add > New Folder. Type "DataModels" and hit **Enter**.

2. In Solution Explorer, right-click the *DataModels* directory, and then select Add > New Item.
3. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *SentimentData.cs*. Then, select the **Add** button. The *SentimentData.cs* file opens in the code editor. Add the following using statement to the top of *SentimentData.cs*:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code to the **SentimentData.cs** file:

```
public class SentimentData
{
    [LoadColumn(0)]
    public bool Label { get; set; }
    [LoadColumn(1)]
    public string Text { get; set; }
}
```

4. In Solution Explorer, right-click the *DataModels* directory, and then select **Add > New Item**.
5. In the **Add New Item** dialog box, select **Class** and change the **Name** field to *SentimentPrediction.cs*. Then, select the Add button. The *SentimentPrediction.cs* file opens in the code editor. Add the following using statement to the top of *SentimentPrediction.cs*:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.ML.Data;
```

Remove the existing class definition and add the following code to the *SentimentPrediction.cs* file:

```
public class SentimentPrediction
{
    [ColumnName("PredictedLabel")]
    public bool Prediction { get; set; }
}
```

Register PredictionEngine for Use in Application

To make a single prediction, you can use `PredictionEngine`. In order to use `PredictionEngine` in your application you will have to create it every time it is needed. In that case, a best practice to consider is ASP.NET Core dependency injection.

The following link provides more information if you want to learn about [dependency injection](#).

1. Open the *Startup.cs* class and add the following using statement to the top of the file:

```
using System.IO;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.ML;
using Microsoft.ML.Core.Data;
using SentimentAnalysisWebAPI.DataModels;
```

2. Add the following lines of code to the *ConfigureServices* method:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddScoped<MLContext>();
    services.AddScoped<PredictionEngine<SentimentData, SentimentPrediction>>((ctx) =>
    {
        MLContext mlContext = ctx.GetRequiredService<MLContext>();
        string modelFilePathName = "MLModels/sentiment_model.zip";

        //Load model from file
        ITransformer model;
        using (var stream = File.OpenRead(modelFilePathName))
        {
            model = mlContext.Model.Load(stream);
        }

        // Return prediction engine
        return model.CreatePredictionEngine<SentimentData, SentimentPrediction>(mlContext);
    });
}
```

WARNING

`PredictionEngine` is not thread-safe. A way that you can limit the cost of creating the object is by making its service lifetime *Scoped*. *Scoped* objects are the same within a request but different across requests. Visit the following link to learn more about [service lifetimes](#).

At a high level, this code initializes the objects and services automatically when requested by the application instead of having to manually do it.

Create Predict Controller

To process your incoming HTTP requests, you need to create a controller.

1. In Solution Explorer, right-click the *Controllers* directory, and then select **Add > Controller**.
2. In the **Add New Item** dialog box, select **API Controller Empty** and select **Add**.
3. In the prompt change the **Controller Name** field to *PredictController.cs*. Then, select the Add button. The *PredictController.cs* file opens in the code editor. Add the following using statement to the top of *PredictController.cs*:

```
using System;
using Microsoft.AspNetCore.Mvc;
using SentimentAnalysisWebAPI.DataModels;
using Microsoft.ML;
```

Remove the existing class definition and add the following code to the *PredictController.cs* file:

```
public class PredictController : ControllerBase
{
    private readonly PredictionEngine<SentimentData, SentimentPrediction> _predictionEngine;

    public PredictController(PredictionEngine<SentimentData, SentimentPrediction> predictionEngine)
    {
        _predictionEngine = predictionEngine; //Define prediction engine
    }

    [HttpPost]
    public ActionResult<string> Post([FromBody]SentimentData input)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest();
        }

        // Make a prediction
        SentimentPrediction prediction = _predictionEngine.Predict(input);

        //If prediction is true then it is toxic. If it is false, the it is not.
        string isToxic = Convert.ToBoolean(prediction.Prediction) ? "Toxic" : "Not Toxic";

        return Ok(isToxic);
    }
}
```

This is assigning the `PredictionEngine` by passing it to the controller's constructor which you get via dependency injection. Then, in the POST method of this controller the `PredictionEngine` is being used to make predictions and return the results back to the user if successful.

Test Web API Locally

Once everything is set up, it's time to test the application.

1. Run the application.
2. Open Powershell and enter the following code where PORT is the port your application is listening on.

```
Invoke-RestMethod "https://localhost:<PORT>/api/predict" -Method Post -Body (@{Text="This is a very rude movie"} | ConvertTo-Json) -ContentType "application/json"
```

If successful, the output should look similar to the text below:

```
Toxic
```

Congratulations! You have successfully served your model to make predictions over the internet using an ASP.NET Core API.

Create a game match up list app with Infer.NET and probabilistic programming

3/8/2019 • 4 minutes to read • [Edit Online](#)

NOTE

This topic refers to ML.NET, which is currently in Preview, and material may be subject to change. For more information, visit the [ML.NET introduction](#).

This how-to and related sample are currently using **ML.NET version 0.10**. For more information, see the release notes at the [dotnet/machinelearning GitHub repo](#).

This how-to guide teaches you about probabilistic programming using Infer.NET. Probabilistic programming is a machine learning approach where custom models are expressed as computer programs. It allows for incorporating domain knowledge in the models and makes the machine learning system more interpretable. It also supports online inference – the process of learning as new data arrives. Infer.NET is used in various products at Microsoft in Azure, Xbox, and Bing.

What is probabilistic programming?

Probabilistic programming allows you to create statistical models of real-world processes.

Prerequisites

- Local development environment setup

This how-to guide expects you to have a machine you can use for development. The .NET [Get Started in 10 minutes](#) tutorial has instructions for setting up your local development environment on Mac, PC, or Linux.

Create your app

1. Open a new command prompt and run the following commands:

```
dotnet new console -o myApp  
cd myApp
```

The `dotnet` command creates a `new` application of type `console`. The `-o` parameter creates a directory named `myApp` where your app is stored and populates it with the required files. The `cd myApp` command puts you into the newly created app directory.

Install Infer.NET package

To use Infer.NET, you need to install the `Microsoft.ML.Probabilistic.Compiler` package. In your command prompt, run the following command:

```
dotnet add package Microsoft.ML.Probabilistic.Compiler
```

Design your model

The example sample uses table tennis or foosball matches played in the office. You have the participants and outcome of each match. You want to infer the player's skills from this data. Assume that each player has a normally distributed latent skill and their given match performance is a noisy version of this skill. The data constrains the winner's performance to be greater than the loser's performance. This is a simplified version of the popular [TrueSkill](#) model, which also supports teams, draws, and other extensions. An [advanced version](#) of this model is used for matchmaking in the best-selling game titles Halo and Gears of War.

You need to list the inferred player skills, alongside with their variance – the measure of uncertainty around the skills.

Game result sample data

GAME	WINNER	LOSER
1	Player 0	Player 1
2	Player 0	Player 3
3	Player 0	Player 4
4	Player 1	Player 2
5	Player 3	Player 1
6	Player 4	Player 2

With a closer look at the sample data, you'll notice that players 3 and 4 both have one win and one loss. Let's see what the rankings look like using probabilistic programming. Notice also there is a player zero because even office match up lists are zero based to us developers.

Write some code

Having designed the model, it's time to express it as a probabilistic program using the Infer.NET modeling API. Open `Program.cs` in your favorite text editor and replace all of its contents with the following code:

```

namespace MyApp

{
    using System;
    using System.Linq;
    using Microsoft.ML.Probabilistic;
    using Microsoft.ML.Probabilistic.Distributions;
    using Microsoft.ML.Probabilistic.Models;

    class Program
    {

        static void Main(string[] args)
        {
            // The winner and loser in each of 6 samples games
            var winnerData = new[] { 0, 0, 0, 1, 3, 4 };
            var loserData = new[] { 1, 3, 4, 2, 1, 2 };

            // Define the statistical model as a probabilistic program
            var game = new Range(winnerData.Length);
            var player = new Range(winnerData.Concat(loserData).Max() + 1);
            var playerSkills = Variable.Array<double>(player);
            playerSkills[player] = Variable.GaussianFromMeanAndVariance(6, 9).ForEach(player);

            var winners = Variable.Array<int>(game);
            var losers = Variable.Array<int>(game);

            using (Variable.ForEach(game))
            {
                // The player performance is a noisy version of their skill
                var winnerPerformance = Variable.GaussianFromMeanAndVariance(playerSkills[winners[game]], 1.0);
                var loserPerformance = Variable.GaussianFromMeanAndVariance(playerSkills[losers[game]], 1.0);

                // The winner performed better in this game
                Variable.ConstrainTrue(winnerPerformance > loserPerformance);
            }

            // Attach the data to the model
            winners.ObservedValue = winnerData;
            losers.ObservedValue = loserData;

            // Run inference
            var inferenceEngine = new InferenceEngine();
            var inferredSkills = inferenceEngine.Infer<Gaussian[]>(playerSkills);

            // The inferred skills are uncertain, which is captured in their variance
            var orderedPlayerSkills = inferredSkills
                .Select((s, i) => new { Player = i, Skill = s })
                .OrderByDescending(ps => ps.Skill.GetMean());

            foreach (var playerSkill in orderedPlayerSkills)
            {
                Console.WriteLine($"Player {playerSkill.Player} skill: {playerSkill.Skill}");
            }
        }
    }
}

```

Run your app

In your command prompt, run the following command:

```
dotnet run
```

Results

Your results should be similar to the following:

```
Compiling model...done.  
Iterating:  
.....|.....|.....|.....|.....| 50  
Player 0 skill: Gaussian(9.517, 3.926)  
Player 3 skill: Gaussian(6.834, 3.892)  
Player 4 skill: Gaussian(6.054, 4.731)  
Player 1 skill: Gaussian(4.955, 3.503)  
Player 2 skill: Gaussian(2.639, 4.288)
```

In the results, notice that player 3 ranks slightly higher than player 4 according to our model. That's because the victory of player 3 over player 1 is more significant than the victory of player 4 over player 2 – note that player 1 beats player 2. Player 0 is the overall champ!

Keep learning

Designing statistical models is a skill on its own. The Microsoft Research Cambridge team has written a [free online book](#), which gives a gentle introduction to the article. Chapter 3 of this book covers the TrueSkill model in more detail. Once you have a model in mind, you can transform it into code using the [extensive documentation](#) on the Infer.NET website.

Machine learning glossary of important terms

3/25/2019 • 5 minutes to read • [Edit Online](#)

The following list is a compilation of important machine learning terms that are useful as you build your custom models in ML.NET.

NOTE

This documentation refers to ML.NET, which is currently in Preview. Material may be subject to change. For more information, see the [ML.NET introduction](#).

Accuracy

In [classification](#), accuracy is the number of correctly classified items divided by the total number of items in the test set. Ranges from 0 (least accurate) to 1 (most accurate). Accuracy is one of evaluation metrics of the model performance. Consider it in conjunction with [precision](#), [recall](#), and [F-score](#).

Area under the curve (AUC)

In [binary classification](#), an evaluation metric that is the value of the area under the curve that plots the true positives rate (on the y-axis) against the false positives rate (on the x-axis). Ranges from 0.5 (worst) to 1 (best). Also known as the area under the ROC curve, i.e., receiver operating characteristic curve. For more information, see the [Receiver operating characteristic](#) article on Wikipedia.

Binary classification

A [classification](#) case where the [label](#) is only one out of two classes. For more information, see the [Binary classification](#) section of the [Machine learning tasks](#) topic.

Classification

When the data is used to predict a category, [supervised machine learning](#) task is called classification. [Binary classification](#) refers to predicting only two categories (for example, classifying an image as a picture of either a 'cat' or a 'dog'). [Multiclass classification](#) refers to predicting multiple categories (for example, when classifying an image as a picture of a specific breed of dog).

Coefficient of determination

In [regression](#), an evaluation metric that indicates how well data fits a model. Ranges from 0 to 1. A value of 0 means that the data is random or otherwise cannot be fit to the model. A value of 1 means that the model exactly matches the data. This is often referred to as r^2 , R^2 , or r-squared.

Feature

A measurable property of the phenomenon being measured, typically a numeric (double) value. Multiple features are referred to as a [Feature vector](#) and typically stored as `double[]`. Features define the important characteristics of the phenomenon being measured. For more information, see the [Feature](#) article on Wikipedia.

Feature engineering

Feature engineering is the process that involves defining a set of [features](#) and developing software that produces feature vectors from available phenomenon data, i.e., feature extraction. For more information, see the [Feature engineering](#) article on Wikipedia.

F-score

In [classification](#), an evaluation metric that balances [precision](#) and [recall](#).

Hyperparameter

A parameter of a machine learning algorithm. Examples include the number of trees to learn in a decision forest or the step size in a gradient descent algorithm. Values of *Hyperparameters* are set before training the model and govern the process of finding the parameters of the prediction function, for example, the comparison points in a decision tree or the weights in a linear regression model. For more information, see the [Hyperparameter](#) article on Wikipedia.

Label

The element to be predicted with the machine learning model. For example, the breed of dog or a future stock price.

Log loss

In [classification](#), an evaluation metric that characterizes the accuracy of a classifier. The smaller log loss is, the more accurate a classifier is.

Mean absolute error (MAE)

In [regression](#), an evaluation metric that is the average of all the model errors, where model error is the distance between the predicted [label](#) value and the correct label value.

Model

Traditionally, the parameters for the prediction function. For example, the weights in a linear regression model or the split points in a decision tree. In ML.NET, a model contains all the information necessary to predict the [label](#) of a domain object (for example, image or text). This means that ML.NET models include the featurization steps necessary as well as the parameters for the prediction function.

Multiclass classification

A [classification](#) case where the [label](#) is one out of three or more classes. For more information, see the [Multiclass classification](#) section of the [Machine learning tasks](#) topic.

N-gram

A feature extraction scheme for text data: any sequence of N words turns into a [feature](#) value.

Numerical feature vector

A [feature](#) vector consisting only of numerical values. This is similar to `double[]`.

Pipeline

All of the operations needed to fit a model to a data set. A pipeline consists of data import, transformation,

featurization, and learning steps. Once a pipeline is trained, it turns into a model.

Precision

In [classification](#), the precision for a class is the number of items correctly predicted as belonging to that class divided by the total number of items predicted as belonging to the class.

Recall

In [classification](#), the recall for a class is the number of items correctly predicted as belonging to that class divided by the total number of items that actually belong to the class.

Regression

A [supervised machine learning](#) task where the output is a real value, for example, double. Examples include predicting stock prices. For more information, see the [Regression](#) section of the [Machine learning tasks](#) topic.

Relative absolute error

In [regression](#), an evaluation metric that is the sum of all absolute errors divided by the sum of distances between correct [label](#) values and the average of all correct label values.

Relative squared error

In [regression](#), an evaluation metric that is the sum of all squared absolute errors divided by the sum of squared distances between correct [label](#) values and the average of all correct label values.

Root of mean squared error (RMSE)

In [regression](#), an evaluation metric that is the square root of the average of the squares of the errors.

Supervised machine learning

A subclass of machine learning in which a desired model predicts the label for yet-unseen data. Examples include classification, regression, and structured prediction. For more information, see the [Supervised learning](#) article on Wikipedia.

Training

The process of identifying a [model](#) for a given training data set. For a linear model, this means finding the weights. For a tree, it involves identifying the split points.

Transform

A [pipeline](#) component that transforms data. For example, from text to vector of numbers.

Unsupervised machine learning

A subclass of machine learning in which a desired model finds hidden (or latent) structure in data. Examples include clustering, topic modeling, and dimensionality reduction. For more information, see the [Unsupervised learning](#) article on Wikipedia.

Machine learning tasks in ML.NET

1/19/2019 • 5 minutes to read • [Edit Online](#)

When building a machine learning model, you first need to define what you are hoping to achieve with your data. Afterwards, you can pick the right machine learning task for your situation. The following list describes the different machine learning tasks that you can choose from and some common use cases.

NOTE

ML.NET is currently in Preview. Not all machine learning tasks are currently supported. To submit a request for a certain task, open an issue in the [dotnet/machinelearning repository](#).

Binary classification

A [supervised machine learning](#) task that is used to predict which of two classes (categories) an instance of data belongs to. The input of a classification algorithm is a set of labeled examples, where each label is an integer of either 0 or 1. The output of a binary classification algorithm is a classifier, which you can use to predict the class of new unlabeled instances. Examples of binary classification scenarios include:

- [Understanding sentiment of Twitter comments](#) as either "positive" or "negative".
- Diagnosing whether a patient has a certain disease or not.
- Making a decision to mark an email as "spam" or not.
- Determining if a photo contains a dog or fruit.

For more information, see the [Binary classification](#) article on Wikipedia.

Recommended learners for binary classification:

- [AveragedPerceptronTrainer](#)
- [StochasticGradientDescentClassificationTrainer](#)
- [LightGbmBinaryTrainer](#)
- [FastTreeBinaryClassificationTrainer](#)
- [SymSgdClassificationTrainer](#)

Binary Classification Learners

The following learners are available for binary classification tasks:

- [AveragedPerceptronTrainer](#)
- [BinaryClassificationGamTrainer](#)
- [FastForestClassification](#)
- [FastTreeBinaryClassificationTrainer](#)
- [FieldAwareFactorizationMachineTrainer](#)
- [LightGbmBinaryTrainer](#)
- [LinearSvmTrainer](#)
- [LogisticRegression](#)
- [PriorTrainer](#)
- [RandomTrainer](#)
- [StochasticGradientDescentClassificationTrainer](#)

- [SymSgdClassificationTrainer](#)

Multiclass classification

A [supervised machine learning](#) task that is used to predict the class (category) of an instance of data. The input of a classification algorithm is a set of labeled examples. Each label normally starts as text. It is then run through the TermTransform, which converts it to the Key (numeric) type. The output of a classification algorithm is a classifier, which you can use to predict the class of new unlabeled instances. Examples of multi-class classification scenarios include:

- Determining the breed of a dog as a "Siberian Husky", "Golden Retriever", "Poodle", etc.
- Understanding movie reviews as "positive", "neutral", or "negative".
- Categorizing hotel reviews as "location", "price", "cleanliness", etc.

For more information, see the [Multiclass classification](#) article on Wikipedia.

Recommended learners for Multi-class:

- OVA-AveragedPerceptronTrainer
- SdcaMultiClassTrainer
- LightGbmMulticlassTrainer
- OVA-FastTreeBinaryClassificationTrainer

NOTE

OVA and PKPD upgrades any [binary classification learner](#) to act on multiclass datasets. More information on [Wikipedia] ([https://en.wikipedia.org/wiki/Multiclass\\_classification#One-vs.-rest](https://en.wikipedia.org/wiki/Multiclass_classification#One-vs.-rest)).

Multiclass Classification Learners

The following learners are available for multiclass classification tasks:

- [LightGbmMulticlassTrainer](#)
- [MetaMulticlassTrainer<TTransformer,TModel>](#)
- [MultiClassNaiveBayesTrainer](#)
- [Ova](#)
- [Pkpd](#)
- [SdcaMultiClassTrainer](#)

Regression

A [supervised machine learning](#) task that is used to predict the value of the label from a set of related features. The label can be of any real value and is not from a finite set of values as in classification tasks. Regression algorithms model the dependency of the label on its related features to determine how the label will change as the values of the features are varied. The input of a regression algorithm is a set of examples with labels of known values. The output of a regression algorithm is a function, which you can use to predict the label value for any new set of input features. Examples of regression scenarios include:

- Predicting house prices based on house attributes such as number of bedrooms, location, or size.
- Predicting future stock prices based on historical data and current market trends.
- Predicting sales of a product based on advertising budgets.

Recommended learners for regression:

- [FastTreeTweedieTrainer](#)

- [LightGbmRegressorTrainer](#)
- [SdcaRegressionTrainer](#)
- [FastTreeRegressionTrainer](#)

Regression Learners

The following learners are available for regression tasks:

- [FastTreeRegressionTrainer](#)
- [FastTreeTweedieTrainer](#)
- [LightGbmRegressorTrainer](#)
- [OlsLinearRegressionTrainer](#)
- [OnlineGradientDescentTrainer](#)
- [PoissonRegression](#)
- [RegressionGamTrainer](#)
- [SdcaRegressionTrainer](#)
- [FastTree.SingleTrainer](#)
- [LightGBM.SingleTrainer](#)

Clustering

An [unsupervised machine learning](#) task that is used to group instances of data into clusters that contain similar characteristics. Clustering can also be used to identify relationships in a dataset that you might not logically derive by browsing or simple observation. The inputs and outputs of a clustering algorithm depends on the methodology chosen. You can take a distribution, centroid, connectivity, or density-based approach. ML.NET currently supports a centroid-based approach using K-Means clustering. Examples of clustering scenarios include:

- Understanding segments of hotel guests based on habits and characteristics of hotel choices.
- Identifying customer segments and demographics to help build targeted advertising campaigns.
- Categorizing inventory based on manufacturing metrics.

Clustering Learners

The following learners are available for clustering tasks:

- [KMeansPlusPlusTrainer](#)

Anomaly detection

This task creates an anomaly detection model by using Principal Component Analysis (PCA). PCA-Based Anomaly Detection helps you build a model in scenarios where it is easy to obtain training data from one class, such as valid transactions, but difficult to obtain sufficient samples of the targeted anomalies.

An established technique in machine learning, PCA is frequently used in exploratory data analysis because it reveals the inner structure of the data and explains the variance in the data. PCA works by analyzing data that contains multiple variables. It looks for correlations among the variables and determines the combination of values that best captures differences in outcomes. These combined feature values are used to create a more compact feature space called the principal components.

Anomaly detection encompasses many important tasks in machine learning:

- Identifying transactions that are potentially fraudulent.
- Learning patterns that indicate that a network intrusion has occurred.
- Finding abnormal clusters of patients.
- Checking values entered into a system.

Because anomalies are rare events by definition, it can be difficult to collect a representative sample of data to use for modeling. The algorithms included in this category have been especially designed to address the core challenges of building and training models by using imbalanced data sets.

Anomaly detection learners

The following learners are available for anomaly detection tasks:

- [RandomizedPcaTrainer](#)

Ranking

A ranking task constructs a ranker from a set of labeled examples. This example set consists of instance groups that can be scored with a given criteria. The ranking labels are { 0, 1, 2, 3, 4 } for each instance. The ranker is trained to rank new instance groups with unknown scores for each instance. ML.NET ranking learners are [machine learned ranking](#) based.

Ranking learners

The following learners are available for ranking tasks:

- [FastTreeRankingTrainer](#)
- [LightGbmRankingTrainer](#)

Recommendation

A recommendation task enables producing a list of recommended products or services. ML.NET uses [Matrix factorization \(MF\)](#), a [collaborative filtering](#) algorithm for recommendations when you have historical product rating data in your catalog. For example, you have historical movie rating data for your users and want to recommend other movies they are likely to watch next.

Recommendation learners

The following learners are available for recommendation tasks:

- [MatrixFactorizationTrainer](#)
- [MatrixFactorizationPredictionTransformer](#)

Machine learning data transforms - ML.NET

3/5/2019 • 6 minutes to read • [Edit Online](#)

The following tables contain information about all of the data transforms supported in ML.NET.

NOTE

ML.NET is currently in Preview. Not all data transforms are currently supported. To submit a request for a certain transform, open an issue in the [dotnet/machinelearning](#) GitHub repository.

Combiners and segregators

TRANSFORM	DEFINITION
GroupTransform	Groups values of a scalar column into a vector based on a contiguous group ID.
UngroupTransform	Un-groups vector columns into sequences of rows, inverse of Group transform.

Conversions

TRANSFORM	DEFINITION
HashingTransformer	Hashes either single valued columns or vector columns. For vector columns, it hashes each slot separately. It can hash either text values or key values.
HashJoiningTransform	Converts multiple column values into hashes. This transform accepts both numeric and text inputs, both single and vector-valued columns.
KeyToBinaryVectorMappingTransformer	Converts a key to a binary vector column.
KeyToValueMappingTransformer	Utilizes KeyValues metadata to map key indices to the corresponding values in the KeyValues metadata.
KeyToVectorMappingTransformer	Converts a key to a vector column.
TypeConvertingTransformer	Changes underlying column type provided the type can be converted.
ValueToKeyMappingTransformer	Converts input values (words, numbers, etc.) to index in a dictionary.

Deep learning

TRANSFORM	DEFINITION
OnnxTransform	Provides data to an existing ONNX model and returns the score (prediction).
TensorFlowTransform	Can either score with pretrained TensorFlow model or retrain TensorFlow model.

Feature extraction

TRANSFORM	DEFINITION
CustomStopWordsRemovingTransform	Removes specified list of stop words by comparing individual tokens (case-insensitive comparison) to the stopwords.
ImageGrayscaleTransform	Takes one or more ImageType columns and converts them to a grayscale representation of the same image.
ImageLoaderTransform	Takes one or more ReadOnlyMemory columns and loads them as an ImageType.
ImagePixelExtractorTransform	Takes one or more ImageType columns and converts them into a vector representation.
ImageResizerTransform	Takes one or more ImageType columns and resizes them to the provided height and width.
LatentDirichletAllocationTransformer	Implements LightLDA, a state-of-the-art implementation of Latent Dirichlet Allocation.
LoadTransform	Loads specific transforms from the specified model file. Allows for 'cherry picking' transforms from a serialized chain, or to apply a pre-trained transform to a different (but still compatible) data view.
NgramExtractingTransformer	Produces a bag of counts of ngrams (sequences of consecutive values of length 1-n) in a given vector of keys. It does so by building a dictionary of ngrams and using the id in the dictionary as the index in the bag.
NgramExtractorTransform	Turns a collection of tokenized text (vector of ReadOnlyMemory), or vectors of keys into numerical feature vectors. The feature vectors are counts of ngrams (sequences of consecutive tokens -words or keys- of length 1-n).
NgramHashExtractingTransformer	Turns a collection of tokenized text (vector of ReadOnlyMemory) into numerical feature vectors using hashing.
NgramHashingTransformer	Produces a bag of counts of ngrams (sequences of consecutive words of length 1-n) in a given text.
OneHotEncodingTransformer	Converts the categorical value into an indicator array by building a dictionary of categories based on the data and using the id in the dictionary as the index in the array

TRANSFORM	DEFINITION
PcaTransform	Computes the projection of the feature vector onto a low-rank subspace.
SentimentAnalyzingTransformer	Uses a pretrained sentiment model to score input strings.
StopWordsRemovingTransformer	Removes language-specific list of stop words (most common words) by comparing individual tokens (case-insensitive comparison) to the stopwords.
WordBagBuildingTransformer	Produces a bag of counts of ngrams (sequences of consecutive words) in a given text. It does so by building a dictionary of ngrams and using the id in the dictionary as the index in the bag.
WordHashBagProducingTransformer	Produces a bag of counts of ngrams (sequences of consecutive words of length 1-n) in a given text. It does so by hashing each ngram and using the hash value as the index in the bag.
WordTokenizingTransformer	Splits the text into words using the separator character(s).

Image model featurizers

TRANSFORM	DEFINITION
AlexNetExtension	This is an extension method to be used with the DnnImageFeaturizerEstimator in order to use a pretrained AlexNet model. The NuGet containing this extension is also guaranteed to include the binary model file.
ResNet18Extension	This is an extension method to be used with the DnnImageFeaturizerEstimator to use a pretrained ResNet18 model. The NuGet containing this extension is also guaranteed to include the binary model file.
ResNet50Extension	This is an extension method to be used with the DnnImageFeaturizerEstimator to use a pretrained ResNet50model. The NuGet containing this extension is also guaranteed to include the binary model file.
ResNet101Extension	This is an extension method to be used with the DnnImageFeaturizerEstimator to use a pretrained ResNet101 model. The NuGet containing this extension is also guaranteed to include the binary model file.

Label parsing

TRANSFORM	DEFINITION
LabelConvertTransform	Converts labels.
LabelIndicatorTransform	Remaps multiclass labels to binary True, False labels, primarily for use with OVA.

Missing values

TRANSFORM	DEFINITION
MissingValueDroppingTransformer	Drops missing values from columns.
MissingValueIndicatorTransform	Creates a boolean output column with the same number of slots as the input column, where the output value is true if the value in the input column is missing.
MissingValueReplacingTransformer	Handle missing values by replacing them with either the default value or the mean/min/max value (for non-text columns only).

Normalization

TRANSFORM	DEFINITION
LpNormalizingTransformer	Lp-Norm (vector/row-wise) normalization transform.
MeanVarDblAggregator	Computes the mean and variance for a vector valued column. It tracks the current mean and the M2 (sum of squared diffs of the values from the mean), the number of NaNs and the number of non-zero elements.
MeanVarSngAggregator	Computes the mean and variance for a vector valued column. It tracks the current mean and the M2 (sum of squared diffs of the values from the mean), the number of NaNs and the number of non-zero elements.
MinMaxDblAggregator	Tracks min, max, number of non-sparse values (vCount) and number of ProcessValue() calls (trainCount) for a vector valued column.
NormalizeTransform	Standardizes feature ranges.
NormalizingTransformer	Standardizes feature ranges.

Onnx

TRANSFORM	DEFINITION
OnnxTransform	Scores pre-trained ONNX models which use the ONNX standard v1.2

Preprocessing

TRANSFORM	DEFINITION
BootstrapSamplingTransformer	Approximates bootstrap sampling using Poisson sampling.
RandomFourierFeaturizingTransformer	Produces random Fourier feature.

TRANSFORM	DEFINITION
TokenizingByCharactersTransformer	Character-oriented tokenizer where text is considered a sequence of characters.
VectorWhiteningTransformer	Simplifies optimization to assist with identifying weights.

Row Filters

TRANSFORM	DEFINITION
RowShufflingTransformer	Shuffles a randomized cursor attempt to perform using a pool of a given number of rows.
SkipFilter	Allows limiting input to a subset of rows by skipping a number of rows.
SkipTakeFilter	Allows limiting input to a subset of rows at an optional offset. Can be used to implement data paging. When created with SkipTakeFilter.SkipArguments behaves as SkipFilter .
TakeFilter	Allows limiting input to a subset of rows by taking N first rows.

Schema

TRANSFORM	DEFINITION
ColumnCopyingTransformer	Duplicates columns from the dataset.
ColumnSelectingTransformer	Selects a set of columns to drop or keep from a given input.
SlotsDroppingTransformer	Drops slots from columns.
OptionalColumnTransform	Creates a new column with the specified type and default values.
RangeFilter	Filters a dataview on a column of type Single, Double or Key (contiguous). Keeps the values that are in the specified min/max range. NaNs are always filtered out. If the input is a Key type, the min/max are considered percentages of the number of values.

TensorFlow

TRANSFORM	DEFINITION
TensorFlowTransform	Either scores with pretrained TensorFlow model or retrains TensorFlow model.

Text processing and featurization

TRANSFORM	DEFINITION
TextNormalizingTransformer	A text normalization transform that allows normalizing text case, removing diacritical marks, punctuation marks and/or numbers. The transform operates on text input as well as vector of tokens/text (vector of <code>ReadOnlyMemory</code>).
TokenizingByCharactersTransformer	Character-oriented tokenizer where text is considered a sequence of characters.

Time series

TRANSFORM	DEFINITION
ExponentialAverageTransform	Takes a weighted average of the values: $\text{ExpAvg}(y_t) = a * y_t + (1-a) * \text{ExpAvg}(y_{t-1})$.
IidChangePointDetector	Implements the change point detector transform for an i.i.d. sequence (random sample) based on adaptive kernel density estimation and martingales.
IidSpikeDetector	Implements the spike detector transform for an i.i.d. sequence (random sample) based on adaptive kernel density estimation.
MovingAverageTransform	Provides a weighted average of the sliding window values.
PercentileThresholdTransform	Decides whether the time-series current value belongs to the sliding window top values percentile.
PValueTransform	Computes the series current value empirical p-value based on the other values in the sliding window.
SlidingWindowTransform	Outputs a sliding window on a time series of type <code>Single</code> .
SsaChangePointDetector	Implements the change point detector transform based on Singular Spectrum modeling of the time-series.
SsaSpikeDetector	Implements the spike detector transform based on Singular Spectrum modeling of the time-series.

Miscellaneous

TRANSFORM	DEFINITION
CompositeTransformer	Creates a Composite DataTransform.
CustomMappingTransformer<TSrc,TDst>	Generates additional columns to the provided <code>IDataView</code> . It doesn't change the number of rows and can be seen as a result of application of the user's function to every row of the input data.
GenerateNumberTransform	Adds a column with a generated number sequence.

TRANSFORM	DEFINITION
ProducIdTransform	Produces a column with the cursor's ID as a column.
RandomNumberGenerator	Generates a random number.

.NET samples and tutorials

2/13/2019 • 5 minutes to read • [Edit Online](#)

The .NET documentation contains a set of samples and tutorials that teach you about .NET. This topic describes how to find, view, and download .NET Core, ASP.NET Core, and C# samples and tutorials. Find resources to learn the F# programming language on the [F# Foundation's site](#). If you're interested in exploring C# using an online code editor, start with [this interactive tutorial](#) and continue with [C# interactive tutorial](#). Viewing and downloading samples

Many topics show source code and samples that are available for viewing or download from GitHub. To view a sample, just follow the sample link. To download the code, follow these instructions:

1. Download the repository that contains the sample code by performing one of the following procedures:
 - Download a ZIP of the repository to your local system. Un-ZIP the compressed archive.
 - [Fork](#) the repository and [clone](#) the fork to your local system. Forking and cloning permits you to make contributions to the documentation by committing changes to your fork and then creating a pull request for the official docs repository. For more information, see the [.NET Documentation Contributing Guide](#) and the [ASP.NET Docs Contributing Guide](#).
 - Clone the repository locally. If you clone a docs repository directly to your local system, you won't be able to make commits directly against the official repository, so you won't be able to make documentation contributions later. Use the fork and clone procedure previously described if you want to preserve the opportunity to contribute to the documentation later.
2. Navigate within the repository's folders to the sample's location. The relative path to the sample's location appears in your browser's address bar when you follow the link to the sample.
3. To run a sample, you have several options:
 - Use the [dotnet CLI tools](#): In a console window, navigate to the sample's folder and use dotnet CLI commands.
 - Use [Visual Studio](#) or [Visual Studio for Mac](#): Open the sample by selecting **File > Open > Project/Solution** from the menu bar, navigate to the sample project folder, and select the project file (`.csproj` or `.fsproj`).
 - Use [Visual Studio Code](#): Open the sample by selecting **File > Open Folder** from the menu bar and selecting the sample's project folder.
 - Use a different IDE that supports .NET Core projects.
