Error Messages

'#Elseif' must be preceded by a matching '#If' or '#Elseif'

'#Region' and '#End Region' statements are not valid within method bodies-multiline lambdas

'<attribute>' cannot be applied because the format of the GUID '<number>' is not correct

'<classname>' is not CLS-compliant because the interface '<interfacename>' it implements is not CLS-compliant

'<elementname>' is obsolete (Visual Basic Warning)

'<eventname>' is an event, and cannot be called directly

'<expression>' cannot be used as a type constraint

'<functionname>' is not declared (Smart Device-Visual Basic Compiler Error)

'<interfacename>.<membername>' is already implemented by the base class '<baseclassname>'. Re-implementation of <type> assumed

'<keyword>' is valid only within an instance method

'<membername>' cannot expose type '<typename>' outside the project through <containertype> '<containertypename>'

'<membername>' is ambiguous across the inherited interfaces '<interfacename1>' and '<interfacename2>'

<message> This error could also be due to mixing a file reference with a project reference to assembly '<assemblyname>'

'<methodname>' has multiple definitions with identical signatures

'<name>' is ambiguous in the namespace '<namespacename>'

'<name1>' is ambiguous, imported from the namespaces or types '<name2>'

<proceduresignature1> is not CLS-compliant because it overloads <proceduresignature2> which differs from it only by array of array parameter types or by the rank of the array parameter types

'<type1>'<typename>' must implement '<membername>' for interface

'<interfacename>'
<type1>'<typename>' must implement '<methodname>' for interface
'<interfacename>'
'<typename>' cannot inherit from <type> '<basetypename>' because it expands
the access of the base <type> outside the assembly
'<typename>' is a delegate type
'<typename>' is a type and cannot be used as an expression
A double quote is not a valid comment token for delimited fields where
EscapeQuote is set to True
A property or method call cannot include a reference to a private object, either as
an argument or as a return value
A reference was created to embedded interop assembly '<assembly1>' because of
an indirect reference to that assembly from assembly '<assembly2>'
A startup form has not been specified
Access of shared member through an instance; qualifying expression will not be
evaluated
'AddressOf' operand must be the name of a method (without parentheses)
An unexpected error has occurred because an operating system resource required
for single instance startup cannot be acquired
Anonymous type member name can be inferred only from a simple or qualified
name with no arguments
Argument not optional
Array bounds cannot appear in type specifiers
Array declared as for loop control variable cannot be declared with an initial size
Array subscript expression missing
Arrays declared as structure members cannot be declared with an initial size
'As Any' is not supported in 'Declare' statements
Attribute '<attributename>' cannot be applied multiple times
Automation error
Bad checksum value, non hex digits or odd number of hex digits
Bad DLL calling convention
Bad file mode
Bad file name or number
Bad record length

Because this call is not awaited, the current method continues to run before the call is completed

Cannot convert anonymous type to expression tree because it contains a field that is used in the initialization of another field

Cannot create ActiveX Component

Cannot refer to '<name>' because it is a member of the value-typed field '<name>' of class '<classname>' which has 'System.MarshalByRefObject' as a base class

Cannot refer to an instance member of a class from within a shared method or shared member initializer without an explicit instance of the class

Can't create necessary temporary file

Can't open '<filename>' for writing

Class '<classname>' cannot be found

Class does not support Automation or does not support expected interface

'Class' statement must end with a matching 'End Class'

Clipboard format is not valid

Constant expression not representable in type '<typename>'

Constants must be of an intrinsic or enumerated type, not a class, structure, type parameter, or array type

Constructor '<name>' cannot call itself

Copying the value of 'ByRef' parameter '<parametername>' back to the matching argument narrows from type '<typename1>' to type '<typename2>'

'Custom' modifier is not valid on events declared without explicit delegate types

Data type(s) of the type parameter(s) cannot be inferred from these arguments

Declaration expected

Default property '<propertynname1>' conflicts with default property '<propertynname2>' in '<classname>' and so should be declared 'Shadows'

Default property access is ambiguous between the inherited interface members '<defaultpropertynname>' of interface '<interfacename1>' and '<defaultpropertynname>' of interface '<interfacename2>'

Delegate class '<classname>' has no Invoke method, so an expression of this type cannot be the target of a method call

Derived classes cannot raise base class events

Device I/O error

'Dir' function must first be called with a 'PathName' argument

End of statement expected

Error creating assembly manifest: <error message>

Error creating Win32 resources: <error message>

Error in loading DLL

Error saving temporary Win32 resource file '<filename>': <error message>

Errors occurred while compiling the XML schemas in the project

Evaluation of expression or statement timed out

Event '<eventname1>' cannot implement event '<eventname2>' on interface '<interface>' because their delegate types '<delegate1>' and '<delegate2>' do not match

Events cannot be declared with a delegate type that has a return type

Events of shared WithEvents variables cannot be handled by non-shared methods

Expression does not produce a value

Expression has the type '<typename>' which is a restricted type and cannot be used to access members inherited from 'Object' or 'ValueType'

Expression is a value and therefore cannot be the target of an assignment

Expression of type <type> is not queryable

Expression recursively calls the containing property '<propertyname>'

Expression too complex

'Extension' attribute can be applied only to 'Module', 'Sub', or 'Function' declarations

File already open

File is too large to read into a byte array

File name or class name not found during Automation operation

File not found (Visual Basic Run-Time Error)

First operand in a binary 'If' expression must be nullable or a reference type

First statement of this 'Sub New' must be a call to ' MyBase.New' or ' MyClass.New' (No Accessible Constructor Without Parameters)

First statement of this 'Sub New' must be an explicit call to ' MyBase.New' or ' MyClass.New' because the '<constructorname>' in the base class '<baseclassname>' of '<derivedclassname>' is marked obsolete: '<errormessage>'

'For Each' on type '<typename>' is ambiguous because the type implements multiple instantiations of 'System.Collections.Generic.IEnumerable(Of T)'

Friend assembly reference <reference> is invalid

Function '<procedurename>' doesn't return a value on all code paths

Function evaluation is disabled because a previous function evaluation timed out

Generic parameters used as optional parameter types must be class constrained

'Get' accessor of property '<propertlename>' is not accessible

Handles clause requires a WithEvents variable defined in the containing type or one of its base types

Identifier expected

Identifier is too long

Initializer expected

Input past end of file

Internal error happened at <location>

Implicit conversion from '<typename1>' to '<typename2>' in copying the value of 'ByRef' parameter '<parametername>' back to the matching argument.

'Is' requires operands that have reference types, but this operand has the value type '<typename>'

' IsNot' operand of type 'typename' can only be compared to 'Nothing', because 'typename' is a nullable type

Labels that are numbers must be followed by colons

Lambda expression will not be removed from this event handler

Lambda expressions are not valid in the first expression of a 'Select Case' statement

Late bound resolution; runtime errors could occur

Latebound overload resolution cannot be applied to '<procedurename>' because the accessing instance is an interface type

Leading '.' or '!' can only appear inside a 'With' statement

Line is too long

'Line' statements are no longer supported (Visual Basic Compiler Error)

Method does not have a signature compatible with the delegate

Methods of 'System.Nullable(Of T)' cannot be used as operands of the 'AddressOf' operator

'Module' statements can occur only at file or namespace level

Name <membername> is not CLS-compliant

Name '<name>' is not declared

Name <namespacename> in the root namespace <fullnamespacename> is not

CLS-compliant

Namespace or type specified in the Imports '<qualifiedelementname>' doesn't contain any public member or cannot be found

Namespace or type specified in the project-level Imports '<qualifiedelementname>' doesn't contain any public member or cannot be found

Need property array index

Nested function does not have a signature that is compatible with delegate '<delegatename>'

No accessible 'Main' method with an appropriate signature was found in '<name>'

Non-CLS-compliant <membername> is not allowed in a CLS-compliant interface

Nullable type inference is not supported in this context

Number of indices exceeds the number of dimensions of the indexed array

Object or class does not support the set of events

Object required

Object variable or With block variable not set

Operator declaration must be one of: +,-,*,-,^, &, Like, Mod, And, Or, Xor, Not, <<, >>, =, <>, <, <=, >, >=, CType, IsTrue, IsFalse

'Optional' expected

Optional parameters must specify a default value

Ordinal is not valid

Out of memory (Visual Basic Compiler Error)

Out of stack space

Out of string space

Overflow (Visual Basic Error)

Overflow (Visual Basic Run-Time Error)

Path not found

Path-File access error

Permission denied

Procedure call or argument is not valid

Property '<propertyname>' doesn't return a value on all code paths

Property array index is not valid

Property let procedure not defined and property get procedure did not return an object

Property not found

Property or method not found

Range variable <variable> hides a variable in an enclosing block, a previously defined range variable, or an implicitly declared variable in a query expression

Range variable name can be inferred only from a simple or qualified name with no arguments

Reference required to assembly '<assemblyidentity>' containing type '<typename>', but a suitable reference could not be found due to ambiguity between projects '<projectname1>' and '<projectname2>'

Reference required to assembly '<assemblyname>' containing the base class '<classname>'

Requested operation is not available (BC35000)

Resume without error

Return type of function '<procedurename>' is not CLS-compliant

'Set' accessor of property '<propertyname>' is not accessible

Some subkeys cannot be deleted

Statement cannot end a block outside of a line 'If' statement

Statement is not valid in a namespace

Statement is not valid inside a method-multiline lambda

String constants must end with a double quote

Structure '<structurename>' must contain at least one instance member variable or at least one instance event declaration not marked 'Custom'

'Sub Main' was not found in '<name>'

Sub or Function not defined

Subscript out of range

TextFieldParser is unable to complete the read operation because maximum buffer size has been exceeded

The type for variable '<variablename>' will not be inferred because it is bound to a field in an enclosing scope

This array is fixed or temporarily locked

This key is already associated with an element of this collection

Too many files

Type '<typename>' has no constructors

Type <typename> is not CLS-compliant

Type '<typename>' is not defined

Type arguments could not be inferred from the delegate

Type mismatch

Type of '<variablename>' cannot be inferred because the loop bounds and the step variable do not widen to the same type

Type of member '<membername>' is not CLS-compliant

Type of optional value for optional parameter <parametername> is not CLS-compliant

Type of parameter '<parametername>' is not CLS-compliant

Type parameters cannot be used as qualifiers

Unable to create strong-named assembly from key file '<filename>': <error>

Unable to embed resource file '<filename>': <error message>

Unable to emit assembly: <error message>

Unable to find required file '<filename>'

Unable to get serial port names because of an internal system error

Unable to link to resource file '<filename>': <error message>

Unable to load information for class '<classname>'

Unable to write output to memory

Unable to write temporary file because temporary path is not available

Unable to write to output file '<filename>': <error>

Underlying type <typename> of Enum is not CLS-compliant

Using the iteration variable in a lambda expression may have unexpected results

Value of type '<typename1>' cannot be converted to '<typename2>'

Value of type '<typename1>' cannot be converted to '<typename2>' (Multiple file references)

Value of type 'type1' cannot be converted to 'type2'

Variable '<variablename>' hides a variable in an enclosing block

Variable '<variablename>' is used before it has been assigned a value

Variable uses an Automation type not supported in Visual Basic

XML axis properties do not support late binding

XML comment exception must have a 'cref' attribute

XML entity references are not supported

XML literals and XML properties are not supported in embedded code within ASP.NET

Samples and Tutorials

Welcome to .NET

3/9/2019 • 2 minutes to read • [Edit Online](#)

See [Get started with .NET Core](#) to learn how to create .NET Core apps.

Build many types of apps with .NET, such as cloud, IoT, and games using free cross-platform tools. Your apps can run on Android, iOS, Linux, macOS, and Windows. Deploy apps to servers or desktops and publish to app stores for deployment on mobile devices. .NET is accessible to students and hobbyists, and all are welcome to participate in a lively international developer community and make direct contributions to many of the .NET technologies.

News

For news about .NET, check the following blogs:

- [.NET Blog](#)
- [ASP.NET Blog](#)
- [The Visual Studio Blog](#)
- [The Visual Basic Team](#)

Also follow the latest .NET events:

- [What's new in C#](#)
- [What's new for Visual Basic](#)

Documentation

This documentation covers the breadth of .NET across platforms and languages. You can get started with .NET and its languages in any of the following sections:

- [.NET Guide](#)
- [.NET Core Guide](#)
- [.NET Framework Guide](#)
- [C# Guide](#)
- [F# Guide](#)
- [Visual Basic Guide](#)
- [ML.NET Guide](#)

Additionally, you can browse the [.NET API reference](#).

Open source

This documentation is completely [open source](#). You can contribute in any way you like, from creating issues to

writing documentation. Additionally, much of .NET itself is also open source:

- [.NET Core Home](#)
- [.NET Libraries](#)
- [.NET Core Runtime](#)
- [Roslyn \(C# and Visual Basic\) Compiler Platform and IDE Tools](#)
- [F# Compiler and IDE Tools](#)

You can join other people who are already active in the [.NET community](#) to find out what's new or ask for help.

.NET Guide

1/19/2019 • 2 minutes to read • [Edit Online](#)

The .NET Guide provides a large amount of information about .NET. Depending on your familiarity with .NET, you may wish to explore different sections of this guide and other sections of the .NET documentation.

New to .NET

If you want a high-level overview about .NET, check out [What is .NET?](#).

If you're new to .NET, check out the [Get Started](#) article.

If you prefer to have a guided tour through major features of .NET, check out the [Tour of .NET](#).

You can also read about [.NET Architectural Components](#) to get an overview of the various "pieces" of .NET and how they fit together.

New to .NET Core

If you're new to .NET Core, check out [Get Started with .NET Core](#).

New to .NET Standard

If you're new to .NET Standard, check out [.NET Standard](#).

Porting .NET Framework Code to .NET Core

If you're looking to port an application, service, or some component of a system to .NET Core, check out [Porting to .NET Core from .NET Framework](#).

Porting a NuGet package from .NET Framework to .NET Standard or .NET Core

If you're looking to port a NuGet package to .NET Standard, check out [Porting to .NET Core from .NET Framework](#). Tooling for .NET Standard and .NET Core are shared, so the content will be relevant for porting to .NET Standard as well as .NET Core.

Interested in Major .NET Concepts

If you're interested in some of the major concepts of .NET, check out:

- [.NET Standard](#)
- [Native Interoperability](#)
- [Garbage Collection](#)
- [Base Types in .NET](#)
- [Collections](#)
- [Dates, times, and time zones](#)
- [Asynchronous Programming](#)

Additionally, check out each language guide to learn about the three major .NET languages:

- [C# Guide](#)
- [F# Guide](#)
- [Visual Basic Guide](#)

API Reference

Check out the [.NET API Reference](#) to see the breadth of APIs available.

Get Started

12/22/2018 • 2 minutes to read • [Edit Online](#)

There are a number of ways to get started with .NET. Because .NET is a massive platform, there are multiple articles in this documentation which show how you can get started with .NET, each from a different perspective.

Get started using .NET languages

- The [C# Getting Started](#) articles and [C# Tutorials](#) provide a number of ways to get started in a C#-centric way.
- The [F# Getting Started](#) tutorials provide three primary ways you can use F#: with Visual Studio, Visual Studio Code, or command-line tools.
- The [Visual Basic Getting Started](#) articles provide guides for using Visual Basic in Visual Studio.

Get started using .NET Core

- [Getting Started with .NET Core](#) provides an overview of articles which show how to get started with .NET Core on different operating systems and using different tools.
- The [.NET Core Tutorials](#) detail a number of ways you can get started with .NET Core using your operating system and tooling of choice.

Get started using Docker on .NET Framework

[Docker on .NET Framework](#) shows how you can use .NET Framework on Windows Docker containers.

Tour of .NET

1/19/2019 • 9 minutes to read • [Edit Online](#)

.NET is a general purpose development platform. It has several key features, such as support for multiple programming languages, asynchronous and concurrent programming models, and native interoperability, which enable a wide range of scenarios across multiple platforms.

This article offers a guided tour through some of the key features of the .NET. See the [.NET Architectural Components](#) topic to learn about the architectural pieces of .NET and what they're used for.

How to run the code samples

To learn how to set up a development environment to run the code samples, see the [Getting Started](#) topic. Copy and paste code samples from this page into your environment to execute them.

Programming languages

.NET supports multiple programming languages. The .NET implementations implement the [Common Language Infrastructure \(CLI\)](#), which among other things specifies a language-independent runtime and language interoperability. This means that you choose any .NET language to build apps and services on .NET.

Microsoft actively develops and supports three .NET languages: C#, F#, and Visual Basic (VB).

- C# is simple, powerful, type-safe, and object-oriented, while retaining the expressiveness and elegance of C-style languages. Anyone familiar with C and similar languages finds few problems in adapting to C#. Check out the [C# Guide](#) to learn more about C#.
- F# is a cross-platform, functional-first programming language that also supports traditional object-oriented and imperative programming. Check out the [F# Guide](#) to learn more about F#.
- Visual Basic is an easy language to learn that you use to build a variety of apps that run on .NET. Among the .NET languages, the syntax of VB is the closest to ordinary human language, often making it easier for people new to software development.

Automatic memory management

.NET uses [garbage collection \(GC\)](#) to provide automatic memory management for programs. The GC operates on a lazy approach to memory management, preferring app throughput to the immediate collection of memory. To learn more about the .NET GC, check out [Fundamentals of garbage collection \(GC\)](#).

The following two lines both allocate memory:

```
var title = ".NET Primer";
var list = new List<string>();
```

There's no analogous keyword to de-allocate memory, as de-allocation happens automatically when the garbage collector reclaims the memory through its scheduled run.

The garbage collector is one of the services that help ensure *memory safety*. A program is memory safe if it accesses only allocated memory. For instance, the runtime ensures that an app doesn't access unallocated memory beyond the bounds of an array.

In the following example, the runtime throws an `IndexOutOfRangeException` exception to enforce memory safety:

```
int[] numbers = new int[42];
int number = numbers[42]; // Will throw an exception (indexes are 0-based)
```

Working with unmanaged resources

Some objects reference *unmanaged resources*. Unmanaged resources are resources that aren't automatically maintained by the .NET runtime. For example, a file handle is an unmanaged resource. A `FileStream` object is a managed object, but it references a file handle, which is unmanaged. When you're done using the `FileStream`, you need to release the file handle.

In .NET, objects that reference unmanaged resources implement the `IDisposable` interface. When you're done using the object, you call the object's `Dispose()` method, which is responsible for releasing any unmanaged resources. .NET languages provide a convenient `using` syntax for such objects, as shown in the following example:

```
using System.IO;

using (FileStream stream = GetFileStream(context))
{
    // Operations on the stream
}
```

Once the `using` block completes, the .NET runtime automatically calls the `stream` object's `Dispose()` method, which releases the file handle. The runtime also does this if an exception causes control to leave the block.

For more details, see the following topics:

- For C#, see the [using Statement \(C# Reference\)](#) topic.
- For F#, see [Resource Management: The use Keyword](#).
- For VB, see the [Using Statement \(Visual Basic\)](#) topic.

Type safety

An object is an instance of a specific type. The only operations allowed for a given object are those of its type. A `Dog` type may have `Jump` and `WagTail` methods but not a `SumTotal` method. A program only calls the methods belonging to a given type. All other calls result in either a compile-time error or a run-time exception (in case of using dynamic features or `object`).

.NET languages are object-oriented with hierarchies of base and derived classes. The .NET runtime only allows object casts and calls that align with the object hierarchy. Remember that every type defined in any .NET language derives from the base `Object` type.

```
Dog dog = AnimalShelter.AdoptDog(); // Returns a Dog type.
Pet pet = (Pet)dog; // Dog derives from Pet.
pet.ActCute();
Car car = (Car)dog; // Will throw - no relationship between Car and Dog.
object temp = (object)dog; // Legal - a Dog is an object.
```

Type safety is also used to help enforce encapsulation by guaranteeing the fidelity of the accessor keywords. Accessor keywords are artifacts which control access to members of a given type by other code. These are usually used for various kinds of data within a type that are used to manage its behavior.

```
private Dog _nextDogToBeAdopted = AnimalShelter.AdoptDog()
```

C#, VB, and F# support local *type inference*. Type inference means that the compiler deduces the type of the expression on the left-hand side from the expression on the right-hand side. This doesn't mean that the type safety is broken or avoided. The resulting type does have a strong type with everything that implies. From the previous example, `dog` is rewritten to introduce type inference, and the remainder of the example is unchanged:

```
var dog = AnimalShelter.AdoptDog();
var pet = (Pet)dog;
pet.ActCute();
Car car = (Car)dog; // will throw - no relationship between Car and Dog
object temp = (object)dog; // legal - a Dog is an object
car = (Car)temp; // will throw - the runtime isn't fooled
car.Accelerate() // the dog won't like this, nor will the program get this far
```

F# has even further type inference capabilities than the method-local type inference found in C# and VB. To learn more, see [Type Inference](#).

Delegates and lambdas

A delegate is represented by a method signature. Any method with that signature can be assigned to the delegate and is executed when the delegate is invoked.

Delegates are like C++ function pointers except that they're type safe. They're a kind of disconnected method within the CLR type system. Regular methods are attached to a class and are only directly callable through static or instance calling conventions.

In .NET, delegates are commonly used in event handlers, in defining asynchronous operations, and in lambda expressions, which are a cornerstone of LINQ. Learn more in the [Delegates and lambdas](#) topic.

Generics

Generics allow the programmer to introduce a *type parameter* when designing their classes that allows the client code (the users of the type) to specify the exact type to use in place of the type parameter.

Generics were added to help programmers implement generic data structures. Before their arrival in order for a type such as the `List` type to be generic, it would have to work with elements that were of type `object`. This had various performance and semantic problems, along with possible subtle runtime errors. The most notorious of the latter is when a data structure contains, for instance, both integers and strings, and an `InvalidCastException` is thrown on working with the list's members.

The following sample shows a basic program running using an instance of `List<T>` types:

```
using System;
using System.Collections.Generic;

namespace GenericsSampleShort
{
    public static void Main(string[] args)
    {
        // List<string> is the client way of specifying the actual type for the type parameter T
        List<string> listOfStrings = new List<string> { "First", "Second", "Third" };

        // listOfStrings can accept only strings, both on read and write.
        listOfStrings.Add("Fourth");

        // Below will throw a compile-time error, since the type parameter
        // specifies this list as containing only strings.
        listOfStrings.Add(1);
    }
}
```

For more information, see the [Generic types \(Generics\) overview](#) topic.

Async programming

Async programming is a first-class concept within .NET with async support in the runtime, framework libraries, and .NET language constructs. Internally, they're based on objects (such as `Task`), which take advantage of the operating system to perform I/O-bound jobs as efficiently as possible.

To learn more about async programming in .NET, start with the [Async overview](#) topic.

Language Integrated Query (LINQ)

LINQ is a powerful set of features for C# and VB that allow you to write simple, declarative code for operating on data. The data can be in many forms (such as in-memory objects, a SQL database, or an XML document), but the LINQ code you write typically doesn't differ by data source.

To learn more and see some samples, see the [LINQ \(Language Integrated Query\)](#) topic.

Native interoperability

Every operating system includes an application programming interface (API) that provides system services. .NET provides several ways to call those APIs.

The main way to do native interoperability is via "platform invoke" or P/Invoke for short, which is supported across Linux and Windows platforms. A Windows-only way of doing native interoperability is known as "COM interop," which is used to work with [COM components](#) in managed code. It's built on top of the P/Invoke infrastructure, but it works in subtly different ways.

Most of Mono's (and thus Xamarin's) interoperability support for Java and Objective-C are built similarly, that is, they use the same principles.

For more information about native interoperability, see the [Native interoperability](#) article.

Unsafe code

Depending on language support, the CLR lets you access native memory and do pointer arithmetic via `unsafe` code. These operations are needed for certain algorithms and system interoperability. Although powerful, use of unsafe code is discouraged unless it's necessary to interop with system APIs or implement the most efficient algorithm. Unsafe code may not execute the same way in different environments and also loses the benefits of a

garbage collector and type safety. It's recommended to confine and centralize unsafe code as much as possible and test that code thoroughly.

The following example is a modified version of the `ToString()` method from the `StringBuilder` class. It illustrates how using `unsafe` code can efficiently implement an algorithm by moving around chunks of memory directly:

```
public override String ToString()
{
    if (Length == 0)
        return String.Empty;

    string ret = string.FastAllocateString(Length);
    StringBuilder chunk = this;
    unsafe
    {
        fixed (char* destinationPtr = ret)
        {
            do
            {
                if (chunk.m_ChunkLength > 0)
                {
                    // Copy these into local variables so that they are stable even in the presence of ----s
                    // hackers might do this
                    char[] sourceArray = chunk.m_ChunkChars;
                    int chunkOffset = chunk.m_ChunkOffset;
                    int chunkLength = chunk.m_ChunkLength;

                    // Check that we will not overrun our boundaries.
                    if ((uint)(chunkLength + chunkOffset) <= ret.Length && (uint)chunkLength <=
                    (uint)sourceArray.Length)
                    {
                        fixed (char* sourcePtr = sourceArray)
                            string.wstrcpy(destinationPtr + chunkOffset, sourcePtr, chunkLength);
                    }
                    else
                    {
                        throw new ArgumentOutOfRangeException("chunkLength",
                            Environment.GetResourceString("ArgumentOutOfRangeException_Index"));
                    }
                }
                chunk = chunk.m_ChunkPrevious;
            } while (chunk != null);
        }
    }
    return ret;
}
```

Next steps

If you're interested in a tour of C# features, check out [Tour of C#](#).

If you're interested in a tour of F# features, see [Tour of F#](#).

If you want to get started with writing code of your own, visit [Getting Started](#).

To learn about important components of .NET, check out [.NET Architectural Components](#).

.NET architectural components

1/23/2019 • 4 minutes to read • [Edit Online](#)

A .NET app is developed for and runs in one or more *implementations of .NET*. Implementations of .NET include the .NET Framework, .NET Core, and Mono. There is an API specification common to all implementations of .NET that's called the .NET Standard. This article gives a brief introduction to each of these concepts.

.NET Standard

The .NET Standard is a set of APIs that are implemented by the Base Class Library of a .NET implementation. More formally, it's a specification of .NET APIs that make up a uniform set of contracts that you compile your code against. These contracts are implemented in each .NET implementation. This enables portability across different .NET implementations, effectively allowing your code to run everywhere.

The .NET Standard is also a [target framework](#). If your code targets a version of the .NET Standard, it can run on any .NET implementation which supports that version of the .NET Standard.

To learn more about the .NET Standard and how to target it, see the [.NET Standard](#) topic.

.NET implementations

Each implementation of .NET includes the following components:

- One or more runtimes. Examples: CLR for .NET Framework, CoreCLR and CoreRT for .NET Core.
- A class library that implements the .NET Standard and may implement additional APIs. Examples: .NET Framework Base Class Library, .NET Core Base Class Library.
- Optionally, one or more application frameworks. Examples: [ASP.NET](#), [Windows Forms](#), and [Windows Presentation Foundation \(WPF\)](#) are included in the .NET Framework.
- Optionally, development tools. Some development tools are shared among multiple implementations.

There are four primary .NET implementations that Microsoft actively develops and maintains: .NET Core, .NET Framework, Mono, and UWP.

.NET Core

.NET Core is a cross-platform implementation of .NET and designed to handle server and cloud workloads at scale. It runs on Windows, macOS and Linux. It implements the .NET Standard, so code that targets the .NET Standard can run on .NET Core. ASP.NET Core runs on .NET Core.

To learn more about .NET Core, see the [.NET Core Guide](#) and [Choosing between .NET Core and .NET Framework for server apps](#).

.NET Framework

The .NET Framework is the original .NET implementation that has existed since 2002. It's the same .NET Framework that existing .NET developers have always used. Versions 4.5 and later implement the .NET Standard, so code that targets the .NET Standard can run on those versions of the .NET Framework. It contains additional Windows-specific APIs, such as APIs for Windows desktop development with Windows Forms and WPF. The .NET Framework is optimized for building Windows desktop applications.

To learn more about the .NET Framework, see the [.NET Framework Guide](#).

Mono

Mono is a .NET implementation that is mainly used when a small runtime is required. It is the runtime that

powers Xamarin applications on Android, Mac, iOS, tvOS and watchOS and is focused primarily on a small footprint. Mono also powers games built using the Unity engine.

It supports all of the currently published .NET Standard versions.

Historically, Mono implemented the larger API of the .NET Framework and emulated some of the most popular capabilities on Unix. It is sometimes used to run .NET applications that rely on those capabilities on Unix.

Mono is typically used with a just-in-time compiler, but it also features a full static compiler (ahead-of-time compilation) that is used on platforms like iOS.

To learn more about Mono, see the [Mono documentation](#).

Universal Windows Platform (UWP)

UWP is an implementation of .NET that is used for building modern, touch-enabled Windows applications and software for the Internet of Things (IoT). It's designed to unify the different types of devices that you may want to target, including PCs, tablets, phablets, phones, and even the Xbox. UWP provides many services, such as a centralized app store, an execution environment (AppContainer), and a set of Windows APIs to use instead of Win32 (WinRT). Apps can be written in C++, C#, VB.NET, and JavaScript. When using C# and VB.NET, the .NET APIs are provided by .NET Core.

To learn more about UWP, see [Intro to the Universal Windows Platform](#).

.NET runtimes

A runtime is the execution environment for a managed program. The OS is part of the runtime environment but is not part of the .NET runtime. Here are some examples of .NET runtimes:

- Common Language Runtime (CLR) for the .NET Framework
- Core Common Language Runtime (CoreCLR) for .NET Core
- .NET Native for Universal Windows Platform
- The Mono runtime for Xamarin.iOS, Xamarin.Android, Xamarin.Mac, and the Mono desktop framework

.NET tooling and common infrastructure

You have access to an extensive set of tools and infrastructure components that work with every implementation of .NET. These include, but are not limited to the following:

- The .NET languages and their compilers
- The .NET project system (based on `.csproj`, `.vbproj`, and `.fsproj` files)
- [MSBuild](#), the build engine used to build projects
- [NuGet](#), Microsoft's package manager for .NET
- Open-source build orchestration tools, such as [CAKE](#) and [FAKE](#)

.NET Standard

2/28/2019 • 9 minutes to read • [Edit Online](#)

The [.NET Standard](#) is a formal specification of .NET APIs that are intended to be available on all .NET implementations. The motivation behind the .NET Standard is establishing greater uniformity in the .NET ecosystem. [ECMA 335](#) continues to establish uniformity for .NET implementation behavior, but there's no similar spec for the .NET Base Class Libraries (BCL) for .NET library implementations.

The .NET Standard enables the following key scenarios:

- Defines uniform set of BCL APIs for all .NET implementations to implement, independent of workload.
 - Enables developers to produce portable libraries that are usable across .NET implementations, using this same set of APIs.
 - Reduces or even eliminates conditional compilation of shared source due to .NET APIs, only for OS APIs.

The various .NET implementations target specific versions of .NET Standard. Each .NET implementation version advertises the highest .NET Standard version it supports, a statement that means it also supports previous versions. For example, the .NET Framework 4.6 implements .NET Standard 1.3, which means that it exposes all APIs defined in .NET Standard versions 1.0 through 1.3. Similarly, the .NET Framework 4.6.1 implements .NET Standard 1.4, while .NET Core 1.0 implements .NET Standard 1.6.

.NET implementation support

The following table lists the minimum platform versions that support each .NET Standard version.

1 The versions listed for .NET Framework apply to .NET Core 2.0 SDK and later versions of the tooling. Older versions used a different mapping for .NET Standard 1.5 and higher. You can [download tooling for .NET Core tools for Visual Studio 2015](#) if you cannot upgrade to Visual Studio 2017.

2 The versions listed here represent the rules that NuGet uses to determine whether a given .NET Standard library is applicable. While NuGet considers .NET Framework 4.6.1 as supporting .NET Standard 1.5 through 2.0, there are several issues with consuming .NET Standard libraries that were built for those versions from .NET Framework 4.6.1 projects. For .NET Framework projects that need to use such libraries, we recommend that you upgrade the project to target .NET Framework 4.7.2 or higher.

- The columns represent .NET Standard versions. Each header cell is a link to a document that shows which APIs got added in that version of .NET Standard.
- The rows represent the different .NET implementations.
- The version number in each cell indicates the *minimum* version of the implementation you'll need in order to target that .NET Standard version.
- For an interactive table, see [.NET Standard versions](#).

To find the highest version of .NET Standard that you can target, do the following steps:

1. Find the row that indicates the .NET implementation you want to run on.
2. Find the column in that row that indicates your version starting from right to left.
3. The column header indicates the .NET Standard version that your target supports. You may also target any lower .NET Standard version. Higher .NET Standard versions will also support your implementation.
4. Repeat this process for each platform you want to target. If you have more than one target platform, you should pick the smaller version among them. For example, if you want to run on .NET Framework 4.5 and .NET Core 1.0, the highest .NET Standard version you can use is .NET Standard 1.1.

Which .NET Standard version to target

When choosing a .NET Standard version, you should consider this trade-off:

- The higher the version, the more APIs are available to you.
- The lower the version, the more platforms implement it.

In general, we recommend you to target the *lowest* version of .NET Standard possible. So, after you find the highest .NET Standard version you can target, follow these steps:

1. Target the next lower version of .NET Standard and build your project.
2. If your project builds successfully, repeat step 1. Otherwise, retarget to the next higher version and that's the version you should use.

However, targeting lower .NET Standard versions introduces a number of support dependencies. If your project targets .NET Standard 1.x, we recommend that you *also* target .NET Standard 2.0. This simplifies the dependency graph for users of your library that run on .NET Standard 2.0 compatible frameworks, and it reduces the number of packages they need to download.

.NET Standard versioning rules

There are two primary versioning rules:

- Additive: .NET Standard versions are logically concentric circles: higher versions incorporate all APIs from previous versions. There are no breaking changes between versions.
- Immutable: Once shipped, .NET Standard versions are frozen. New APIs first become available in specific .NET implementations, such as .NET Core. If the .NET Standard review board believes the new APIs should be available for all .NET implementations, they're added in a new .NET Standard version.

Specification

The .NET Standard specification is a standardized set of APIs. The specification is maintained by .NET

implementors, specifically Microsoft (includes .NET Framework, .NET Core, and Mono) and Unity. A public feedback process is used as part of establishing new .NET Standard versions through [GitHub](#).

Official artifacts

The official specification is a set of .cs files that define the APIs that are part of the standard. The [ref directory](#) in the [dotnet/standard repository](#) defines the .NET Standard APIs.

The [NETStandard.Library](#) metapackage ([source](#)) describes the set of libraries that define (in part) one or more .NET Standard versions.

A given component, like `System.Runtime`, describes:

- Part of .NET Standard (just its scope).
- Multiple versions of .NET Standard, for that scope.

Derivative artifacts are provided to enable more convenient reading and to enable certain developer scenarios (for example, using a compiler).

- [API list in markdown](#)
- Reference assemblies, distributed as [NuGet packages](#) and referenced by the [NETStandard.Library](#) metapackage.

Package representation

The primary distribution vehicle for the .NET Standard reference assemblies is [NuGet packages](#).

Implementations are delivered in a variety of ways, appropriate for each .NET implementation.

NuGet packages target one or more [frameworks](#). The .NET Standard packages target the ".NET Standard" framework. You can target the .NET Standard framework using the `netstandard` [compact TFM](#) (for example, `netstandard1.4`). Libraries that are intended to run on multiple runtimes should target this framework. For the broadest set of APIs, target `netstandard2.0` since the number of available APIs more than doubled between .NET Standard 1.6 and 2.0.

The `NETStandard.Library` metapackage references the complete set of NuGet packages that define .NET Standard. The most common way to target `netstandard` is by referencing this metapackage. It describes and provides access to the ~40 .NET libraries and associated APIs that define .NET Standard. You can reference additional packages that target `netstandard` to get access to additional APIs.

Versioning

The specification is not singular, but an incrementally growing and linearly versioned set of APIs. The first version of the standard establishes a baseline set of APIs. Subsequent versions add APIs and inherit APIs defined by previous versions. There is no established provision for removing APIs from the standard.

.NET Standard is not specific to any one .NET implementation, nor does it match the versioning scheme of any of those runtimes.

APIs added to any of the implementations (such as, .NET Framework, .NET Core and Mono) can be considered as candidates to add to the specification, particularly if they are thought to be fundamental in nature. New [versions of .NET Standard](#) are created based on .NET implementation releases, enabling you to target new APIs from a .NET Standard PCL. The versioning mechanics are described in more detail in [.NET Core Versioning](#).

.NET Standard versioning is important for usage. Given a .NET Standard version, you can use libraries that target that same or lower version. The following approach describes the workflow for using .NET Standard PCLs, specific to .NET Standard targeting.

- Select a .NET Standard version to use for your PCL.
- Use libraries that depend on the same .NET Standard version or lower.

- If you find a library that depends on a higher .NET Standard version, you either need to adopt that same version or decide not to use that library.

Targeting .NET Standard

You can [build .NET Standard Libraries](#) using a combination of the `netstandard` framework and the `NETStandard.Library` metapackage. You can see examples of [targeting the .NET Standard with .NET Core tools](#).

.NET Framework compatibility mode

Starting with .NET Standard 2.0, the .NET Framework compatibility mode was introduced. This compatibility mode allows .NET Standard projects to reference .NET Framework libraries as if they were compiled for .NET Standard. Referencing .NET Framework libraries doesn't work for all projects, such as libraries that use Windows Presentation Foundation (WPF) APIs.

For more information, see [.NET Framework compatibility mode](#).

.NET Standard libraries and Visual Studio

In order to build .NET Standard libraries in Visual Studio, make sure you have [Visual Studio 2017 version 15.3](#) or later installed on Windows, or [Visual Studio for Mac version 7.1](#) or later installed on macOS.

If you only need to consume .NET Standard 2.0 libraries in your projects, you can also do that in Visual Studio 2015. However, you need NuGet client 3.6 or higher installed. You can download the NuGet client for Visual Studio 2015 from the [NuGet downloads](#) page.

Comparison to Portable Class Libraries

.NET Standard is the replacement for [Portable Class Libraries \(PCL\)](#). The .NET Standard improves on the experience of creating portable libraries by curating a standard BCL and establishing greater uniformity across .NET implementations as a result. A library that targets .NET Standard is a PCL or a ".NET Standard-based PCL". Existing PCLs are "profile-based PCLs".

.NET Standard and PCL profiles were created for similar purposes but also differ in key ways.

Similarities:

- Define APIs that can be used for binary code sharing.

Differences:

- .NET Standard is a curated set of APIs, while PCL profiles are defined by intersections of existing platforms.
- .NET Standard linearly versions, while PCL profiles do not.
- PCL profiles represent Microsoft platforms while the .NET Standard is platform-agnostic.

PCL compatibility

.NET Standard is compatible with a subset of PCL profiles. .NET Standard 1.0, 1.1 and 1.2 each overlap with a set of PCL profiles. This overlap was created for two reasons:

- Enable .NET Standard-based PCLs to reference profile-based PCLs.
- Enable profile-based PCLs to be packaged as .NET Standard-based PCLs.

Profile-based PCL compatibility is provided by the [Microsoft.NETCore.Portable.Compatibility](#) NuGet package. This dependency is required when referencing NuGet packages that contain profile-based PCLs.

Profile-based PCLs packaged as `netstandard` are easier to consume than typically packaged profile-based PCLs. `netstandard` packaging is compatible with existing users.

You can see the set of PCL profiles that are compatible with the .NET Standard:

PCL PROFILE	.NET STANDARD	PCL PLATFORMS
Profile7	1.1	.NET Framework 4.5, Windows 8
Profile31	1.0	Windows 8.1, Windows Phone Silverlight 8.1
Profile32	1.2	Windows 8.1, Windows Phone 8.1
Profile44	1.2	.NET Framework 4.5.1, Windows 8.1
Profile49	1.0	.NET Framework 4.5, Windows Phone Silverlight 8
Profile78	1.0	.NET Framework 4.5, Windows 8, Windows Phone Silverlight 8
Profile84	1.0	Windows Phone 8.1, Windows Phone Silverlight 8.1
Profile111	1.1	.NET Framework 4.5, Windows 8, Windows Phone 8.1
Profile151	1.2	.NET Framework 4.5.1, Windows 8.1, Windows Phone 8.1
Profile157	1.0	Windows 8.1, Windows Phone 8.1, Windows Phone Silverlight 8.1
Profile259	1.0	.NET Framework 4.5, Windows 8, Windows Phone 8.1, Windows Phone Silverlight 8

- [.NET Standard Versions](#)

What's new in the .NET Standard

3/9/2019 • 3 minutes to read • [Edit Online](#)

The .NET Standard is a formal specification that defines a versioned set of APIs that must be available on .NET implementations that comply with that version of the standard. The .NET Standard is targeted at library developers. A library that targets a .NET Standard version can be used on any .NET Framework, .NET Core, or Xamarin implementation that supports that version of the standard.

The most recent version of the .NET Standard is 2.0. It is included with the .NET Core 2.0 SDK, as well as with Visual Studio 2017 Version 15.3 with the .NET Core workload installed.

Supported .NET implementations

The .NET Standard 2.0 is supported by the following .NET implementations:

- .NET Core 2.0 or later
- .NET Framework 4.6.1 or later
- Mono 5.4 or later
- Xamarin.iOS 10.14 or later
- Xamarin.Mac 3.8 or later
- Xamarin.Android 8.0 or later
- Universal Windows Platform 10.0.16299 or later

What's new in the .NET Standard 2.0

The .NET Standard 2.0 includes the following new features:

A vastly expanded set of APIs

Through version 1.6, the .NET Standard included a comparatively small subset of APIs. Among those excluded were many APIs that were commonly used in the .NET Framework or Xamarin. This complicates development, since it requires that developers find suitable replacements for familiar APIs when they develop applications and libraries that target multiple .NET implementations. The .NET Standard 2.0 addresses this limitation by adding over 20,000 more APIs than were available in .NET Standard 1.6, the previous version of the standard. For a list of the APIs that have been added to the .NET Standard 2.0, see [.NET Standard 2.0 vs 1.6](#).

Some of the additions to the [System](#) namespace in .NET Standard 2.0 include:

- Support for the [AppDomain](#) class.
- Better support for working with arrays from additional members in the [Array](#) class.
- Better support for working with attributes from additional members in the [Attribute](#) class.
- Better calendar support and additional formatting options for [DateTime](#) values.
- Additional [Decimal](#) rounding functionality.
- Additional functionality in the [Environment](#) class.
- Enhanced control over the garbage collector through the [GC](#) class.
- Enhanced support for string comparison, enumeration, and normalization in the [String](#) class.
- Support for daylight saving adjustments and transition times in the [TimeZoneInfo.AdjustmentRule](#) and [TimeZoneInfo.TransitionTime](#) classes.
- Significantly enhanced functionality in the [Type](#) class.
- Better support for deserialization of exception objects by adding an exception constructor with [SerializationInfo](#)

and [StreamingContext](#) parameters.

Support for .NET Framework libraries

The overwhelming majority of libraries target the .NET Framework rather than .NET Standard. However, most of the calls in those libraries are to APIs that are included in the .NET Standard 2.0. Starting with the .NET Standard 2.0, you can access .NET Framework libraries from a .NET Standard library by using a [compatibility shim](#). This compatibility layer is transparent to developers; you don't have to do anything to take advantage of .NET Framework libraries.

The single requirement is that the APIs called by the .NET Framework class library must be included in the .NET Standard 2.0.

Support for Visual Basic

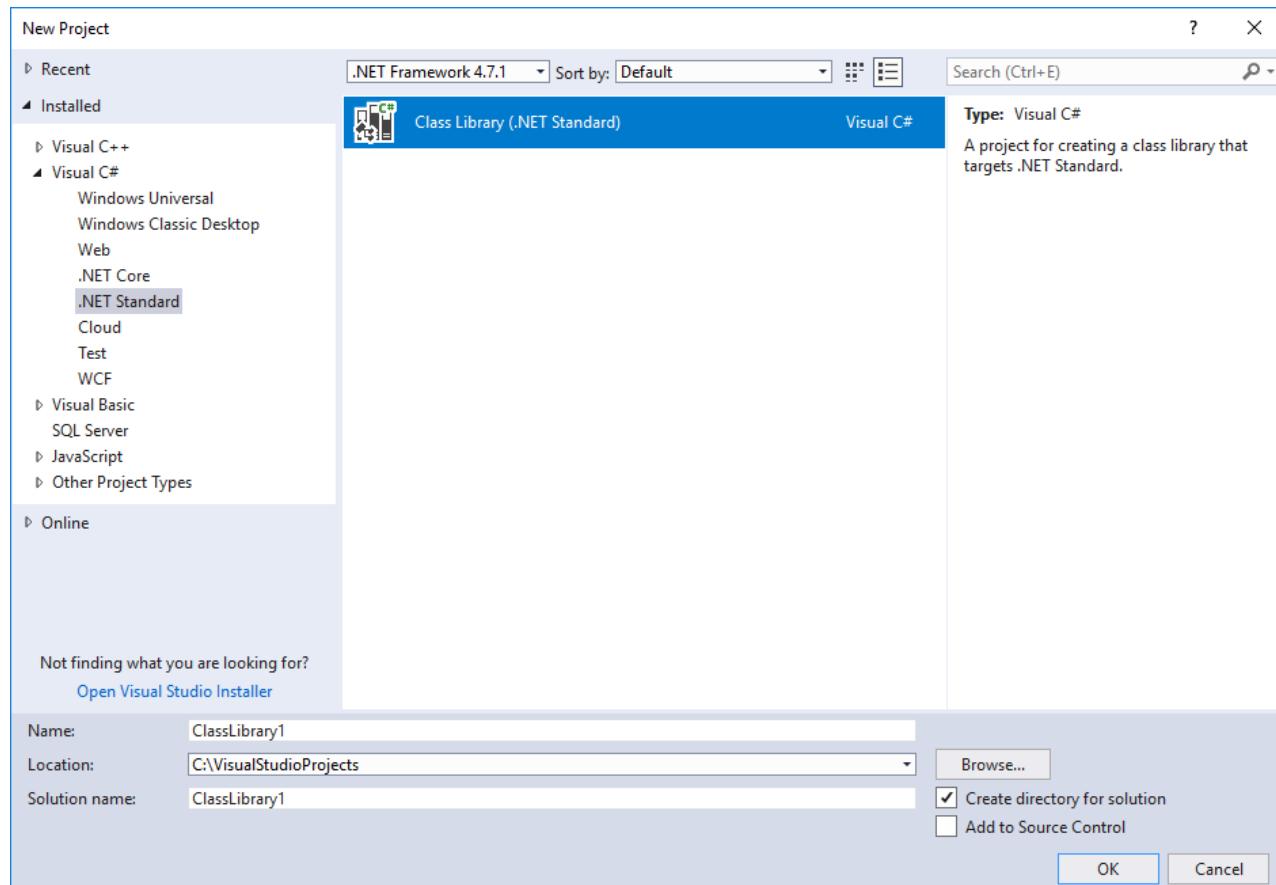

You can now develop .NET Standard libraries in Visual Basic. For Visual Basic developers using Visual Studio 2017 Version 15.3 or later with the .NET Core workload installed, Visual Studio now includes a .NET Standard Class Library template. For Visual Basic developers who use other development tools and environments, you can use the `dotnet new` command to create a .NET Standard Library project. For more information, see the [Tooling support for .NET Standard libraries](#).

Tooling support for .NET Standard libraries

With the release of .NET Core 2.0 and .NET Standard 2.0, both Visual Studio 2017 and the [.NET Core Command Line Interface \(CLI\)](#) include tooling support for creating .NET Standard libraries.

If you install Visual Studio with the **.NET Core cross-platform development** workload, you can create a .NET Standard 2.0 library project by using a project template, as the following figure shows:

- [C#](#)
- [Visual Basic](#)

If you're using the .NET Core CLI, the following `dotnet new` command creates a class library project that targets the .NET Standard 2.0:

```
dotnet new classlib
```

Target frameworks

1/23/2019 • 4 minutes to read • [Edit Online](#)

When you target a framework in an app or library, you're specifying the set of APIs that you'd like to make available to the app or library. You specify the target framework in your project file using Target Framework Monikers (TFMs).

An app or library can target a version of [.NET Standard](#). .NET Standard versions represent standardized sets of APIs across all .NET implementations. For example, a library can target .NET Standard 1.6 and gain access to APIs that function across .NET Core and .NET Framework using the same codebase.

An app or library can also target a specific .NET implementation to gain access to implementation-specific APIs. For example, an app that targets Xamarin.iOS (for example, `xamarin.ios10`) gets access to Xamarin-provided iOS API wrappers for iOS 10, or an app that targets the Universal Windows Platform (UWP, `uap10.0`) has access to APIs that compile for devices that run Windows 10.

For some target frameworks (for example, the .NET Framework), the APIs are defined by the assemblies that the framework installs on a system and may include application framework APIs (for example, ASP.NET).

For package-based target frameworks (for example, .NET Standard and .NET Core), the APIs are defined by the packages included in the app or library. A *metapackage* is a NuGet package that has no content of its own but is a list of dependencies (other packages). A NuGet package-based target framework implicitly specifies a metapackage that references all the packages that together make up the framework.

Latest target framework versions

The following table defines the most common target frameworks, how they're referenced, and which version of the [.NET Standard](#) they implement. These target framework versions are the latest stable versions. Pre-release versions aren't shown. A Target Framework Moniker (TFM) is a standardized token format for specifying the target framework of a .NET app or library.

TARGET FRAMEWORK	LATEST STABLE VERSION	TARGET FRAMEWORK MONIKER (TFM)	IMPLEMENTED .NET STANDARD VERSION
.NET Standard	2.0	netstandard2.0	N/A
.NET Core	2.2	netcoreapp2.2	2.0
.NET Framework	4.7.2	net472	2.0

Supported target framework versions

A target framework is typically referenced by a TFM. The following table shows the target frameworks supported by the .NET Core SDK and the NuGet client. Equivalents are shown within brackets. For example, `win81` is an equivalent TFM to `netcore451`.

TARGET FRAMEWORK	TFM

TARGET FRAMEWORK	TFM
.NET Standard	netstandard1.0 netstandard1.1 netstandard1.2 netstandard1.3 netstandard1.4 netstandard1.5 netstandard1.6 netstandard2.0
.NET Core	netcoreapp1.0 netcoreapp1.1 netcoreapp2.0 netcoreapp2.1 netcoreapp2.2
.NET Framework	net11 net20 net35 net40 net403 net45 net451 net452 net46 net461 net462 net47 net471 net472
Windows Store	netcore [netcore45] netcore45 [win] [win8] netcore451 [win81]
.NET Micro Framework	netmf
Silverlight	sl4 sl5
Windows Phone	wp [wp7] wp7 wp75 wp8 wp81 wpa81
Universal Windows Platform	uap [uap10.0] uap10.0 [win10] [netcore50]

How to specify target frameworks

Target frameworks are specified in your project file. When a single target framework is specified, use the **TargetFramework** element. The following console app project file demonstrates how to target .NET Core 2.2:

```

<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>netcoreapp2.2</TargetFramework>
  </PropertyGroup>

</Project>

```

When you specify multiple target frameworks, you may conditionally reference assemblies for each target framework. In your code, you can conditionally compile against those assemblies by using preprocessor symbols with *if-then-else* logic.

The following library project file targets APIs of .NET Standard (`netstandard1.4`) and APIs of the .NET Framework (`net40` and `net45`). Use the plural **TargetFrameworks** element with multiple target frameworks. Note how the `Condition` attributes include implementation-specific packages when the library is compiled for the two .NET Framework TFM's:

```

<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netstandard1.4;net40;net45</TargetFrameworks>
  </PropertyGroup>

  <!-- Conditionally obtain references for the .NET Framework 4.0 target -->
  <ItemGroup Condition=" '$(TargetFramework)' == 'net40' ">
    <Reference Include="System.Net" />
  </ItemGroup>

  <!-- Conditionally obtain references for the .NET Framework 4.5 target -->
  <ItemGroup Condition=" '$(TargetFramework)' == 'net45' ">
    <Reference Include="System.Net.Http" />
    <Reference Include="System.Threading.Tasks" />
  </ItemGroup>

</Project>

```

Within your library or app, you write conditional code to compile for each target framework:

```

public class MyClass
{
    static void Main()
    {
#if NET40
        Console.WriteLine("Target framework: .NET Framework 4.0");
#endif NET45
        Console.WriteLine("Target framework: .NET Framework 4.5");
#else
        Console.WriteLine("Target framework: .NET Standard 1.4");
#endif
    }
}

```

The build system is aware of preprocessor symbols representing the target frameworks shown in the [Supported target framework versions](#) table. When using a symbol that represents a .NET Standard or .NET Core TFM, replace the dot with an underscore and change lowercase letters to uppercase (for example, the symbol for `netstandard1.4` is `NETSTANDARD1_4`).

The complete list of preprocessor symbols for .NET Core target frameworks is:

TARGET FRAMEWORKS	SYMBOLS
.NET Framework	NET20 , NET35 , NET40 , NET45 , NET451 , NET452 , NET46 , NET461 , NET462 , NET47 , NET471 , NET472
.NET Standard	NETSTANDARD1_0 , NETSTANDARD1_1 , NETSTANDARD1_2 , NETSTANDARD1_3 , NETSTANDARD1_4 , NETSTANDARD1_5 , NETSTANDARD1_6 , NETSTANDARD2_0
.NET Core	NETCOREAPP1_0 , NETCOREAPP1_1 , NETCOREAPP2_0 , NETCOREAPP2_1 , NETCOREAPP2_2

Deprecated target frameworks

The following target frameworks are deprecated. Packages targeting these target frameworks should migrate to the indicated replacements.

DEPRECATED TFM	REPLACEMENT
aspnet50 aspnetcore50 dnxcore50 dnx dnx45 dnx451 dnx452	netcoreapp
dotnet dotnet50 dotnet51 dotnet52 dotnet53 dotnet54 dotnet55 dotnet56	netstandard
netcore50	uap10.0
win	netcore45
win8	netcore45
win81	netcore451
win10	uap10.0
winrt	netcore45

.NET Glossary

3/8/2019 • 11 minutes to read • [Edit Online](#)

The primary goal of this glossary is to clarify meanings of selected terms and acronyms that appear frequently in the .NET documentation without definitions.

AOT

Ahead-of-time compiler.

Similar to [JIT](#), this compiler also translates [IL](#) to machine code. In contrast to JIT compilation, AOT compilation happens before the application is executed and is usually performed on a different machine. Because AOT tool chains don't compile at runtime, they don't have to minimize time spent compiling. That means they can spend more time optimizing. Since the context of AOT is the entire application, the AOT compiler also performs cross-module linking and whole-program analysis, which means that all references are followed and a single executable is produced.

See [CoreRT](#) and [.NET Native](#).

ASP.NET

The original ASP.NET implementation that ships with the .NET Framework.

Sometimes ASP.NET is an umbrella term that refers to both ASP.NET implementations including ASP.NET Core. The meaning that the term carries in any given instance is determined by context. Refer to [ASP.NET 4.x](#) when you want to make it clear that you're not using ASP.NET to mean both implementations.

See [ASP.NET documentation](#).

ASP.NET Core

A cross-platform, high-performance, open source implementation of ASP.NET built on .NET Core.

See [ASP.NET Core documentation](#).

assembly

A [.dll/.exe](#) file that can contain a collection of APIs that can be called by applications or other assemblies.

An assembly may include types such as interfaces, classes, structures, enumerations, and delegates. Assemblies in a project's *bin* folder are sometimes referred to as *binaries*. See also [library](#).

CLR

Common Language Runtime.

The exact meaning depends on the context, but this usually refers to the runtime of the .NET Framework. The CLR handles memory allocation and management. The CLR is also a virtual machine that not only executes apps but also generates and compiles code on-the-fly using a [JIT](#) compiler. The current Microsoft CLR implementation is Windows only.

CoreCLR

.NET Core Common Language Runtime.

This CLR is built from the same code base as the CLR. Originally, CoreCLR was the runtime of Silverlight and was designed to run on multiple platforms, specifically Windows and OS X. CoreCLR is now part of .NET Core and represents a simplified version of the CLR. It's still a [cross-platform](#) runtime, now including support for many Linux distributions. CoreCLR is also a virtual machine with JIT and code execution capabilities.

CoreFX

.NET Core Base Class Library (BCL)

A set of libraries that comprise the System.* (and to a limited extent Microsoft.*) namespaces. The BCL is a general purpose, lower-level framework that higher-level application frameworks, such as ASP.NET Core, build on. The source code of the .NET Core BCL is contained in the [CoreFX repository](#). However, the majority of the .NET Core APIs are also available in the .NET Framework, so you can think of CoreFX as a fork of the .NET Framework BCL.

CoreRT

.NET Core runtime.

In contrast to the CLR/CoreCLR, CoreRT is not a virtual machine, which means it doesn't include the facilities to generate and run code on-the-fly because it doesn't include a [JIT](#). It does, however, include the [GC](#) and the ability for runtime type identification (RTTI) and reflection. However, its type system is designed so that metadata for reflection isn't required. This enables having an [AOT](#) tool chain that can link away superfluous metadata and (more importantly) identify code that the app doesn't use. CoreRT is in development.

See [Intro to .NET Native and CoreRT](#)

cross-platform

The ability to develop and execute an application that can be used on multiple different operating systems, such as Linux, Windows and iOS, without having to re-write specifically for each one. This enables code re-use and consistency between applications on different platforms.

ecosystem

All of the runtime software, development tools, and community resources that are used to build and run applications for a given technology.

The term ".NET ecosystem" differs from similar terms such as ".NET stack" in its inclusion of third-party apps and libraries. Here's an example in a sentence:

- "The motivation behind the [.NET Standard](#) is to establish greater uniformity in the .NET ecosystem."

framework

In general, a comprehensive collection of APIs that facilitates development and deployment of applications that are based on a particular technology. In this general sense, ASP.NET Core and Windows Forms are examples of application frameworks. See also [library](#).

The word "framework" has a more specific technical meaning in the following terms:

- [.NET Framework](#)
- [target framework](#)
- [TFM \(target framework moniker\)](#)

In the existing documentation, "framework" sometimes refers to an [implementation of .NET](#). For example, an

article may call .NET Core a framework. We plan to eliminate this confusing usage from the documentation.

GC

Garbage collector.

The garbage collector is an implementation of automatic memory management. The GC frees memory occupied by objects that are no longer in use.

See [Garbage Collection](#).

IL

Intermediate language.

Higher-level .NET languages, such as C#, compile down to a hardware-agnostic instruction set, which is called Intermediate Language (IL). IL is sometimes referred to as MSIL (Microsoft IL) or CIL (Common IL).

JIT

Just-in-time compiler.

Similar to AOT, this compiler translates IL to machine code that the processor understands. Unlike AOT, JIT compilation happens on demand and is performed on the same machine that the code needs to run on. Since JIT compilation occurs during execution of the application, compile time is part of the run time. Thus, JIT compilers have to balance time spent optimizing code against the savings that the resulting code can produce. But a JIT knows the actual hardware and can free developers from having to ship different implementations.

implementation of .NET

An implementation of .NET includes the following:

- One or more runtimes. Examples: CLR, CoreCLR, CoreRT.
- A class library that implements a version of the .NET Standard and may include additional APIs. Examples: .NET Framework Base Class Library, .NET Core Base Class Library.
- Optionally, one or more application frameworks. Examples: ASP.NET, Windows Forms, and WPF are included in the .NET Framework.
- Optionally, development tools. Some development tools are shared among multiple implementations.

Examples of .NET implementations:

- [.NET Framework](#)
- [.NET Core](#)
- [Universal Windows Platform \(UWP\)](#)

library

A collection of APIs that can be called by apps or other libraries. A .NET library is composed of one or more [assemblies](#).

The words library and [framework](#) are often used synonymously.

metapackage

A NuGet package that has no library of its own but is only a list of dependencies. The included packages can optionally establish the API for a target framework.

See [Packages, Metapackages and Frameworks](#)

Mono

Mono is an open source, [cross-platform](#) .NET implementation that is mainly used when a small runtime is required. It is the runtime that powers Xamarin applications on Android, Mac, iOS, tvOS and watchOS and is focused primarily on apps that require a small footprint.

It supports all of the currently published .NET Standard versions.

Historically, Mono implemented the larger API of the .NET Framework and emulated some of the most popular capabilities on Unix. It is sometimes used to run .NET applications that rely on those capabilities on Unix.

Mono is typically used with a just-in-time compiler, but it also features a full static compiler (ahead-of-time compilation) that is used on platforms like iOS.

To learn more about Mono, see the [Mono documentation](#).

.NET

The umbrella term for [.NET Standard](#) and all [.NET implementations](#) and workloads. Always capitalized, never ".Net".

See the [.NET Guide](#)

.NET Core

A cross-platform, high-performance, open source implementation of .NET. Includes the Core Common Language Runtime (CoreCLR), the Core AOT Runtime (CoreRT, in development), the Core Base Class Library, and the Core SDK.

See [.NET Core](#).

.NET Core CLI

A cross-platform toolchain for developing .NET Core applications.

See [.NET Core command-line interface \(CLI\) tools](#).

.NET Core SDK

A set of libraries and tools that allow developers to create .NET Core applications and libraries. Includes the [.NET Core CLI](#) for building apps, .NET Core libraries and runtime for building and running apps, and the dotnet executable (`dotnet.exe`) that runs CLI commands and runs applications.

See [.NET Core SDK Overview](#).

.NET Framework

An implementation of .NET that runs only on Windows. Includes the Common Language Runtime (CLR), the Base Class Library, and application framework libraries such as ASP.NET, Windows Forms, and WPF.

See [.NET Framework Guide](#).

.NET Native

A compiler tool chain that produces native code ahead-of-time (AOT), as opposed to just-in-time (JIT).

Compilation happens on the developer's machine similar to the way a C++ compiler and linker works. It removes unused code and spends more time optimizing it. It extracts code from libraries and merges them into the executable. The result is a single module that represents the entire app.

UWP was the first application framework supported by .NET Native. Now, we support building native console apps for Windows, macOS, and Linux.

See [Intro to .NET Native and CoreRT](#)

.NET Standard

A formal specification of .NET APIs that are available in each .NET implementation.

The .NET Standard specification is sometimes called a library in the documentation. Because a library includes API implementations, not only specifications (interfaces), it's misleading to call .NET Standard a "library." We plan to eliminate that usage from the documentation, except in reference to the name of the .NET Standard metapackage (`NETStandard.Library`).

See [.NET Standard](#).

NGEN

Native (image) generation.

You can think of this technology as a persistent JIT compiler. It usually compiles code on the machine where the code is executed, but compilation typically occurs at install time.

package

A NuGet package — or just a package — is a `.zip` file with one or more assemblies of the same name along with additional metadata such as the author name.

The `.zip` file has a `.nupkg` extension and may contain assets, such as `.dll` files and `.xml` files, for use with multiple target frameworks and versions. When installed in an app or library, the appropriate assets are selected based on the target framework specified by the app or library. The assets that define the interface are in the `ref` folder, and the assets that define the implementation are in the `lib` folder.

platform

An operating system and the hardware it runs on, such as Windows, macOS, Linux, iOS, and Android.

Here are examples of usage in sentences:

- ".NET Core is a cross-platform implementation of .NET."
- "PCL profiles represent Microsoft platforms, while the .NET Standard is agnostic to platform."

The .NET documentation frequently uses ".NET platform" to mean either an implementation of .NET or the .NET stack including all implementations. Both of these usages tend to get confused with the primary (OS/hardware) meaning, so we plan to eliminate these usages from the documentation.

runtime

The execution environment for a managed program.

The OS is part of the runtime environment but is not part of the .NET runtime. Here are some examples of .NET runtimes:

- Common Language Runtime (CLR)

- Core Common Language Runtime (CoreCLR)
- .NET Native (for UWP)
- Mono runtime

The .NET documentation sometimes uses "runtime" to mean an implementation of .NET. For example, in the following sentences "runtime" should be replaced with "implementation":

- "The various .NET runtimes implement specific versions of .NET Standard."
- "Libraries that are intended to run on multiple runtimes should target this framework." (referring to .NET Standard)
- "The various .NET runtimes implement specific versions of .NET Standard. ... Each .NET runtime version advertises the highest .NET Standard version it supports ..."

We plan to eliminate this inconsistent usage.

stack

A set of programming technologies that are used together to build and run applications.

"The .NET stack" refers to the .NET Standard and all .NET implementations. The phrase "a .NET stack" may refer to one implementation of .NET.

target framework

The collection of APIs that a .NET app or library relies on.

An app or library can target a version of .NET Standard (for example, .NET Standard 2.0), which is specification for a standardized set of APIs across all .NET implementations. An app or library can also target a version of a specific .NET implementation, in which case it gets access to implementation-specific APIs. For example, an app that targets Xamarin.iOS gets access to Xamarin-provided iOS API wrappers.

For some target frameworks (for example, the .NET Framework) the available APIs are defined by the assemblies that a .NET implementation installs on a system, which may include application framework APIs (for example, ASP.NET, WinForms). For package-based target frameworks (such as .NET Standard and .NET Core), the framework APIs are defined by the packages installed in the app or library. In that case, the target framework implicitly specifies a metapackage that references all the packages that together make up the framework.

See [Target Frameworks](#).

TFM

Target framework moniker.

A standardized token format for specifying the target framework of a .NET app or library. Target frameworks are typically referenced by a short name, such as `net462`. Long-form TFMs (such as `.NETFramework,Version=4.6.2`) exist but are not generally used to specify a target framework.

See [Target Frameworks](#).

UWP

Universal Windows Platform.

An implementation of .NET that is used for building modern, touch-enabled Windows applications and software for the Internet of Things (IoT). It's designed to unify the different types of devices that you may want to target, including PCs, tablets, phablets, phones, and even the Xbox. UWP provides many services, such as a centralized

app store, an execution environment (AppContainer), and a set of Windows APIs to use instead of Win32 (WinRT). Apps can be written in C++, C#, VB.NET, and JavaScript. When using C# and VB.NET, the .NET APIs are provided by .NET Core.

Introduction

.NET Core and ASP.NET Core offer several advantages over traditional .NET development. You should use .NET Core for your server applications if some or all of the following are important to your application's success:

- Cross-platform support.
- Use of microservices.
- Use of Docker containers.
- High performance and scalability requirements.
- Side-by-side versioning of .NET versions by application on the same server.

Traditional .NET applications can and do support many of these requirements, but ASP.NET Core and .NET Core have been optimized to offer improved support for the above scenarios.

More and more organizations are choosing to host their web applications in the cloud using services like Microsoft Azure. You should consider hosting your application in the cloud if the following are important to your application or organization:

- Reduced investment in data center costs (hardware, software, space, utilities, server management, etc.).
- Flexible pricing (pay based on usage, not for idle capacity).
- Extreme reliability.

- Improved app mobility; easily change where and how your app is deployed.
- Flexible capacity; scale up or down based on actual needs.

Building web applications with ASP.NET Core, hosted in Azure, offers many competitive advantages over traditional alternatives. ASP.NET Core is optimized for modern web application development practices and cloud hosting scenarios. In this guide, you'll learn how to architect your ASP.NET Core applications to best take advantage of these capabilities.

Purpose

This guide provides end-to-end guidance on building *monolithic* web applications using ASP.NET Core and Azure. In this context, "monolithic" refers to the fact that these applications are deployed as a single unit, not as a collection of interacting services and applications.

This guide is complementary to the "[.NET Microservices. Architecture for Containerized .NET Applications](#)" which focuses more on Docker, Microservices, and Deployment of Containers to host enterprise applications.

.NET Microservices. Architecture for Containerized .NET Applications

- **e-book**
<https://aka.ms/MicroservicesEbook>
- **Sample Application**
<https://aka.ms/microservicesarchitecture>

Who should use this guide

The audience for this guide is mainly developers, development leads, and architects who are interested in building modern web applications using Microsoft technologies and services in the cloud.

A secondary audience is technical decision makers who are already familiar ASP.NET or Azure and are looking for information on whether it makes sense to upgrade to ASP.NET Core for new or existing projects.

How you can use this guide

This guide has been condensed into a relatively small document that focuses on building web applications with modern .NET technologies and Windows Azure. As such, it can be read in its entirety to provide a foundation of understanding such applications and their technical considerations. The guide, along with its sample application, can also serve as a starting point or reference. Use the associated sample application as a template for your own applications, or to see how you might organize your application's component parts. Refer back to the guide's principles and coverage of architecture and technology options and decision considerations when you're weighing these choices for your own application.

Feel free to forward this guide to your team to help ensure a common understanding of these considerations and opportunities. Having everybody working from a common set of terminology and underlying principles helps ensure consistent application of architectural patterns and practices.

Introduction

When you decide to modernize your web applications or services and move them to the cloud, you don't necessarily have to fully rearchitect your apps. Rearchitecting an application by using an advanced approach like microservices isn't always an option because of cost and time restraints. Depending on the type of application, rearchitecting an app also might not be necessary. To optimize the cost-effectiveness of your organization's cloud migration strategy, it's important to consider the needs of your business and requirements of your apps. You'll need to determine:

- Which apps require a transformation or rearchitecting.
- Which apps need to be only partially modernized.
- Which apps you can "lift and shift" directly to the cloud.

About this guide

This guide focuses primarily on initial modernization of existing Microsoft .NET Framework web or service-oriented applications, meaning the action of moving a workload to a newer or more modern environment without significantly altering the application's code and basic architecture.

This guide also highlights the benefits of moving your apps to the cloud and partially modernizing apps by using a

specific set of new technologies and approaches, like Windows Containers and related compute-platforms in Azure supporting Windows Containers.

Path to the cloud for existing .NET applications

Organizations typically choose to move to the cloud for the agility and speed they can get for their applications. You can set up thousands of servers (VMs) in the cloud in minutes, compared to the weeks it typically takes to set up on-premises servers.

There isn't a single, one-size-fits-all strategy for migrating applications to the cloud. The right migration strategy for you will depend on your organization's needs and priorities, and the kind of applications you are migrating. Not all applications warrant the investment of moving to a platform as a service ([PaaS](#)) model or developing a [cloud-native](#) application model. In many cases, you can take a phased or incremental approach to invest in moving your assets to the cloud, based on your business needs.

For modern applications with the best long-term agility and value for the organization, you might benefit from investing in [cloud-native](#) application architectures. However, for applications that are existing or legacy assets, the key is to spend minimal time and money (no rearchitecting or code changes) while moving them to the cloud, to realize significant benefits.

Figure 1-1 shows the possible paths you can take when you move existing .NET applications to the cloud in incremental phases.

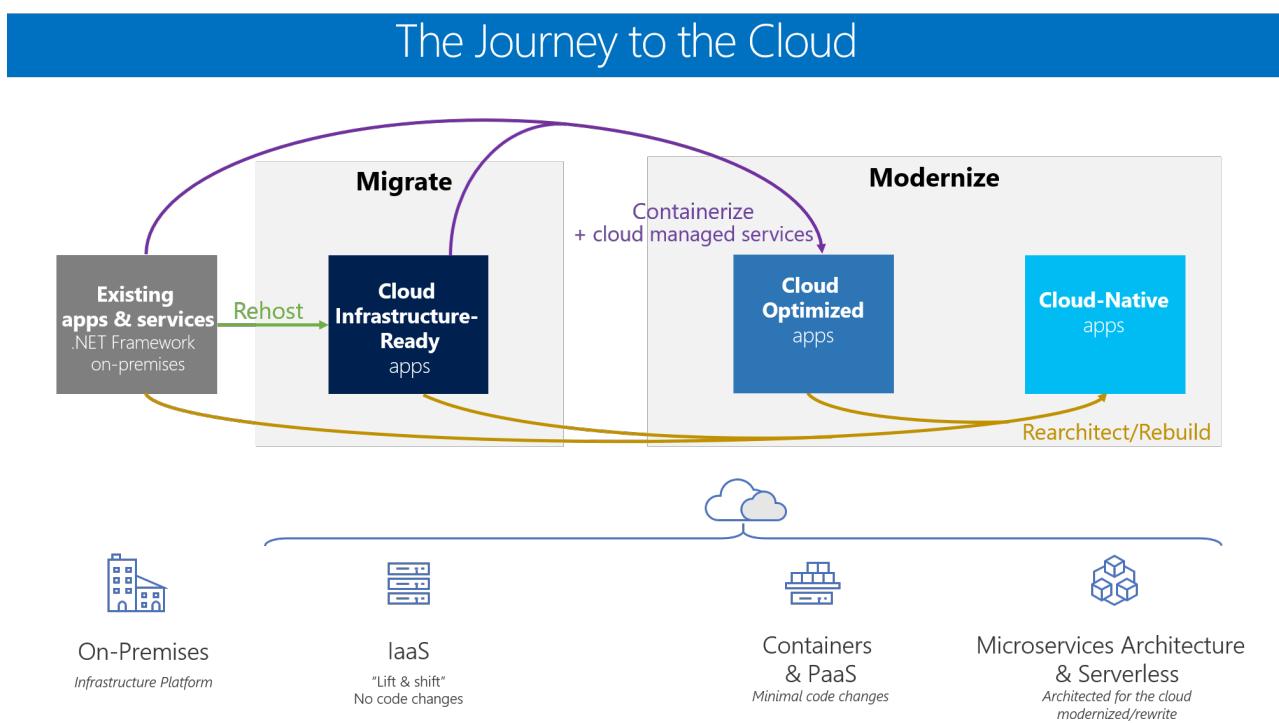

Figure 1-1. Modernization paths for existing .NET applications and services

Each migration approach has different benefits and reasons for using it. You can choose a single approach when you migrate apps to the cloud, or choose certain components from multiple approaches. Individual applications aren't limited to a single approach or maturity state. For instance, a common hybrid approach would have certain on-premises components plus other components in the cloud.

The definition and short explanation for each application maturity level are the following:

Level 1: Cloud Infrastructure-Ready applications: In this migration approach, you simply migrate or rehost your current on-premises applications to an infrastructure as a service ([IaaS](#)) platform. Your apps have almost the same

composition as before, but now you deploy them to VMs in the cloud. This simple type of migration is typically known in the industry as "Lift & Shift."

Level 2: Cloud Optimized applications: At this level and still without rearchitecting or altering significant code, you can gain additional benefits from running your app in the cloud with modern technologies like containers and additional cloud-managed services. You improve the agility of your applications to ship faster by refining your enterprise development operations (DevOps) processes. You achieve this by using technologies like Windows Containers, which is based on Docker Engine. Containers remove the friction that's caused by application dependencies when you deploy in multiple stages. In this maturity model, you can deploy containers on IaaS or PaaS while using additional cloud-managed services related to databases, cache as a service, monitoring, and continuous integration/continuous deployment (CI/CD) pipelines.

The third level of maturity is the ultimate goal in the cloud, but it's optional for many apps and not the main focus of this guide:

Level 3: Cloud-Native applications: This migration approach typically is driven by business need and targets modernizing your mission-critical applications. At this level, you use PaaS services to move your apps to PaaS computing platforms. You implement [cloud-native](#) applications and microservices architecture to evolve applications with long-term agility, and to scale to new limits. This type of modernization usually requires architecting specifically for the cloud. New code often must be written, especially when you move to cloud-native application and microservice-based models. This approach can help you gain benefits that are difficult to achieve in your monolithic and on-premises application environment.

Table 1-1 describes the main benefits of and reasons for choosing each migration or modernization approach.

CLOUD INFRASTRUCTURE-READY <i>LIFT AND SHIFT</i>	CLOUD-OPTIMIZED <i>MODERNIZE</i>	CLOUD-NATIVE <i>MODERNIZE, REARCHITECT AND REWRITE</i>
Application's compute target		
Applications deployed to VMs in Azure	Monolithic or N-Tier apps deployed to Azure App Service, Azure Container Instance (ACI), VMs with containers, Azure Service Fabric, or AKS (Azure Kubernetes Service)	Containerized microservices on Azure Kubernetes Service (AKS), Service Fabric and/or serverless microservices based on Azure Functions.
Data target		
SQL or any relational database on a VM	Azure SQL Database Managed Instance or another managed database in the cloud.	Fined-grain databases per microservice, based on Azure SQL Database, Azure Cosmos DB, or another managed database in the cloud
Advantages		
<ul style="list-style-type: none">• No rearchitecting, no new code• Least effort for quick migration• Least-common denominator supported in Azure• Basic availability guarantees• After moving to the cloud, it's easier to modernize even more	<ul style="list-style-type: none">• No rearchitecting• Minimal code/config changes• Improved deployment and DevOps agility to release because of containers• Increased density and lower deployment costs• Portability of apps and dependencies• Flexibility of host targets: PaaS approaches or IaaS	<ul style="list-style-type: none">• Architect for the cloud, you get the best benefits from the cloud but new code is needed• Microservices cloud-native approaches• Modern mission-critical applications, cloud-resilient hyper-scalable• Fully managed services• Optimized for scale• Optimized for autonomous agility by subsystem• Built on deployment and DevOps

CLOUD INFRASTRUCTURE-READY LIFT AND SHIFT	CLOUD-OPTIMIZED MODERNIZE	CLOUD-NATIVE MODERNIZE, REARCHITECT AND REWRITE
Challenges		
<ul style="list-style-type: none"> Smaller cloud value, other than shift in operating expense or closing datacenters Little is managed: No OS or middleware patching; might use infrastructure solutions, like Terraform, Spinnaker, or Puppet 	<ul style="list-style-type: none"> Containerizing is an additional step in the learning curve for developers and IT Operations DevOps and CI/CD pipelines is usually 'a must' for this approach. If not currently present in the culture of the organization, it might be an additional challenge 	<ul style="list-style-type: none"> Requires rearchitecture for cloud native apps and microservice architectures and usually requires significant code refactoring or rewriting when modernizing (increased time and budget) DevOps and CI/CD pipelines is usually 'a must' for this approach. If not currently present in the culture of the organization, it might be an additional challenge

Table 1-1. Benefits and challenges of modernization paths for existing .NET applications and services

Key technologies and architectures by maturity level

.NET Framework applications initially started with the .NET Framework version 1.0, which was released in late 2001. Then, companies moved towards newer versions (such as 2.0, 3.5 and .NET 4.x). Most of those applications ran on Windows Server and Internet Information Server (IIS), and used a relational database, like SQL Server, Oracle, MySQL, or any other RDBMS.

Most existing .NET applications might nowadays be based on .NET Framework 4.x, or even on .NET Framework 3.5, and use web frameworks like ASP.NET MVC, ASP.NET Web Forms, ASP.NET Web API, Windows Communication Foundation (WCF), ASP.NET SignalR, and ASP.NET Web Pages. These established .NET Framework technologies depend on Windows. That dependency is important to consider if you are simply migrating legacy apps and you want to make minimal changes to your application infrastructure.

Figure 1-2 shows the primary technologies and architecture styles used at each of the three cloud maturity levels:

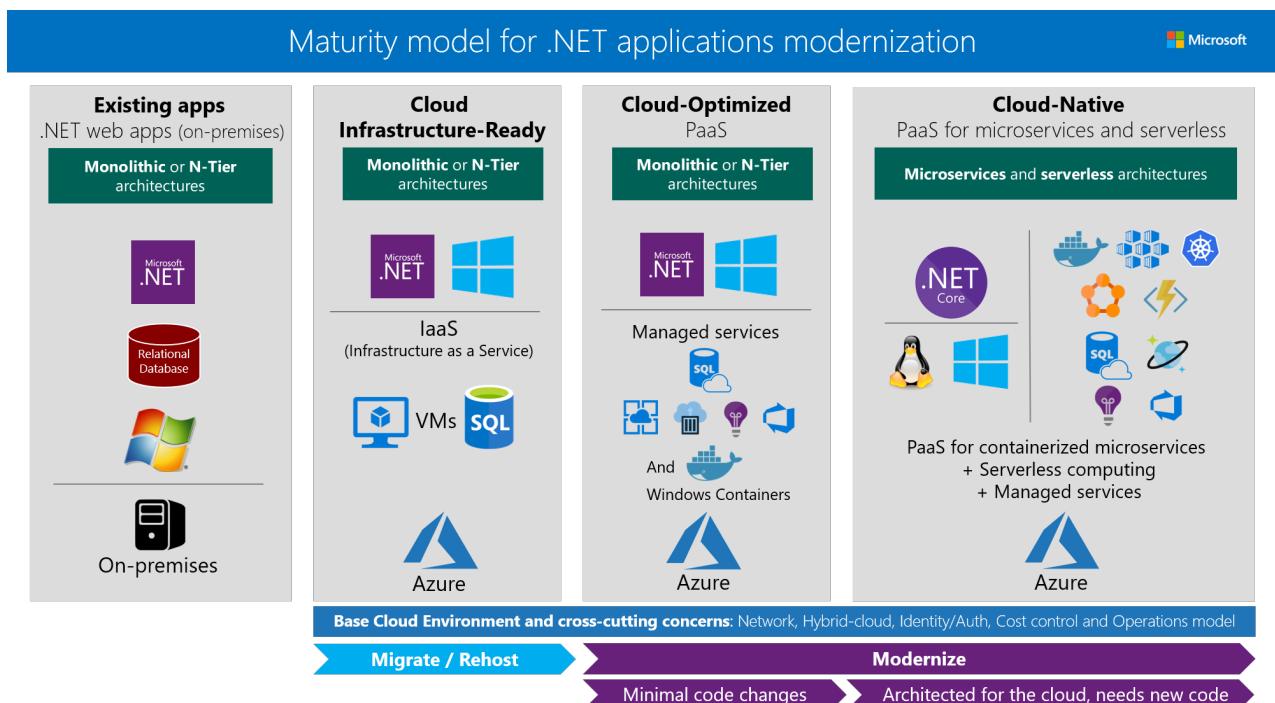

Figure 1-2. Primary technologies for each maturity level for modernizing existing .NET web applications

Figure 1-2 highlights the most common scenarios, but many hybrid and mixed variations are possible when it

comes to architecture. For example, the maturity models apply not only to monolithic architectures in existing web apps, but also to service orientation, N-Tier, and other architecture style variations. The higher focus or percentage on one or another architecture type and related technologies determines the overall maturity level of your applications.

Each maturity level in the modernization process is associated with the following key technologies and approaches:

- **Cloud Infrastructure-Ready** (rehost or basic lift & shift): As a first step, many organizations want only to quickly execute a cloud-migration strategy. In this case, applications are rehosted. Most rehosting can be automated by using [Azure Migrate](#), a service that provides the guidance, insights, and mechanisms needed to assist you in migrating to Azure based on cloud tools like [Azure Site Recovery](#) and [Azure Database Migration Service](#). You can also set up rehosting manually, so that you can learn infrastructure details about your assets when you move legacy apps to the cloud. For example, you can move your applications to VMs in Azure with little modification—probably with only minor configuration changes. The networking in this case is similar to an on-premises environment, especially if you create virtual networks in Azure.
- **Cloud-Optimized** (Managed Services and Windows Containers): This model is about making a few important deployment optimizations to gain some significant benefits from the cloud, without changing the core architecture of the application. The fundamental step here is to add [Windows Containers](#) support to your existing .NET Framework applications. This important step (containerization) doesn't require touching the code, so the overall lift and shift effort is light. You can use tools like [Image2Docker](#) or Visual Studio, with its tools for [Docker](#). Visual Studio automatically chooses smart defaults for ASP.NET applications and Windows Containers images. These tools offer both a rapid inner loop, and a fast path to get the containers to Azure. Your agility is improved when you deploy to multiple environments. Then, moving to production, you can deploy your Windows Containers to [Azure Web App for Containers](#), [Azure Container Instances (ACI), and Azure VMs with Windows Server 2016 and containers if you prefer an IaaS approach. For slightly more complex multi-container applications, into orchestrators like [Azure Service Fabric](#) or [Azure Kubernetes Service \(AKS/ACS\)](#). During this initial modernization, you can also add assets from the cloud, such as monitoring with tools like [Azure Application Insights](#); CI/CD pipelines for your app lifecycles with [Azure DevOps Services](#); and many more data resource services that are available in Azure. For instance, you can modify a monolithic web app that was originally developed by using traditional [ASP.NET Web Forms](#) or [ASP.NET MVC](#), but now you deploy it by using Windows Containers. When you use Windows Containers, you should also migrate your data to a database in [Azure SQL Database Managed Instance](#), all without changing the core architecture of your application.
- **Cloud-Native**: As introduced, you should think about architecting [cloud-native](#) applications when you are targeting large and complex applications with multiple independent development teams working on different microservices that can be developed and deployed autonomously. Also, due to granularized and independent scalability per microservice. These architectural approaches face very important challenges and complexities but can be greatly simplified by using cloud PaaS and orchestrators like [Azure Kubernetes Service \(AKS/ACS\)](#) (managed Kubernetes), [Azure Service Fabric, and [Azure Functions](#) for a serverless approach. All these approaches (like microservices and Serverless) typically require you to architect for the cloud and write new code—code that is adapted to specific PaaS platforms, or code that aligns with specific architectures, like microservices.

Figure 1-3 shows the internal technologies that you can use for each maturity level:

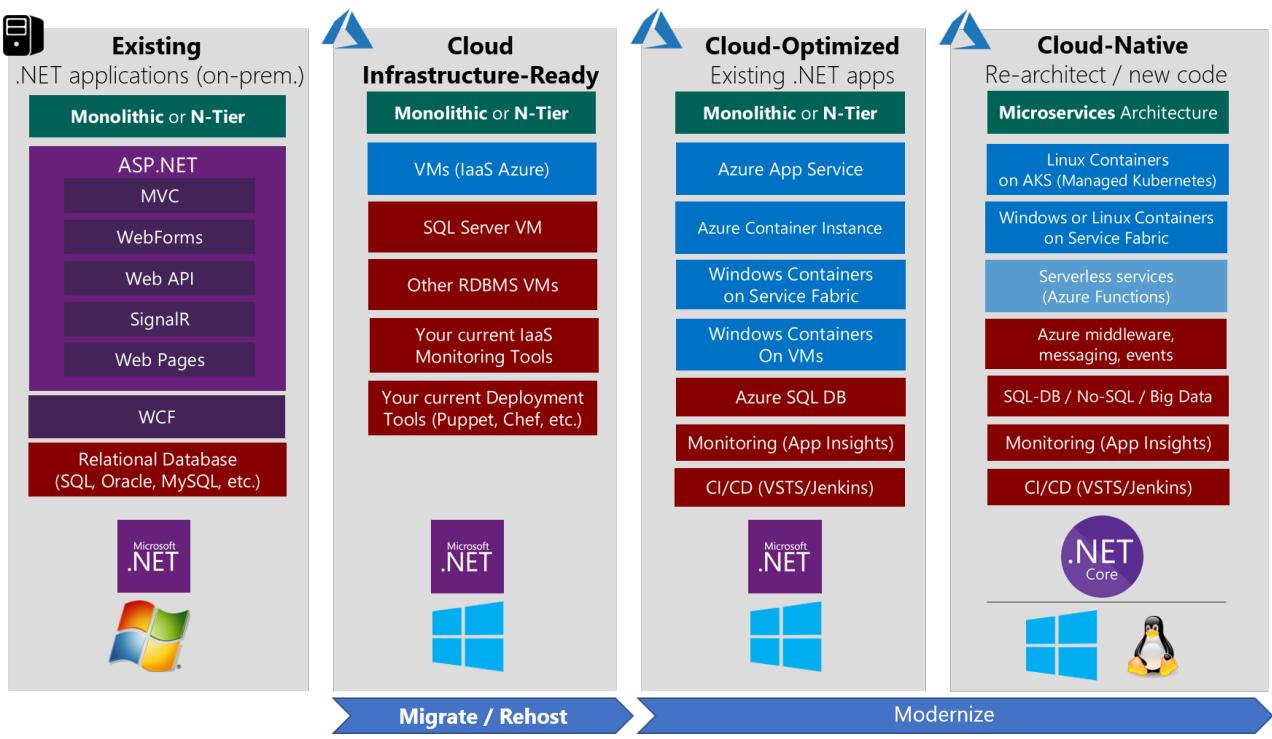

Figure 1-3. Internal technologies for each modernization maturity level

Lift and shift scenario

For lift and shift migrations, keep in mind that you can use many different variations of lift and shift in your application scenarios. If you only rehost your application, you might have a scenario like the one shown in Figure 1-4, where you use VMs in the cloud only for your application and for your database server.

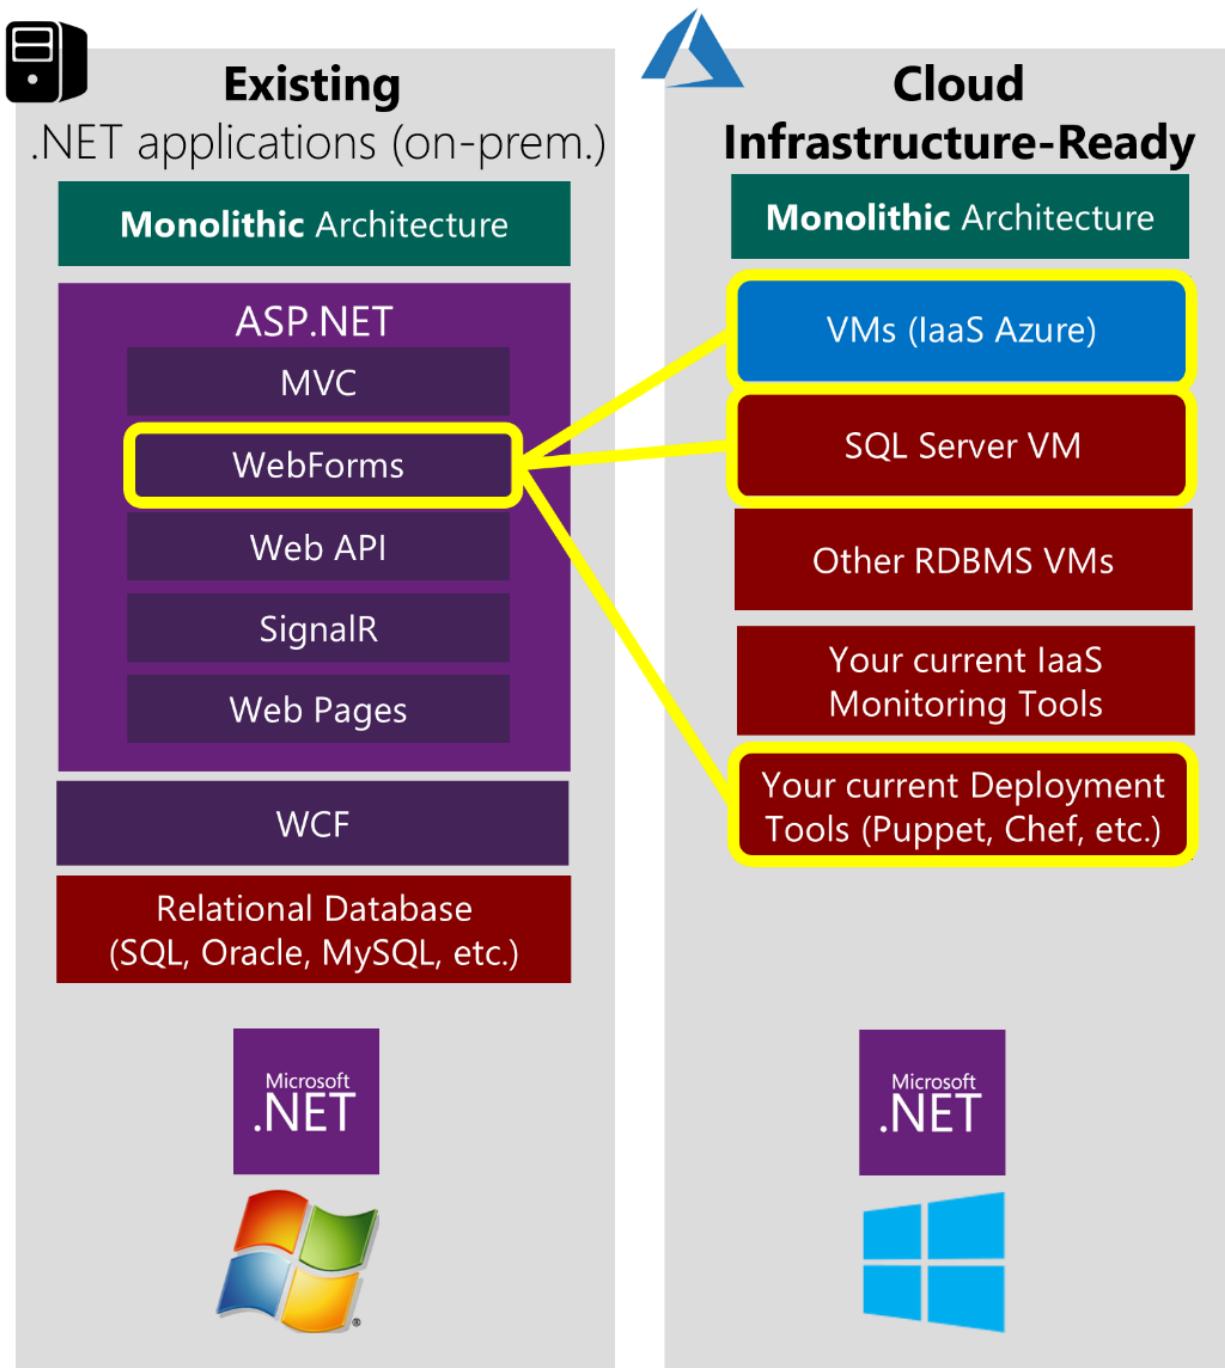

Figure 1-4. Example of a pure IaaS scenario in the cloud

Modernization scenarios

For modernization scenarios, you might have a pure Cloud-Optimized application that uses elements only from that maturity level. Or, you might have an intermediate-state application with some elements from Cloud Infrastructure-Ready and other elements from Cloud-Optimized (a "pick and choose" or mixed model), like in Figure 1-5.

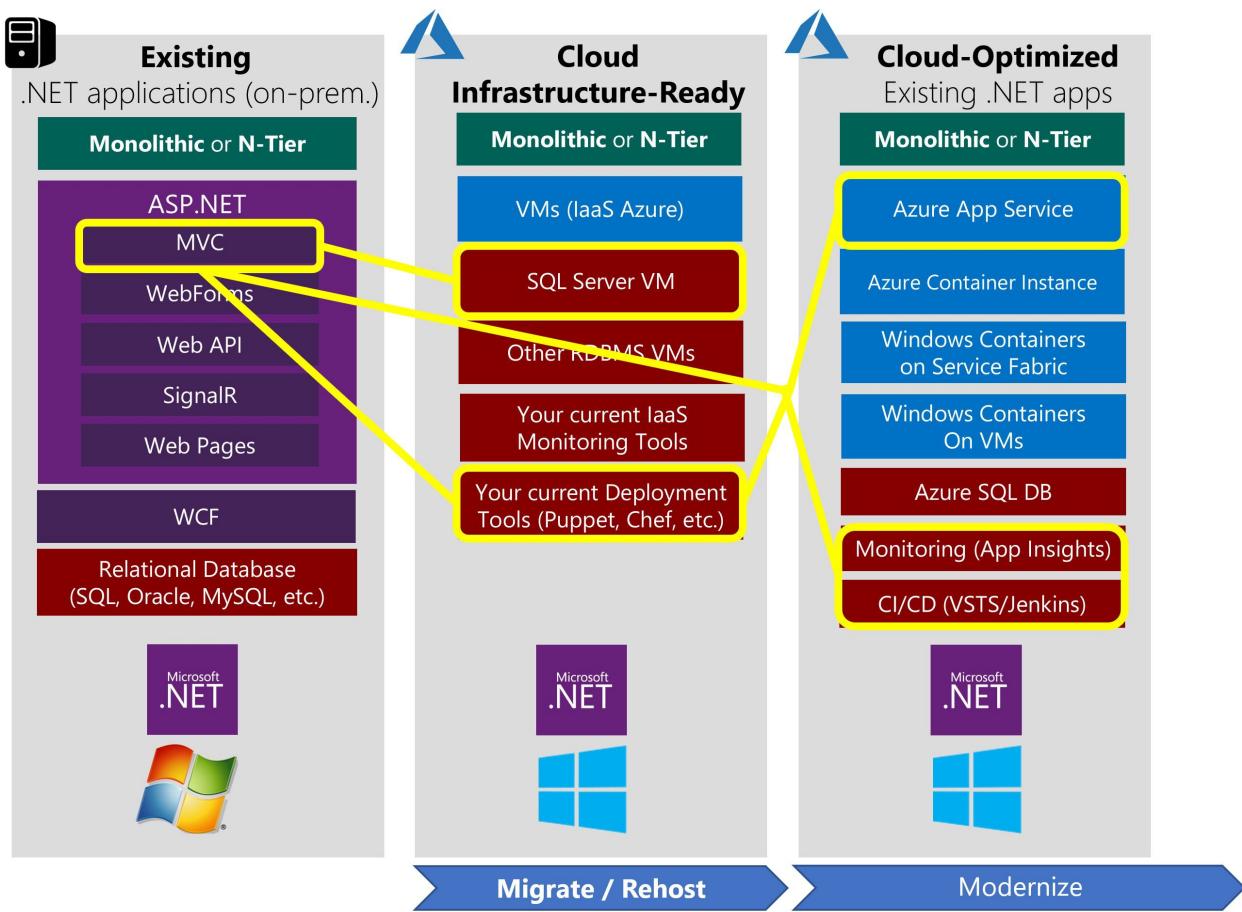

Figure 1-5. Example "pick and choose" scenario, with database on IaaS, DevOps, and containerization assets

Next, as the ideal scenario for many existing .NET Framework applications to migrate, you could migrate to a Cloud-Optimized application, to get significant benefits from little work. This approach also sets you up for Cloud-Native as a possible future evolution. Figure 1-6 shows an example.

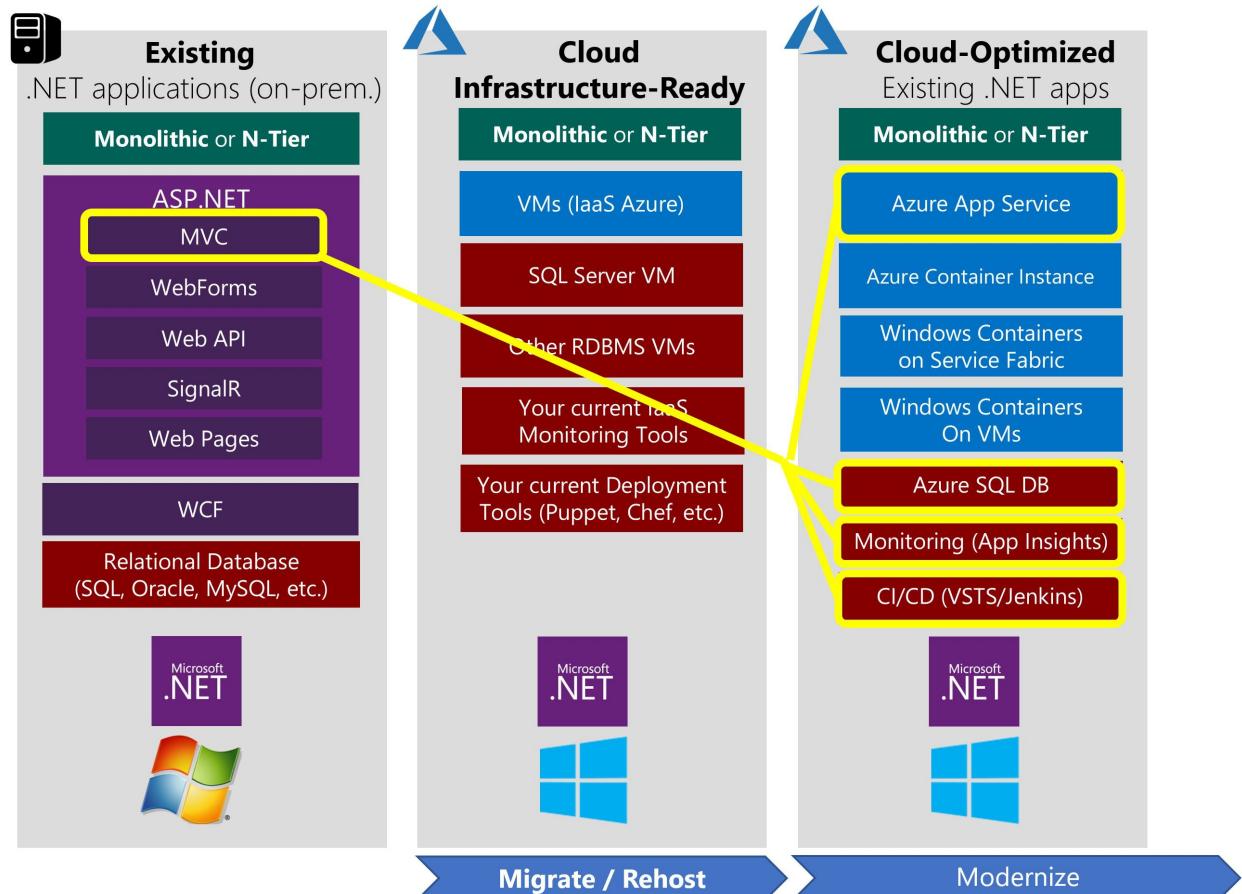

Figure 1-6. Example Cloud-Optimized apps scenario, with Windows Containers and managed services

Going even further, you could extend your existing Cloud-Optimized application by adding a few microservices for specific scenarios. This would move you partially to the level of Cloud-Native model, which is not the main focus of the present guidance.

What this guide does not cover

This guide covers a specific subset of the example scenarios, as shown in Figure 1-7. This guide focuses only on lift and shift scenarios, and ultimately, on the Cloud-Optimized model. In the Cloud-Optimized model, a .NET Framework application is modernized by using Windows Containers, plus additional components like monitoring and CI/CD pipelines. Each component is fundamental to deploying applications to the cloud, faster, and with agility.

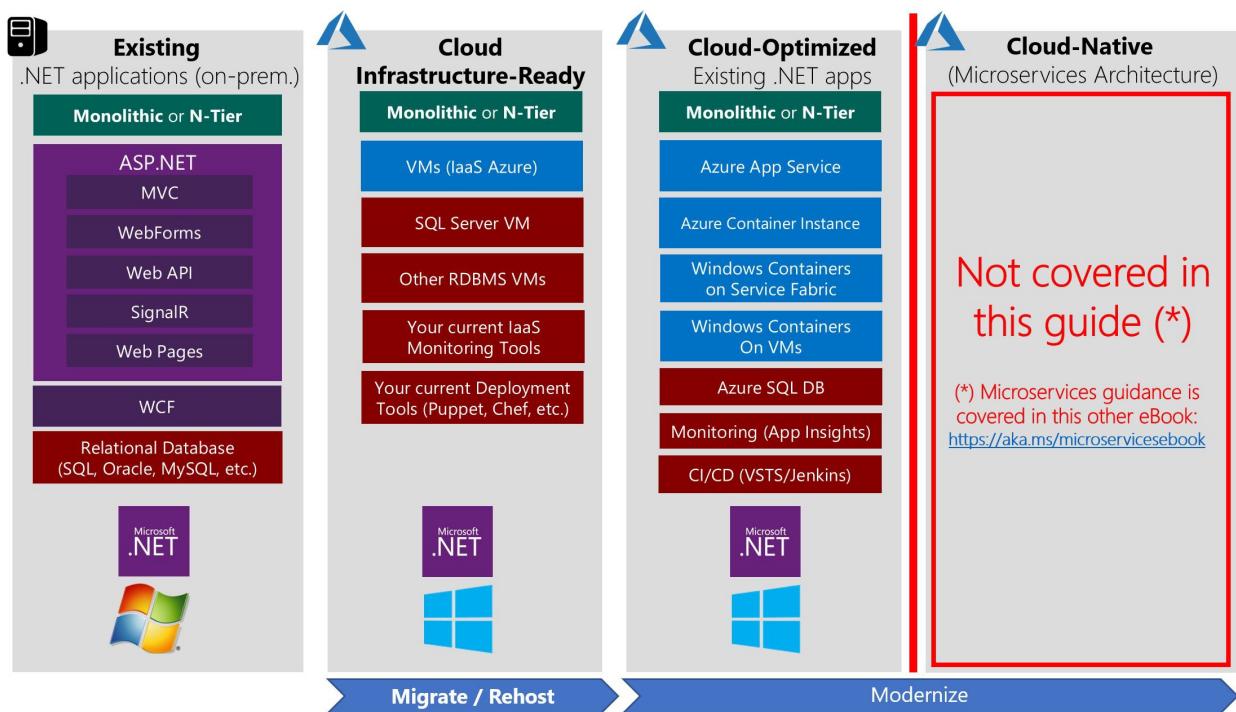

Figure 1-7. Cloud-Native is not covered in this guide

The focus of this guide is specific. It shows you the path you can take to achieve a lift and shift of your existing .NET applications, without rearchitecting, and with no code changes. Ultimately, it shows you how to make your application Cloud-Optimized.

This guide doesn't show you how to create Cloud-Native applications, such as how to evolve to a microservices architecture. To rearchitect your applications or to create brand-new applications that are based on microservices, see the e-book [.NET Microservices: Architecture for containerized .NET applications](https://aka.ms/microservicesebook).

Who should use this guide

This guide was written for developers and solution architects who want to modernize existing ASP.NET web applications or WCF services that are based on the .NET Framework, for improved agility in shipping and releasing applications.

You also might find this guide useful if you are a technical decision maker, such as an enterprise architect or a development lead/director who just wants an overview of the benefits that you can get by using Windows Containers, and by deploying to the cloud when using Microsoft Azure.

How to use this guide

This guide addresses the "why"-why you might want to modernize your existing applications, and the specific benefits you get from using Windows Containers when you move your apps to the cloud. The content in the first few chapters of the guide is designed for architects and technical decision makers who want an overview, but who don't need to focus on implementation and technical, step-by-step details.

The last chapter of this guide introduces multiple walkthroughs that focus on specific deployment scenarios. This guide offers shorter versions of the walkthroughs, to summarize the scenarios and highlight their benefits. The full walkthroughs drill down into setup and implementation details, and are published as a set of [wiki posts](#) in the same public [GitHub repo](#) where related sample apps reside (discussed in the next section). The last chapter and the step-by-step wiki walkthroughs on GitHub will be of more interest to developers and architects who want to focus on implementation details.

Sample apps for modernizing legacy apps: eShopModernizing

The [eShopModernizing](#) repo on GitHub offers two sample applications that simulate legacy monolithic web applications. One web app is developed by using ASP.NET MVC; the second web app is developed by using ASP.NET Web Forms and the third app is an N-Tier app with a WinForms client desktop app consuming a WCF service backend. All these apps are based on the traditional .NET Framework. These sample apps don't use .NET Core or ASP.NET Core as they are supposed to be existing/legacy .NET Framework applications to be modernized.

These sample apps have a second version, with modernized code, and which are fairly straightforward. The most important difference between the app versions is that the second versions use Windows Containers as the deployment choice. There also are a few additions to the second versions, like Azure Storage Blobs for managing images, Azure Active Directory for managing security, and Azure Application Insights for monitoring and auditing the applications.

Send your feedback

This guide was written to help you understand your options for improving and modernizing existing .NET web applications. The guide and related sample applications are evolving. Your feedback is welcome! If you have comments about how this guide might be more helpful, please send them to dotnet-architecture-ebooks-feedback@service.microsoft.com.

Introduction to containers and Docker

2/16/2019 • 2 minutes to read • [Edit Online](#)

Containerization is an approach to software development in which an application or service, its dependencies, and its configuration (abstracted as deployment manifest files) are packaged together as a container image. You then can test the containerized application as a unit and deploy it as a container image instance to the host operating system (OS).

Just as shipping containers allow goods to be transported by ship, train, or truck regardless of the cargo inside, software containers act as a standard unit of software deployment that can contain different code and dependencies. Containerizing software this way enables developers and IT professionals to deploy them across environments with little or no modification.

Containers also isolate applications from each other on a shared OS. Containerized applications run on top of a container host that in turn runs on the OS (Linux or Windows). Containers therefore have a much smaller footprint than virtual machine (VM) images.

Each container can run a whole web application or a service, as shown in Figure 1-1. In this example, Docker host is a container host, and App1, App2, Svc1, and Svc2 are containerized applications or services.

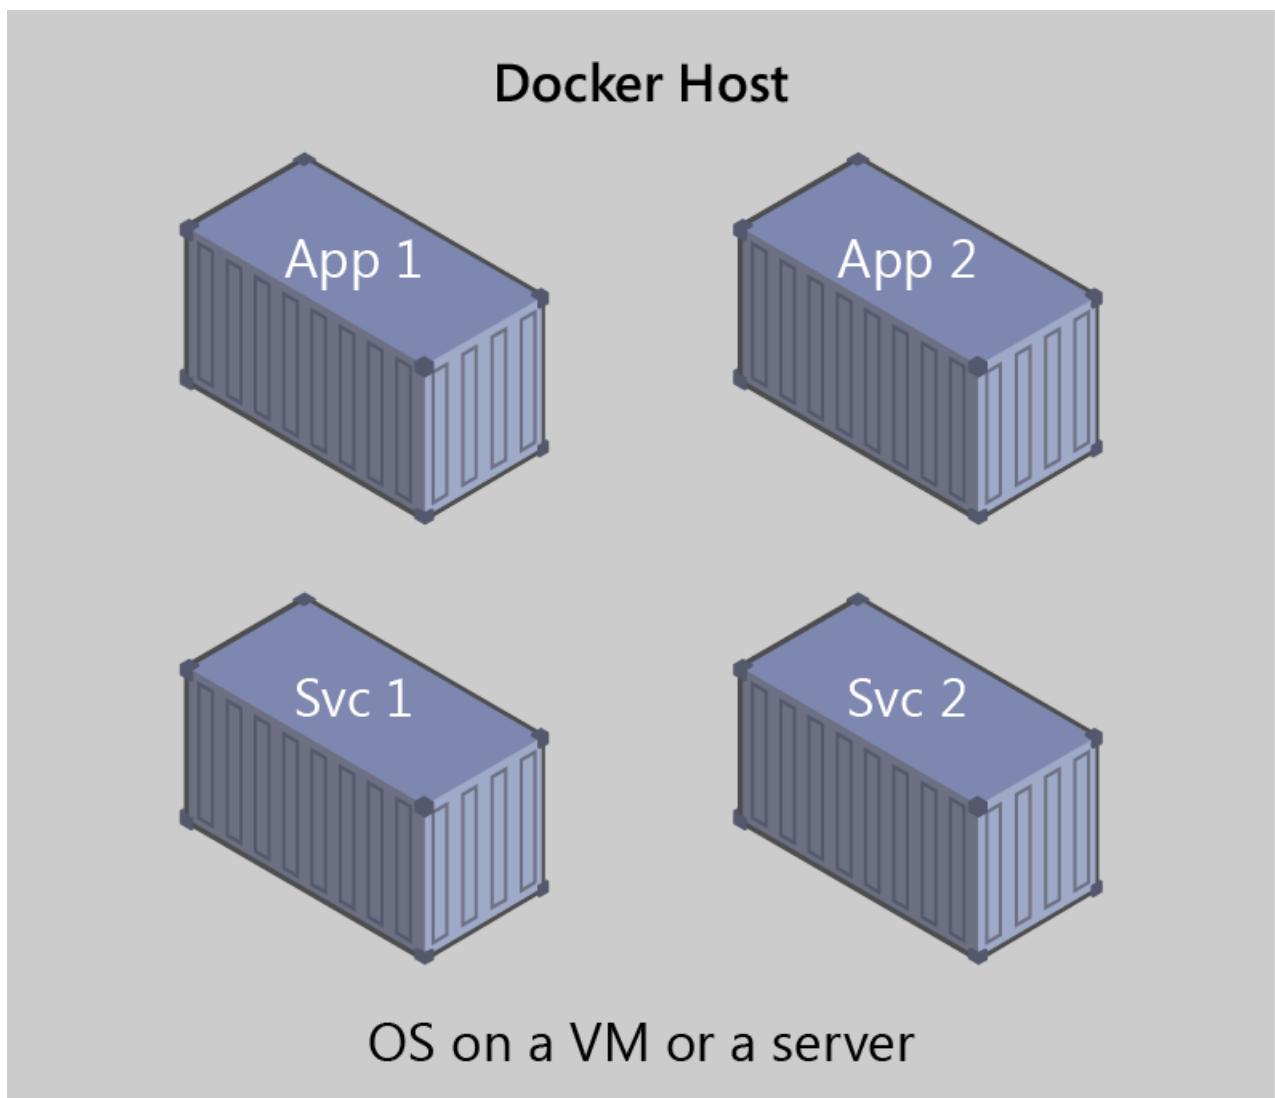

Figure 1-1. Multiple containers running on a container host

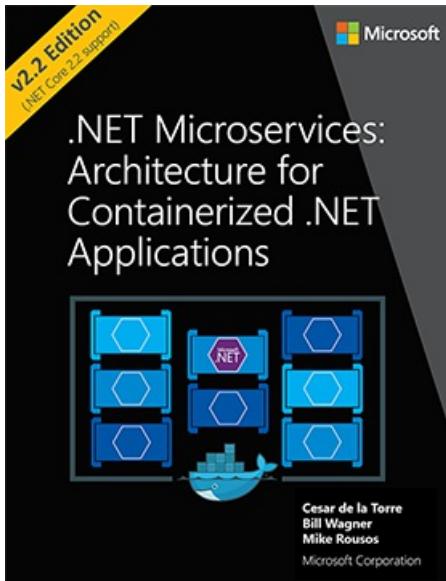

Another benefit you can derive from containerization is scalability. You can scale out quickly by creating new containers for short-term tasks. From an application point of view, instantiating an image (creating a container) is similar to instantiating a process like a service or web app. For reliability, however, when you run multiple instances of the same image across multiple host servers, you typically want each container (image instance) to run in a different host server or VM in different fault domains.

In short, containers offer the benefits of isolation, portability, agility, scalability, and control across the entire application lifecycle workflow. The most important benefit is the environment isolation provided between Dev and Ops.

.NET Microservices: Architecture for Containerized .NET Applications

3/26/2019 • 6 minutes to read • [Edit Online](#)

EDITION v2.2.00 - Updated to ASP.NET Core 2.2

This guide is an introduction to developing microservices-based applications and managing them using containers. It discusses architectural design and implementation approaches using .NET Core and Docker containers.

To make it easier to get started, the guide focuses on a reference containerized and microservice-based application that you can explore. The reference application is available at the [eShopOnContainers](#) GitHub repo.

Action links

- Download this eBook in your format of choice: | [PDF](#) | [MOBI](#) | [EPUB](#) |
- Clone/Fork the reference application [eShopOnContainers](#) on GitHub
- Watch the [introductory video on Channel 9](#)
- Get to know the [Microservices Architecture](#) right away

Introduction

Enterprises are increasingly realizing cost savings, solving deployment problems, and improving DevOps and production operations by using containers. Microsoft has been releasing container innovations for Windows and Linux by creating products like Azure Container Service and Azure Service Fabric, and by partnering with industry leaders like Docker, Mesosphere, and Kubernetes. These products deliver container solutions that help companies build and deploy applications at cloud speed and scale, whatever their choice of platform or tools.

Docker is becoming the de facto standard in the container industry, supported by the most significant vendors in the Windows and Linux ecosystems. (Microsoft is one of the main cloud vendors supporting Docker.) In the future, Docker will probably be ubiquitous in any datacenter in the cloud or on-premises.

In addition, the [microservices](#) architecture is emerging as an important approach for distributed mission-critical

applications. In a microservice-based architecture, the application is built on a collection of services that can be developed, tested, deployed, and versioned independently.

About this guide

This guide is an introduction to developing microservices-based applications and managing them using containers. It discusses architectural design and implementation approaches using .NET Core and Docker containers. To make it easier to get started with containers and microservices, the guide focuses on a reference containerized and microservice-based application that you can explore. The sample application is available at the [eShopOnContainers](#) GitHub repo.

This guide provides foundational development and architectural guidance primarily at a development environment level with a focus on two technologies: Docker and .NET Core. Our intention is that you read this guide when thinking about your application design without focusing on the infrastructure (cloud or on-premises) of your production environment. You will make decisions about your infrastructure later, when you create your production-ready applications. Therefore, this guide is intended to be infrastructure agnostic and more development-environment-centric.

After you have studied this guide, your next step would be to learn about production-ready microservices on Microsoft Azure.

Version

This guide has been revised to cover **.NET Core 2.2** version plus many additional updates related to the same "wave" of technologies (that is, Azure and additional 3rd party technologies) coinciding in time with .NET Core 2.2. That's why the book version has also been updated to version **2.2**.

What this guide does not cover

This guide does not focus on the application lifecycle, DevOps, CI/CD pipelines, or team work. The complementary guide [Containerized Docker Application Lifecycle with Microsoft Platform and Tools](#) focuses on that subject. The current guide also does not provide implementation details on Azure infrastructure, such as information on specific orchestrators.

Additional resources

- **Containerized Docker Application Lifecycle with Microsoft Platform and Tools** (downloadable e-book)
<https://aka.ms/dockerlifecyclebook>

Who should use this guide

We wrote this guide for developers and solution architects who are new to Docker-based application development and to microservices-based architecture. This guide is for you if you want to learn how to architect, design, and implement proof-of-concept applications with Microsoft development technologies (with special focus on .NET Core) and with Docker containers.

You will also find this guide useful if you are a technical decision maker, such as an enterprise architect, who wants an architecture and technology overview before you decide on what approach to select for new and modern distributed applications.

How to use this guide

The first part of this guide introduces Docker containers, discusses how to choose between .NET Core and the .NET Framework as a development framework, and provides an overview of microservices. This content is for architects and technical decision makers who want an overview but don't need to focus on code implementation details.

The second part of the guide starts with the [Development process for Docker based applications](#) section. It focuses on development and microservice patterns for implementing applications using .NET Core and Docker. This section will be of most interest to developers and architects who want to focus on code and on patterns and implementation details.

Related microservice and container-based reference application: eShopOnContainers

The eShopOnContainers application is an open-source reference app for .NET Core and microservices that is designed to be deployed using Docker containers. The application consists of multiple subsystems, including several e-store UI front ends (a Web MVC app, a Web SPA, and a native mobile app). It also includes the back-end microservices and containers for all required server-side operations.

The purpose of the application is to showcase architectural patterns. **IT IS NOT A PRODUCTION-READY TEMPLATE** to start real-world applications. In fact, the application is in a permanent beta state, as it's also used to test new potentially interesting technologies as they show up.

Send us your feedback!

We wrote this guide to help you understand the architecture of containerized applications and microservices in .NET. The guide and related reference application will be evolving, so we welcome your feedback! If you have comments about how this guide can be improved, please send them to:

Introduction

Serverless is the evolution of cloud platforms in the direction of pure cloud native code. Serverless brings developers closer to business logic while insulating them from infrastructure concerns. It's a pattern that doesn't imply "no server" but rather, "less server." Serverless code is event-driven. Code may be triggered by anything from a traditional HTTP web request to a timer or the result of uploading a file. The infrastructure behind serverless allows for instant scale to meet elastic demands and offers micro-billing to truly "pay for what you use." Serverless requires a new way of thinking and approach to building applications and isn't the right solution for every problem. As a developer, you must decide:

- What are the pros and cons of serverless?

- Why should you consider serverless for your own applications?
- How can you build, test, deploy, and maintain your serverless code?
- Where does it make sense to migrate code to serverless in existing applications, and what is the best way to accomplish this transformation?

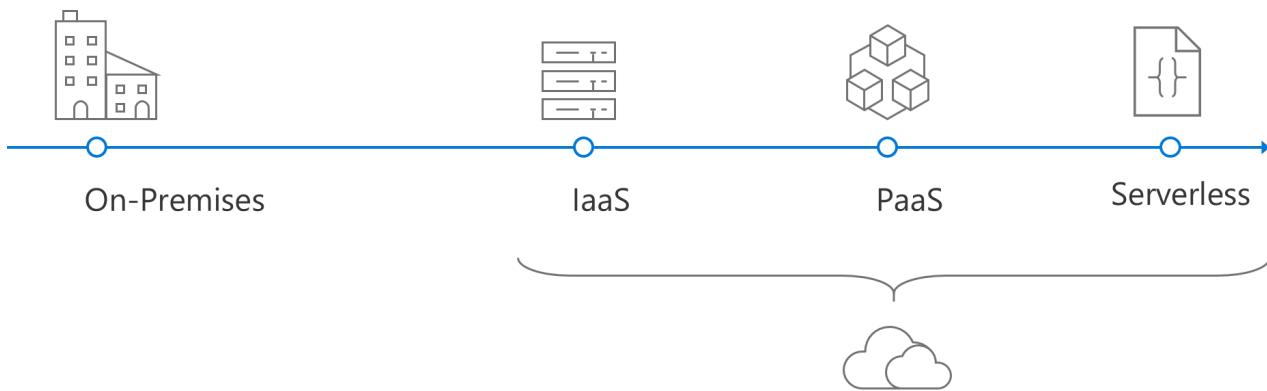

About this guide

This guide focuses on cloud native development of applications that use serverless. The book highlights the benefits and exposes the potential drawbacks of developing serverless apps and provides a survey of serverless architectures. Many examples of how serverless can be used are illustrated along with various serverless design patterns.

This guide explains the components of the Azure serverless platform and focuses specifically on implementation of serverless using [Azure Functions](#). You'll learn about triggers and bindings as well as how to implement serverless apps that rely on state using durable functions. Finally, business examples and case studies will help provide context and a frame of reference to determine whether serverless is the right approach for your projects.

Evolution of cloud platforms

Serverless is the culmination of several iterations of cloud platforms. The evolution began with physical metal in the data center and progressed through Infrastructure as a Service (IaaS) and Platform as a Service (PaaS).

Before the cloud, a discernible boundary existed between development and operations. Deploying an application meant answering myriad questions like:

- What hardware should be installed?
- How is physical access to the machine secured?
- Does the data center require an Uninterruptible Power Supply (UPS)?
- Where are storage backups sent?
- Should there be redundant power?

The list goes on and the overhead was enormous. In many situations, IT departments were forced to deal with incredible waste. The waste was due to over-allocation of servers as backup machines for disaster recovery and standby servers to enable scale-out. Fortunately, the introduction of virtualization technology (like [Hyper-V](#)) with Virtual Machines (VMs) gave rise to Infrastructure as a Service (IaaS). Virtualized infrastructure allowed operations to set up a standard set of servers as the backbone, leading to a flexible environment capable of provisioning unique servers "on demand." More important, virtualization set the stage for using the cloud to provide virtual machines "as a service." Companies could easily get out of the business of worrying about redundant power or physical machines. Instead, they focused on the virtual environment.

IaaS still requires heavy overhead because operations is still responsible for various tasks. These tasks include:

- Patching and backing up servers.

- Installing packages.
- Keeping the operating system up-to-date.
- Monitoring the application.

The next evolution reduced the overhead by providing Platform as a Service (PaaS). With PaaS, the cloud provider handles operating systems, security patches, and even the required packages to support a specific platform. Instead of building a VM then configuring the .NET Framework and standing up Internet Information Services (IIS) servers, developers simply choose a "platform target" such as "web application" or "API endpoint" and deploy code directly. The infrastructure questions are reduced to:

- What size services are needed?
- How do the services scale out (add more servers or nodes)?
- How do the services scale up (increase the capacity of hosting servers or nodes)?

Serverless further abstracts servers by focusing on event-driven code. Instead of a platform, developers can focus on a microservice that does one thing. The two key questions for building the serverless code are:

- What triggers the code?
- What does the code do?

With serverless, infrastructure is abstracted. In some cases, the developer no longer worries about the host at all. Whether or not an instance of IIS, Kestrel, Apache, or some other web server is running to manage web requests, the developer focuses on an HTTP trigger. The trigger provides the standard, cross-platform payload for the request. The payload not only simplifies the development process, but facilitates testing and in some cases, makes the code easily portable across platforms.

Another feature of serverless is micro-billing. It's common for web applications to host Web API endpoints. In traditional bare metal, IaaS and even PaaS implementations, the resources to host the APIs are paid for continuously. That means you pay to host the endpoints even when they aren't being accessed. Often you'll find one API is called more than others, so the entire system is scaled based on supporting the popular endpoints. Serverless enables you to scale each endpoint independently and pay for usage, so no costs are incurred when the APIs aren't being called. Migration may in many circumstances dramatically reduce the ongoing cost to support the endpoints.

What this guide doesn't cover

This guide specifically emphasizes architecture approaches and design patterns and isn't a deep dive into the implementation details of Azure Functions, [Logic Apps](#), or other serverless platforms. This guide doesn't cover, for example, advanced workflows with Logic Apps or features of Azure Functions such as configuring Cross-Origin Resource Sharing (CORS), applying custom domains, or uploading SSL certificates. These details are available through the online [Azure Functions documentation](#).

Additional resources

- [Azure Architecture center](#)
- [Best practices for cloud applications](#)

Who should use the guide

This guide was written for developers and solution architects who want to build enterprise applications with .NET that may use serverless components either on premises or in the cloud. It's useful to developers, architects, and technical decision makers interested in:

- Understanding the pros and cons of serverless development
- Learning how to approach serverless architecture

- Example implementations of serverless apps

How to use the guide

The first part of this guide examines why serverless is a viable option by comparing several different architecture approaches. It examines both the technology and development lifecycle, because all aspects of software development are impacted by architecture decisions. The guide then examines use cases and design patterns and includes reference implementations using Azure Functions. Each section contains additional resources to learn more about a particular area. The guide concludes with resources for walkthroughs and hands-on exploration of serverless implementation.

Send your feedback

The guide and related samples are constantly evolving, so your feedback is welcomed! If you have comments about how this guide can be improved, use the feedback section at the bottom of any page built on [GitHub issues](#).

Open-source library guidance

11/28/2018 • 2 minutes to read • [Edit Online](#)

This guidance provides recommendations for developers to create high-quality .NET libraries. This documentation focuses on the *what* and the *why* when building a .NET library, not the *how*.

Aspects of high-quality open-source .NET libraries:

- **Inclusive** - Good .NET libraries strive to support many platforms, programming languages, and applications.
- **Stable** - Good .NET libraries coexist in the .NET ecosystem, running in applications built with many libraries.
- **Designed to evolve** - .NET libraries should improve and evolve over time, while supporting existing users.
- **Debuggable** - .NET libraries should use the latest tools to create a great debugging experience for users.
- **Trusted** - .NET libraries have developers' trust by publishing to NuGet using security best practices.

[Get Started](#)

Types of recommendations

Each article presents four types of recommendations: **Do**, **Consider**, **Avoid**, and **Do not**. The type of recommendation indicates how strongly it should be followed.

You should almost always follow a **Do** recommendation. For example:

DO distribute your library using a NuGet package.

On the other hand, **Consider** recommendations should generally be followed, but there are legitimate exceptions to the rule and you shouldn't feel bad about not following the guidance:

CONSIDER using [SemVer 2.0.0](#) to version your NuGet package.

Avoid recommendations mention things that are generally not a good idea, but breaking the rule sometimes makes sense:

AVOID NuGet package references that demand an exact version.

And finally, **Do not** recommendations indicate something you should almost never do:

DO NOT publish strong-named and non-strong-named versions of your library. For example, `Contoso.Api` and `Contoso.Api.StrongNamed`.

[NEXT](#)

Choosing between .NET Core and .NET Framework for server apps

3/8/2019 • 6 minutes to read • [Edit Online](#)

There are two supported implementations for building server-side applications with .NET: .NET Framework and .NET Core. Both share many of the same components and you can share code across the two. However, there are fundamental differences between the two and your choice depends on what you want to accomplish. This article provides guidance on when to use each.

Use .NET Core for your server application when:

- You have cross-platform needs.
- You are targeting microservices.
- You are using Docker containers.
- You need high-performance and scalable systems.
- You need side-by-side .NET versions per application.

Use .NET Framework for your server application when:

- Your app currently uses .NET Framework (recommendation is to extend instead of migrating).
- Your app uses third-party .NET libraries or NuGet packages not available for .NET Core.
- Your app uses .NET technologies that aren't available for .NET Core.
- Your app uses a platform that doesn't support .NET Core.

When to choose .NET Core

The following sections give a more detailed explanation of the previously stated reasons for picking .NET Core.

Cross-platform needs

If your application (web/service) needs to run on multiple platforms (Windows, Linux, and macOS), use .NET Core.

.NET Core supports the previously mentioned operating systems as your development workstation. Visual Studio provides an Integrated Development Environment (IDE) for Windows and macOS. You can also use Visual Studio Code, which runs on macOS, Linux, and Windows. Visual Studio Code supports .NET Core, including IntelliSense and debugging. Most third-party editors, such as Sublime, Emacs, and VI, work with .NET Core. These third-party editors get editor IntelliSense using [Omnisharp](#). You can also avoid any code editor and directly use the [.NET Core CLI tools](#), available for all supported platforms.

Microservices architecture

A microservices architecture allows a mix of technologies across a service boundary. This technology mix enables a gradual embrace of .NET Core for new microservices that work with other microservices or services. For example, you can mix microservices or services developed with .NET Framework, Java, Ruby, or other monolithic technologies.

There are many infrastructure platforms available. [Azure Service Fabric](#) is designed for large and complex microservice systems. [Azure App Service](#) is a good choice for stateless microservices. Microservices alternatives based on Docker fit any kind of microservices approach, as explained in the [Containers](#) section. All these platforms support .NET Core and make them ideal for hosting your microservices.

For more information about microservices architecture, see [.NET Microservices. Architecture for Containerized](#)

.NET Applications.

Containers

Containers are commonly used in conjunction with a microservices architecture. Containers can also be used to containerize web apps or services that follow any architectural pattern. .NET Framework can be used on Windows containers, but the modularity and lightweight nature of .NET Core makes it a better choice for containers. When creating and deploying a container, the size of its image is much smaller with .NET Core than with .NET Framework. Because it's cross-platform, you can deploy server apps to Linux Docker containers, for example.

Docker containers can be hosted in your own Linux or Windows infrastructure, or in a cloud service such as [Azure Kubernetes Service](#). Azure Kubernetes Service can manage, orchestrate, and scale container-based applications in the cloud.

A need for high-performance and scalable systems

When your system needs the best possible performance and scalability, .NET Core and ASP.NET Core are your best options. High-performance server runtime for Windows Server and Linux makes .NET a top performing web framework on [TechEmpower benchmarks](#).

Performance and scalability are especially relevant for microservices architectures, where hundreds of microservices may be running. With ASP.NET Core, systems run with a much lower number of servers/Virtual Machines (VM). The reduced servers/VMs save costs in infrastructure and hosting.

A need for side by side of .NET versions per application level

To install applications with dependencies on different versions of .NET, we recommend .NET Core. .NET Core offers side-by-side installation of different versions of the .NET Core runtime on the same machine. This side-by-side installation allows multiple services on the same server, each of them on its own version of .NET Core. It also lowers risks and saves money in application upgrades and IT operations.

When to choose .NET Framework

.NET Core offers significant benefits for new applications and application patterns. However, the .NET Framework continues to be the natural choice for many existing scenarios and as such the .NET Framework isn't replaced by .NET Core for all server applications.

Current .NET Framework applications

In most cases, you don't need to migrate your existing applications to .NET Core. Instead, a recommended approach is to use .NET Core as you extend an existing application, such as writing a new web service in ASP.NET Core.

A need to use third-party .NET libraries or NuGet packages not available for .NET Core

Libraries are quickly embracing .NET Standard. .NET Standard enables sharing code across all .NET implementations including .NET Core. With .NET Standard 2.0, this is even easier:

- The API surface became much larger.
- Introduced a .NET Framework compatibility mode. This compatibility mode allows .NET Standard/.NET Core projects to reference .NET Framework libraries. To learn more about the compatibility mode, see [Announcing .NET Standard 2.0](#).

So only in cases where the libraries or NuGet packages use technologies that aren't available in .NET Standard/.NET Core, you need to use the .NET Framework.

A need to use .NET technologies not available for .NET Core

Some .NET Framework technologies aren't available in .NET Core. Some of them might be available in later .NET Core releases. Others don't apply to the new application patterns targeted by .NET Core and may never be available. The following list shows the most common technologies not found in .NET Core:

- ASP.NET Web Forms applications: ASP.NET Web Forms are only available in the .NET Framework. ASP.NET Core cannot be used for ASP.NET Web Forms. There are no plans to bring ASP.NET Web Forms to .NET Core.
- ASP.NET Web Pages applications: ASP.NET Web Pages aren't included in ASP.NET Core.
- WCF services implementation. Even when there's a [WCF-Client library](#) to consume WCF services from .NET Core, WCF server implementation is currently only available in the .NET Framework. This scenario is not part of the current plan for .NET Core but it's being considered for the future.
- Workflow-related services: Windows Workflow Foundation (WF), Workflow Services (WCF + WF in a single service) and WCF Data Services (formerly known as "ADO.NET Data Services") are only available in the .NET Framework. There are no plans to bring WF/WCF+WF/WCF Data Services to .NET Core.
- Language support: Visual Basic and F# are currently supported in .NET Core, but not for all project types. For a list of supported project templates, see [Template options for dotnet new](#).

In addition to the official roadmap, there are other frameworks to be ported to .NET Core. For a full list, see the CoreFX issues marked as [port-to-core](#). This list doesn't represent a commitment from Microsoft to bring those components to .NET Core. They're simply capturing the desire from the community to do so. If you care about any of the components marked as `port-to-core`, participate in the discussions on GitHub. And if you think something is missing, file a new issue in the [CoreFX repository](#).

A need to use a platform that doesn't support .NET Core

Some Microsoft or third-party platforms don't support .NET Core. Some Azure services provide an SDK not yet available for consumption on .NET Core. This is a transitional circumstance, as all of Azure services use .NET Core. In the meantime, you can always use the equivalent REST API instead of the client SDK.

What is "managed code"?

3/8/2019 • 2 minutes to read • [Edit Online](#)

When working with .NET Framework, you will often encounter the term "managed code". This document will explain what this term means and additional information around it.

To put it very simply, managed code is just that: code whose execution is managed by a runtime. In this case, the runtime in question is called the **Common Language Runtime** or CLR, regardless of the implementation ([Mono](#) or .NET Framework or .NET Core). CLR is in charge of taking the managed code, compiling it into machine code and then executing it. On top of that, runtime provides several important services such as automatic memory management, security boundaries, type safety etc.

Contrast this to the way you would run a C/C++ program, also called "unmanaged code". In the unmanaged world, the programmer is in charge of pretty much everything. The actual program is, essentially, a binary that the operating system (OS) loads into memory and starts. Everything else, from memory management to security considerations are a burden of the programmer.

Managed code is written in one of the high-level languages that can be run on top of .NET, such as C#, Visual Basic, F# and others. When you compile code written in those languages with their respective compiler, you don't get machine code. You get **Intermediate Language** code which the runtime then compiles and executes. C++ is the one exception to this rule, as it can also produce native, unmanaged binaries that run on Windows.

Intermediate Language & execution

What is "Intermediate Language" (or IL for short)? It is a product of compilation of code written in high-level .NET languages. Once you compile your code written in one of these languages, you will get a binary that is made out of IL. It is important to note that the IL is independent from any specific language that runs on top of the runtime; there is even a separate specification for it that you can read if you're so inclined.

Once you produce IL from your high-level code, you will most likely want to run it. This is where the CLR takes over and starts the process of **Just-In-Time** compiling, or **JIT-ing** your code from IL to machine code that can actually be run on a CPU. In this way, the CLR knows exactly what your code is doing and can effectively *manage* it.

Intermediate Language is sometimes also called Common Intermediate Language (CIL) or Microsoft Intermediate Language (MSIL).

Unmanaged code interoperability

Of course, the CLR allows passing the boundaries between managed and unmanaged world, and there is a lot of code that does that, even in the [Base Class Libraries](#). This is called **interoperability** or just **interop** for short. These provisions would allow you to, for example, wrap up an unmanaged library and call into it. However, it is important to note that once you do this, when the code passes the boundaries of the runtime, the actual management of the execution is again in the hand of unmanaged code, and thus falls under the same restrictions.

Similar to this, C# is one language that allows you to use unmanaged constructs such as pointers directly in code by utilizing what is known as **unsafe context** which designates a piece of code for which the execution is not managed by the CLR.

- [Overview of the .NET Framework](#)

- [Unsafe Code and Pointers](#)
- [Native interoperability](#)

Automatic Memory Management

1/23/2019 • 7 minutes to read • [Edit Online](#)

Automatic memory management is one of the services that the Common Language Runtime provides during [Managed Execution](#). The Common Language Runtime's garbage collector manages the allocation and release of memory for an application. For developers, this means that you do not have to write code to perform memory management tasks when you develop managed applications. Automatic memory management can eliminate common problems, such as forgetting to free an object and causing a memory leak, or attempting to access memory for an object that has already been freed. This section describes how the garbage collector allocates and releases memory.

Allocating Memory

When you initialize a new process, the runtime reserves a contiguous region of address space for the process. This reserved address space is called the managed heap. The managed heap maintains a pointer to the address where the next object in the heap will be allocated. Initially, this pointer is set to the managed heap's base address. All [reference types](#) are allocated on the managed heap. When an application creates the first reference type, memory is allocated for the type at the base address of the managed heap. When the application creates the next object, the garbage collector allocates memory for it in the address space immediately following the first object. As long as address space is available, the garbage collector continues to allocate space for new objects in this manner.

Allocating memory from the managed heap is faster than unmanaged memory allocation. Because the runtime allocates memory for an object by adding a value to a pointer, it is almost as fast as allocating memory from the stack. In addition, because new objects that are allocated consecutively are stored contiguously in the managed heap, an application can access the objects very quickly.

Releasing Memory

The garbage collector's optimizing engine determines the best time to perform a collection based on the allocations being made. When the garbage collector performs a collection, it releases the memory for objects that are no longer being used by the application. It determines which objects are no longer being used by examining the application's roots. Every application has a set of roots. Each root either refers to an object on the managed heap or is set to null. An application's roots include static fields, local variables and parameters on a thread's stack, and CPU registers. The garbage collector has access to the list of active roots that the [just-in-time \(JIT\) compiler](#) and the runtime maintain. Using this list, it examines an application's roots, and in the process creates a graph that contains all the objects that are reachable from the roots.

Objects that are not in the graph are unreachable from the application's roots. The garbage collector considers unreachable objects garbage and will release the memory allocated for them. During a collection, the garbage collector examines the managed heap, looking for the blocks of address space occupied by unreachable objects. As it discovers each unreachable object, it uses a memory-copying function to compact the reachable objects in memory, freeing up the blocks of address spaces allocated to unreachable objects. Once the memory for the reachable objects has been compacted, the garbage collector makes the necessary pointer corrections so that the application's roots point to the objects in their new locations. It also positions the managed heap's pointer after the last reachable object. Note that memory is compacted only if a collection discovers a significant number of unreachable objects. If all the objects in the managed heap survive a collection, then there is no need for memory compaction.

To improve performance, the runtime allocates memory for large objects in a separate heap. The garbage collector automatically releases the memory for large objects. However, to avoid moving large objects in memory, this

memory is not compacted.

Generations and Performance

To optimize the performance of the garbage collector, the managed heap is divided into three generations: 0, 1, and 2. The runtime's garbage collection algorithm is based on several generalizations that the computer software industry has discovered to be true by experimenting with garbage collection schemes. First, it is faster to compact the memory for a portion of the managed heap than for the entire managed heap. Secondly, newer objects will have shorter lifetimes and older objects will have longer lifetimes. Lastly, newer objects tend to be related to each other and accessed by the application around the same time.

The runtime's garbage collector stores new objects in generation 0. Objects created early in the application's lifetime that survive collections are promoted and stored in generations 1 and 2. The process of object promotion is described later in this topic. Because it is faster to compact a portion of the managed heap than the entire heap, this scheme allows the garbage collector to release the memory in a specific generation rather than release the memory for the entire managed heap each time it performs a collection.

In reality, the garbage collector performs a collection when generation 0 is full. If an application attempts to create a new object when generation 0 is full, the garbage collector discovers that there is no address space remaining in generation 0 to allocate for the object. The garbage collector performs a collection in an attempt to free address space in generation 0 for the object. The garbage collector starts by examining the objects in generation 0 rather than all objects in the managed heap. This is the most efficient approach, because new objects tend to have short lifetimes, and it is expected that many of the objects in generation 0 will no longer be in use by the application when a collection is performed. In addition, a collection of generation 0 alone often reclaims enough memory to allow the application to continue creating new objects.

After the garbage collector performs a collection of generation 0, it compacts the memory for the reachable objects as explained in [Releasing Memory](#) earlier in this topic. The garbage collector then promotes these objects and considers this portion of the managed heap generation 1. Because objects that survive collections tend to have longer lifetimes, it makes sense to promote them to a higher generation. As a result, the garbage collector does not have to reexamine the objects in generations 1 and 2 each time it performs a collection of generation 0.

After the garbage collector performs its first collection of generation 0 and promotes the reachable objects to generation 1, it considers the remainder of the managed heap generation 0. It continues to allocate memory for new objects in generation 0 until generation 0 is full and it is necessary to perform another collection. At this point, the garbage collector's optimizing engine determines whether it is necessary to examine the objects in older generations. For example, if a collection of generation 0 does not reclaim enough memory for the application to successfully complete its attempt to create a new object, the garbage collector can perform a collection of generation 1, then generation 2. If this does not reclaim enough memory, the garbage collector can perform a collection of generations 2, 1, and 0. After each collection, the garbage collector compacts the reachable objects in generation 0 and promotes them to generation 1. Objects in generation 1 that survive collections are promoted to generation 2. Because the garbage collector supports only three generations, objects in generation 2 that survive a collection remain in generation 2 until they are determined to be unreachable in a future collection.

Releasing Memory for Unmanaged Resources

For the majority of the objects that your application creates, you can rely on the garbage collector to automatically perform the necessary memory management tasks. However, unmanaged resources require explicit cleanup. The most common type of unmanaged resource is an object that wraps an operating system resource, such as a file handle, window handle, or network connection. Although the garbage collector is able to track the lifetime of a managed object that encapsulates an unmanaged resource, it does not have specific knowledge about how to clean up the resource. When you create an object that encapsulates an unmanaged resource, it is recommended that you provide the necessary code to clean up the unmanaged resource in a public **Dispose** method. By providing a **Dispose** method, you enable users of your object to explicitly free its memory when they are finished with the

object. When you use an object that encapsulates an unmanaged resource, you should be aware of **Dispose** and call it as necessary. For more information about cleaning up unmanaged resources and an example of a design pattern for implementing **Dispose**, see [Garbage Collection](#).

Common Language Runtime (CLR) overview

2/8/2019 • 4 minutes to read • [Edit Online](#)

The .NET Framework provides a run-time environment called the common language runtime, which runs the code and provides services that make the development process easier.

Compilers and tools expose the common language runtime's functionality and enable you to write code that benefits from this managed execution environment. Code that you develop with a language compiler that targets the runtime is called managed code; it benefits from features such as cross-language integration, cross-language exception handling, enhanced security, versioning and deployment support, a simplified model for component interaction, and debugging and profiling services.

NOTE

Compilers and tools are able to produce output that the common language runtime can consume because the type system, the format of metadata, and the runtime environment (the virtual execution system) are all defined by a public standard, the ECMA Common Language Infrastructure specification. For more information, see [ECMA C# and Common Language Infrastructure Specifications](#).

To enable the runtime to provide services to managed code, language compilers must emit metadata that describes the types, members, and references in your code. Metadata is stored with the code; every loadable common language runtime portable executable (PE) file contains metadata. The runtime uses metadata to locate and load classes, lay out instances in memory, resolve method invocations, generate native code, enforce security, and set run-time context boundaries.

The runtime automatically handles object layout and manages references to objects, releasing them when they are no longer being used. Objects whose lifetimes are managed in this way are called managed data. Garbage collection eliminates memory leaks as well as some other common programming errors. If your code is managed, you can use managed data, unmanaged data, or both managed and unmanaged data in your .NET Framework application. Because language compilers supply their own types, such as primitive types, you might not always know (or need to know) whether your data is being managed.

The common language runtime makes it easy to design components and applications whose objects interact across languages. Objects written in different languages can communicate with each other, and their behaviors can be tightly integrated. For example, you can define a class and then use a different language to derive a class from your original class or call a method on the original class. You can also pass an instance of a class to a method of a class written in a different language. This cross-language integration is possible because language compilers and tools that target the runtime use a common type system defined by the runtime, and they follow the runtime's rules for defining new types, as well as for creating, using, persisting, and binding to types.

As part of their metadata, all managed components carry information about the components and resources they were built against. The runtime uses this information to ensure that your component or application has the specified versions of everything it needs, which makes your code less likely to break because of some unmet dependency. Registration information and state data are no longer stored in the registry where they can be difficult to establish and maintain. Instead, information about the types you define (and their dependencies) is stored with the code as metadata, making the tasks of component replication and removal much less complicated.

Language compilers and tools expose the runtime's functionality in ways that are intended to be useful and intuitive to developers. This means that some features of the runtime might be more noticeable in one environment than in another. How you experience the runtime depends on which language compilers or tools you use. For example, if you are a Visual Basic developer, you might notice that with the common language runtime, the

Visual Basic language has more object-oriented features than before. The runtime provides the following benefits:

- Performance improvements.
- The ability to easily use components developed in other languages.
- Extensible types provided by a class library.
- Language features such as inheritance, interfaces, and overloading for object-oriented programming.
- Support for explicit free threading that allows creation of multithreaded, scalable applications.
- Support for structured exception handling.
- Support for custom attributes.
- Garbage collection.
- Use of delegates instead of function pointers for increased type safety and security. For more information about delegates, see [Common Type System](#).

CLR versions

The version number of the .NET Framework doesn't necessarily correspond to the version number of the CLR it includes. The following table shows how the two version numbers correlate.

.NET FRAMEWORK VERSION	INCLUDES CLR VERSION
1.0	1.0
1.1	1.1
2.0	2.0
3.0	2.0
3.5	2.0
4	4
4.5 (including 4.5.1 and 4.5.2)	4
4.6 (including 4.6.1 and 4.6.2)	4
4.7 (including 4.7.1 and 4.7.2)	4

Language independence and language-independent components

3/9/2019 • 69 minutes to read • [Edit Online](#)

.NET is language independent. This means that, as a developer, you can develop in one of the many languages that target .NET implementations, such as C#, F#, and Visual Basic. You can access the types and members of class libraries developed for .NET implementations without having to know the language in which they were originally written and without having to follow any of the original language's conventions. If you are a component developer, your component can be accessed by any .NET app regardless of its language.

NOTE

This first part of this article discusses creating language-independent components - that is, components that can be consumed by apps that are written in any language. You can also create a single component or app from source code written in multiple languages; see [Cross-Language Interoperability](#) in the second part of this article.

To fully interact with other objects written in any language, objects must expose to callers only those features that are common to all languages. This common set of features is defined by the Common Language Specification (CLS), which is a set of rules that apply to generated assemblies. The Common Language Specification is defined in Partition I, Clauses 7 through 11 of the [ECMA-335 Standard: Common Language Infrastructure](#).

If your component conforms to the Common Language Specification, it is guaranteed to be CLS-compliant and can be accessed from code in assemblies written in any programming language that supports the CLS. You can determine whether your component conforms to the Common Language Specification at compile time by applying the [CLSCompliantAttribute](#) attribute to your source code. For more information, see The [CLSCompliantAttribute](#) attribute.

CLS compliance rules

This section discusses the rules for creating a CLS-compliant component. For a complete list of rules, see Partition I, Clause 11 of the [ECMA-335 Standard: Common Language Infrastructure](#).

NOTE

The Common Language Specification discusses each rule for CLS compliance as it applies to consumers (developers who are programmatically accessing a component that is CLS-compliant), frameworks (developers who are using a language compiler to create CLS-compliant libraries), and extenders (developers who are creating a tool such as a language compiler or a code parser that creates CLS-compliant components). This article focuses on the rules as they apply to frameworks. Note, though, that some of the rules that apply to extenders may also apply to assemblies that are created using [Reflection.Emit](#).

To design a component that is language independent, you only need to apply the rules for CLS compliance to your component's public interface. Your private implementation does not have to conform to the specification.

IMPORTANT

The rules for CLS compliance apply only to a component's public interface, not to its private implementation.

For example, unsigned integers other than [Byte](#) are not CLS-compliant. Because the `Person` class in the following example exposes an `Age` property of type [UInt16](#), the following code displays a compiler warning.

```
using System;

[assembly: CLSCompliant(true)]

public class Person
{
    private UInt16 personAge = 0;

    public UInt16 Age
    { get { return personAge; } }

}

// The attempt to compile the example displays the following compiler warning:
//     Public1.cs(10,18): warning CS3003: Type of 'Person.Age' is not CLS-compliant
```

```

<Assembly: CLSCompliant(True)>

Public Class Person
    Private personAge As UInt16

    Public ReadOnly Property Age As UInt16
        Get
            Return personAge
        End Get
    End Property
End Class
' The attempt to compile the example displays the following compiler warning:
'   Public1.vb(9) : warning BC40027: Return type of function 'Age' is not CLS-compliant.
'
'   Public ReadOnly Property Age As UInt16
'   ~~~

```

You can make the Person class CLS-compliant by changing the type of `Age` property from `UInt16` to `Int16`, which is a CLS-compliant, 16-bit signed integer. You do not have to change the type of the private `personAge` field.

```

using System;

[assembly: CLSCompliant(true)]

public class Person
{
    private Int16 personAge = 0;

    public Int16 Age
    { get { return personAge; } }
}

```

```

<Assembly: CLSCompliant(True)>

Public Class Person
    Private personAge As UInt16

    Public ReadOnly Property Age As Int16
        Get
            Return CType(personAge, Int16)
        End Get
    End Property
End Class

```

A library's public interface consists of the following:

- Definitions of public classes.
- Definitions of the public members of public classes, and definitions of members accessible to derived classes (that is, protected members).
- Parameters and return types of public methods of public classes, and parameters and return types of methods accessible to derived classes.

The rules for CLS compliance are listed in the following table. The text of the rules is taken verbatim from the [ECMA-335 Standard: Common Language Infrastructure](#), which is Copyright 2012 by Ecma International. More detailed information about these rules is found in the following sections.

CATEGORY	SEE	RULE	RULE NUMBER
Accessibility	Member accessibility	Accessibility shall not be changed when overriding inherited methods, except when overriding a method inherited from a different assembly with accessibility <code>family-or-assembly</code> . In this case, the override shall have accessibility <code>family</code> .	10
Accessibility	Member accessibility	The visibility and accessibility of types and members shall be such that types in the signature of any member shall be visible and accessible whenever the member itself is visible and accessible. For example, a public method that is visible outside its assembly shall not have an argument whose type is visible only within the assembly. The visibility and accessibility of types composing an instantiated generic type used in the signature of any member shall be visible and accessible whenever the member itself is visible and accessible. For example, an instantiated generic type present in the signature of a member that is visible outside its assembly shall not have a generic argument whose type is visible only within the assembly.	12
Arrays	Arrays	Arrays shall have elements with a CLS-compliant type, and all dimensions of the array shall have lower bounds of zero. Only the fact that an item is an array and the element type of the array shall be required to distinguish between overloads. When overloading is based on two or more array types the element types shall be named types.	16
Attributes	Attributes	Attributes shall be of type <code>System.Attribute</code> , or a type inheriting from it.	41

CATEGORY	SEE	RULE	RULE NUMBER
Attributes	Attributes	The CLS only allows a subset of the encodings of custom attributes. The only types that shall appear in these encodings are (see Partition IV): <code>System.Type</code> , <code>System.String</code> , <code>System.Char</code> , <code>System.Boolean</code> , <code>System.Byte</code> , <code>System.Int16</code> , <code>System.Int32</code> , <code>System.Int64</code> , <code>System.Single</code> , <code>System.Double</code> , and any enumeration type based on a CLS-compliant base integer type.	34
Attributes	Attributes	The CLS does not allow publicly visible required modifiers (<code>modreq</code> , see Partition II), but does allow optional modifiers (<code>modopt</code> , see Partition II) it does not understand.	35
Constructors	Constructors	An object constructor shall call some instance constructor of its base class before any access occurs to inherited instance data. (This does not apply to value types, which need not have constructors.)	21
Constructors	Constructors	An object constructor shall not be called except as part of the creation of an object, and an object shall not be initialized twice.	22
Enumerations	Enumerations	The underlying type of an enum shall be a built-in CLS integer type, the name of the field shall be "value_#", and that field shall be marked <code>RTSpecialName</code> .	7

CATEGORY	SEE	RULE	RULE NUMBER
Enumerations	Enumerations	There are two distinct kinds of enums, indicated by the presence or absence of the System.FlagsAttribute (see Partition IV Library) custom attribute. One represents named integer values; the other represents named bit flags that can be combined to generate an unnamed value. The value of an <code>enum</code> is not limited to the specified values.	8
Enumerations	Enumerations	Literal static fields of an enum shall have the type of the enum itself.	9
Events	Events	The methods that implement an event shall be marked <code>SpecialName</code> in the metadata.	29
Events	Events	The accessibility of an event and of its accessors shall be identical.	30
Events	Events	The <code>add</code> and <code>remove</code> methods for an event shall both either be present or absent.	31
Events	Events	The <code>add</code> and <code>remove</code> methods for an event shall each take one parameter whose type defines the type of the event and that shall be derived from System.Delegate .	32
Events	Events	Events shall adhere to a specific naming pattern. The <code>SpecialName</code> attribute referred to in CLS rule 29 shall be ignored in appropriate name comparisons and shall adhere to identifier rules.	33
Exceptions	Exceptions	Objects that are thrown shall be of type System.Exception or a type inheriting from it. Nonetheless, CLS-compliant methods are not required to block the propagation of other types of exceptions.	40

CATEGORY	SEE	RULE	RULE NUMBER
General	CLS compliance rules	CLS rules apply only to those parts of a type that are accessible or visible outside of the defining assembly.	1
General	CLS compliance rules	Members of non-CLS compliant types shall not be marked CLS-compliant.	2
Generics	Generic types and members	Nested types shall have at least as many generic parameters as the enclosing type. Generic parameters in a nested type correspond by position to the generic parameters in its enclosing type.	42
Generics	Generic types and members	The name of a generic type shall encode the number of type parameters declared on the non-nested type, or newly introduced to the type if nested, according to the rules defined above.	43
Generics	Generic types and members	A generic type shall redeclare sufficient constraints to guarantee that any constraints on the base type, or interfaces would be satisfied by the generic type constraints.	44
Generics	Generic types and members	Types used as constraints on generic parameters shall themselves be CLS-compliant.	45
Generics	Generic types and members	The visibility and accessibility of members (including nested types) in an instantiated generic type shall be considered to be scoped to the specific instantiation rather than the generic type declaration as a whole. Assuming this, the visibility and accessibility rules of CLS rule 12 still apply.	46
Generics	Generic types and members	For each abstract or virtual generic method, there shall be a default concrete (nonabstract) implementation	47

CATEGORY	SEE	RULE	RULE NUMBER
Interfaces	Interfaces	CLS-compliant interfaces shall not require the definition of non-CLS compliant methods in order to implement them.	18
Interfaces	Interfaces	CLS-compliant interfaces shall not define static methods, nor shall they define fields.	19
Members	Type members in general	Global static fields and methods are not CLS-compliant.	36
Members	--	The value of a literal static is specified through the use of field initialization metadata. A CLS-compliant literal must have a value specified in field initialization metadata that is of exactly the same type as the literal (or of the underlying type, if that literal is an <code>enum</code>).	13
Members	Type members in general	The vararg constraint is not part of the CLS, and the only calling convention supported by the CLS is the standard managed calling convention.	15
Naming conventions	Naming conventions	Assemblies shall follow Annex 7 of Technical Report 15 of the Unicode Standard3.0 governing the set of characters permitted to start and be included in identifiers, available online at Unicode Normalization Forms . Identifiers shall be in the canonical format defined by Unicode Normalization Form C. For CLS purposes, two identifiers are the same if their lowercase mappings (as specified by the Unicode locale-insensitive, one-to-one lowercase mappings) are the same. That is, for two identifiers to be considered different under the CLS they shall differ in more than simply their case. However, in order to override an inherited definition the CLI requires the precise encoding of the original declaration be used.	4

CATEGORY	SEE	RULE	RULE NUMBER
Overloading	Naming conventions	All names introduced in a CLS-compliant scope shall be distinct independent of kind, except where the names are identical and resolved via overloading. That is, while the CTS allows a single type to use the same name for a method and a field, the CLS does not.	5
Overloading	Naming conventions	Fields and nested types shall be distinct by identifier comparison alone, even though the CTS allows distinct signatures to be distinguished. Methods, properties, and events that have the same name (by identifier comparison) shall differ by more than just the return type, except as specified in CLS Rule 39	6
Overloading	Overloads	Only properties and methods can be overloaded.	37

CATEGORY	SEE	RULE	RULE NUMBER
Overloading	Overloads	Properties and methods can be overloaded based only on the number and types of their parameters, except the conversion operators named <code>op_Implicit</code> and <code>op_Explicit</code> , which can also be overloaded based on their return type.	38
Overloading	--	If two or more CLS-compliant methods declared in a type have the same name and, for a specific set of type instantiations, they have the same parameter and return types, then all these methods shall be semantically equivalent at those type instantiations.	48
Properties	Properties	The methods that implement the getter and setter methods of a property shall be marked <code>SpecialName</code> in the metadata.	24
Properties	Properties	A property's accessors shall all be static, all be virtual, or all be instance.	26
Properties	Properties	The type of a property shall be the return type of the getter and the type of the last argument of the setter. The types of the parameters of the property shall be the types of the parameters to the getter and the types of all but the final parameter of the setter. All of these types shall be CLS-compliant, and shall not be managed pointers (that is, shall not be passed by reference).	27
Properties	Properties	Properties shall adhere to a specific naming pattern. The <code>SpecialName</code> attribute referred to in CLS rule 24 shall be ignored in appropriate name comparisons and shall adhere to identifier rules. A property shall have a getter method, a setter method, or both.	28

CATEGORY	SEE	RULE	RULE NUMBER
Type conversion	Type conversion	If either op_Implicit or op_Explicit is provided, an alternate means of providing the coercion shall be provided.	39
Types	Types and type member signatures	Boxed value types are not CLS-compliant.	3
Types	Types and type member signatures	All types appearing in a signature shall be CLS-compliant. All types composing an instantiated generic type shall be CLS-compliant.	11
Types	Types and type member signatures	Typed references are not CLS-compliant.	14
Types	Types and type member signatures	Unmanaged pointer types are not CLS-compliant.	17
Types	Types and type member signatures	CLS-compliant classes, value types, and interfaces shall not require the implementation of non-CLS-compliant members	20
Types	Types and type member signatures	System.Object is CLS-compliant. Any other CLS-compliant class shall inherit from a CLS-compliant class.	23

Types and type member signatures

The [System.Object](#) type is CLS-compliant and is the base type of all object types in the .NET Framework type system. Inheritance in the .NET Framework is either implicit (for example, the [String](#) class implicitly inherits from the [Object](#) class) or explicit (for example, the [CultureNotFoundException](#) class explicitly inherits from the [ArgumentException](#) class, which explicitly inherits from the [Exception](#) class. For a derived type to be CLS compliant, its base type must also be CLS-compliant.

The following example shows a derived type whose base type is not CLS-compliant. It defines a base [Counter](#) class that uses an unsigned 32-bit integer as a counter. Because the class provides counter functionality by wrapping an unsigned integer, the class is marked as non-CLS-compliant. As a result, a derived class, [NonZeroCounter](#), is also not CLS-compliant.

```
using System;

[assembly: CLSCompliant(true)]

[CLSCompliant(false)]
public class Counter
{
    UInt32 ctr;

    public Counter()
    {
        ctr = 0;
    }

    protected Counter(UInt32 ctr)
    {
        this.ctr = ctr;
    }

    public override string ToString()
    {
        return String.Format("{0}. ", ctr);
    }

    public UInt32 Value
    {
        get { return ctr; }
    }

    public void Increment()
    {
        ctr += (uint) 1;
    }
}

public class NonZeroCounter : Counter
{
    public NonZeroCounter(int startIndex) : this((uint) startIndex)
    {

    }

    private NonZeroCounter(UInt32 startIndex) : base(startIndex)
    {

    }
}

// Compilation produces a compiler warning like the following:
// Type3.cs(37,14): warning CS3009: 'NonZeroCounter': base type 'Counter' is not
//           CLS-compliant
// Type3.cs(7,14): (Location of symbol related to previous warning)
```

```

<Assembly: CLSCompliant(True)>

<CLSCompliant(False)> _
Public Class Counter
    Dim ctr As UInt32

    Public Sub New
        ctr = 0
    End Sub

    Protected Sub New(ctr As UInt32)
        Me.ctr = ctr
    End Sub

    Public Overrides Function ToString() As String
        Return String.Format("{0}. ", ctr)
    End Function

    Public ReadOnly Property Value As UInt32
        Get
            Return ctr
        End Get
    End Property

    Public Sub Increment()
        ctr += CType(1, UInt32)
    End Sub
End Class

Public Class NonZeroCounter : Inherits Counter
    Public Sub New(startIndex As Integer)
        MyBase.New(CType(startIndex, UInt32))
    End Sub

    Private Sub New(startIndex As UInt32)
        MyBase.New(CType(startIndex, UInt32))
    End Sub
End Class

' Compilation produces a compiler warning like the following:
' Type3.vb(34) : warning BC40026: 'NonZeroCounter' is not CLS-compliant
' because it derives from 'Counter', which is not CLS-compliant.
'
' Public Class NonZeroCounter : Inherits Counter
' ~~~~~

```

All types that appear in member signatures, including a method's return type or a property type, must be CLS-compliant. In addition, for generic types:

- All types that compose an instantiated generic type must be CLS-compliant.
- All types used as constraints on generic parameters must be CLS-compliant.

The .NET [common type system](#) includes a number of built-in types that are supported directly by the common language runtime and are specially encoded in an assembly's metadata. Of these intrinsic types, the types listed in the following table are CLS-compliant.

CLS-COMPLIANT TYPE	DESCRIPTION
Byte	8-bit unsigned integer
Int16	16-bit signed integer

CLS-COMPLIANT TYPE	DESCRIPTION
Int32	32-bit signed integer
Int64	64-bit signed integer
Single	Single-precision floating-point value
Double	Double-precision floating-point value
Boolean	true or false value type
Char	UTF-16 encoded code unit
Decimal	Non-floating-point decimal number
IntPtr	Pointer or handle of a platform-defined size
String	Collection of zero, one, or more Char objects

The intrinsic types listed in the following table are not CLS-Compliant.

NON-COMPLIANT TYPE	DESCRIPTION	CLS-COMPLIANT ALTERNATIVE
SByte	8-bit signed integer data type	Int16
UInt16	16-bit unsigned integer	Int32
UInt32	32-bit unsigned integer	Int64
UInt64	64-bit unsigned integer	Int64 (may overflow), BigInteger, or Double
IntPtr	Unsigned pointer or handle	IntPtr

The .NET Framework Class Library or any other class library may include other types that aren't CLS-compliant; for example:

- Boxed value types. The following C# example creates a class that has a public property of type `int *` named `Value`. Because an `int *` is a boxed value type, the compiler flags it as non-CLS-compliant.

```

using System;

[assembly: CLSCompliant(true)]

public unsafe class TestClass
{
    private int* val;

    public TestClass(int number)
    {
        val = (int*) number;
    }

    public int* Value {
        get { return val; }
    }
}

// The compiler generates the following output when compiling this example:
//     warning CS3003: Type of 'TestClass.Value' is not CLS-compliant

```

- Typed references, which are special constructs that contain a reference to an object and a reference to a type.

If a type is not CLS-compliant, you should apply the [CLSCompliantAttribute](#) attribute with an *isCompliant* parameter with a value of `false` to it. For more information, see the [CLSCompliantAttribute attribute](#) section.

The following example illustrates the problem of CLS compliance in a method signature and in generic type instantiation. It defines an `InvoiceItem` class with a property of type `UInt32`, a property of type `Nullable(Of UInt32)`, and a constructor with parameters of type `UInt32` and `Nullable(Of UInt32)`. You get four compiler warnings when you try to compile this example.

```

using System;

[assembly: CLSCompliant(true)]

public class InvoiceItem
{
    private uint invId = 0;
    private uint itemId = 0;
    private Nullable<uint> qty;

    public InvoiceItem(uint sku, Nullable<uint> quantity)
    {
        itemId = sku;
        qty = quantity;
    }

    public Nullable<uint> Quantity
    {
        get { return qty; }
        set { qty = value; }
    }

    public uint InvoiceId
    {
        get { return invId; }
        set { invId = value; }
    }
}

// The attempt to compile the example displays the following output:
//     Type1.cs(13,23): warning CS3001: Argument type 'uint' is not CLS-compliant
//     Type1.cs(13,33): warning CS3001: Argument type 'uint?' is not CLS-compliant
//     Type1.cs(19,26): warning CS3003: Type of 'InvoiceItem.Quantity' is not CLS-compliant
//     Type1.cs(25,16): warning CS3003: Type of 'InvoiceItem.InvoiceId' is not CLS-compliant

```

```

<Assembly: CLSCompliant(True)>

Public Class InvoiceItem

    Private invId As UInteger = 0
    Private itemId As UInteger = 0
    Private qty AS Nullable(Of UInteger)

    Public Sub New(sku As UInteger, quantity As Nullable(Of UInteger))
        itemId = sku
        qty = quantity
    End Sub

    Public Property Quantity As Nullable(Of UInteger)
        Get
            Return qty
        End Get
        Set
            qty = value
        End Set
    End Property

    Public Property InvoiceId As UInteger
        Get
            Return invId
        End Get
        Set
            invId = value
        End Set
    End Property
End Class

' The attempt to compile the example displays output similar to the following:
' Type1.vb(13) : warning BC40028: Type of parameter 'sku' is not CLS-compliant.
'

'     Public Sub New(sku As UInteger, quantity As Nullable(Of UInteger))
'         ~~~
' Type1.vb(13) : warning BC40041: Type 'UInteger' is not CLS-compliant.
'

'     Public Sub New(sku As UInteger, quantity As Nullable(Of UInteger))
'         ~~~~~
' Type1.vb(18) : warning BC40041: Type 'UInteger' is not CLS-compliant.
'

'     Public Property Quantity As Nullable(Of UInteger)
'         ~~~~~
' Type1.vb(27) : warning BC40027: Return type of function 'InvoiceId' is not CLS-compliant.
'

'     Public Property InvoiceId As UInteger

```

To eliminate the compiler warnings, replace the non-CLS-compliant types in the `InvoiceItem` public interface with compliant types:

```
using System;

[assembly: CLSCompliant(true)]

public class InvoiceItem
{
    private uint invId = 0;
    private uint itemId = 0;
    private Nullable<int> qty;

    public InvoiceItem(int sku, Nullable<int> quantity)
    {
        if (sku <= 0)
            throw new ArgumentOutOfRangeException("The item number is zero or negative.");
        itemId = (uint) sku;

        qty = quantity;
    }

    public Nullable<int> Quantity
    {
        get { return qty; }
        set { qty = value; }
    }

    public int InvoiceId
    {
        get { return (int) invId; }
        set {
            if (value <= 0)
                throw new ArgumentOutOfRangeException("The invoice number is zero or negative.");
            invId = (uint) value; }
    }
}
```

```

Assembly: CLSCompliant(True)>

Public Class InvoiceItem

    Private invId As UInteger = 0
    Private itemId As UInteger = 0
    Private qty AS Nullable(Of Integer)

    Public Sub New(sku As Integer, quantity As Nullable(Of Integer))
        If sku <= 0 Then
            Throw New ArgumentOutOfRangeException("The item number is zero or negative.")
        End If
        itemId = CUInt(sku)
        qty = quantity
    End Sub

    Public Property Quantity As Nullable(Of Integer)
        Get
            Return qty
        End Get
        Set
            qty = value
        End Set
    End Property

    Public Property InvoiceId As Integer
        Get
            Return CInt(invId)
        End Get
        Set
            invId = CUInt(value)
        End Set
    End Property
End Class

```

In addition to the specific types listed, some categories of types are not CLS compliant. These include unmanaged pointer types and function pointer types. The following example generates a compiler warning because it uses a pointer to an integer to create an array of integers.

```

using System;

[assembly: CLSCompliant(true)]

public class ArrayHelper
{
    unsafe public static Array CreateInstance(Type type, int* ptr, int items)
    {
        Array arr = Array.CreateInstance(type, items);
        int* addr = ptr;
        for (int ctr = 0; ctr < items; ctr++) {
            int value = *addr;
            arr.SetValue(value, ctr);
            addr++;
        }
        return arr;
    }
}

// The attempt to compile this example displays the following output:
//     UnmanagedType1.cs(8,57): warning CS3001: Argument type 'int*' is not CLS-compliant

```

```

using System;

[assembly: CLSCompliant(true)]

public class ArrayHelper
{
    unsafe public static Array CreateInstance(Type type, int* ptr, int items)
    {
        Array arr = Array.CreateInstance(type, items);
        int* addr = ptr;
        for (int ctr = 0; ctr < items; ctr++) {
            int value = *addr;
            arr.SetValue(value, ctr);
            addr++;
        }
        return arr;
    }
}

// The attempt to compile this example displays the following output:
//     UnmanagedPtr1.cs(8,57): warning CS3001: Argument type 'int*' is not CLS-compliant

```

For CLS-compliant abstract classes (that is, classes marked as `abstract` in C#), all members of the class must also be CLS-compliant.

Naming conventions

Because some programming languages are case-insensitive, identifiers (such as the names of namespaces, types, and members) must differ by more than case. Two identifiers are considered equivalent if their lowercase mappings are the same. The following C# example defines two public classes, `Person` and `person`. Because they differ only by case, the C# compiler flags them as not CLS-compliant.

```

using System;

[assembly: CLSCompliant(true)]

public class Person : person
{
}

public class person
{
}

// Compilation produces a compiler warning like the following:
//     Naming1.cs(11,14): warning CS3005: Identifier 'person' differing
//                         only in case is not CLS-compliant
//     Naming1.cs(6,14): (Location of symbol related to previous warning)

```

Programming language identifiers, such as the names of namespaces, types, and members, must conform to the [Unicode Standard 3.0, Technical Report 15, Annex 7](#). This means that:

- The first character of an identifier can be any Unicode uppercase letter, lowercase letter, title case letter, modifier letter, other letter, or letter number. For information on Unicode character categories, see the [System.Globalization.UnicodeCategory](#) enumeration.
- Subsequent characters can be from any of the categories as the first character, and can also include non-spacing marks, spacing combining marks, decimal numbers, connector punctuations, and formatting codes.

Before you compare identifiers, you should filter out formatting codes and convert the identifiers to Unicode Normalization Form C, because a single character can be represented by multiple UTF-16-encoded code units.

Character sequences that produce the same code units in Unicode Normalization Form C are not CLS-compliant. The following example defines a property named `Å`, which consists of the character ANGSTROM SIGN (U+212B), and a second property named `Å` which consists of the character LATIN CAPITAL LETTER A WITH RING ABOVE (U+00C5). The C# compiler flags the source code as non-CLS-compliant.

```
public class Size
{
    private double a1;
    private double a2;

    public double Å
    {
        get { return a1; }
        set { a1 = value; }
    }

    public double Å
    {
        get { return a2; }
        set { a2 = value; }
    }
}

// Compilation produces a compiler warning like the following:
// Naming2a.cs(16,18): warning CS3005: Identifier 'Size.Å' differing only in case is not
//           CLS-compliant
// Naming2a.cs(10,18): (Location of symbol related to previous warning)
// Naming2a.cs(18,8): warning CS3005: Identifier 'Size.Å.get' differing only in case is not
//           CLS-compliant
// Naming2a.cs(12,8): (Location of symbol related to previous warning)
// Naming2a.cs(19,8): warning CS3005: Identifier 'Size.Å.set' differing only in case is not
//           CLS-compliant
// Naming2a.cs(13,8): (Location of symbol related to previous warning)
```

```
<Assembly: CLSCompliant(True)>
Public Class Size
    Private a1 As Double
    Private a2 As Double

    Public Property Å As Double
        Get
            Return a1
        End Get
        Set
            a1 = value
        End Set
    End Property

    Public Property Å As Double
        Get
            Return a2
        End Get
        Set
            a2 = value
        End Set
    End Property
End Class

' Compilation produces a compiler warning like the following:
' Naming1.vb(9) : error BC30269: 'Public Property Å As Double' has multiple definitions
'           with identical signatures.

'
'     Public Property Å As Double
'             ~
```

Member names within a particular scope (such as the namespaces within an assembly, the types within a

namespace, or the members within a type) must be unique except for names that are resolved through overloading. This requirement is more stringent than that of the common type system, which allows multiple members within a scope to have identical names as long as they are different kinds of members (for example, one is a method and one is a field). In particular, for type members:

- Fields and nested types are distinguished by name alone.
- Methods, properties, and events that have the same name must differ by more than just return type.

The following example illustrates the requirement that member names must be unique within their scope. It defines a class named `Converter` that includes four members named `Conversion`. Three are methods, and one is a property. The method that includes an `Int64` parameter is uniquely named, but the two methods with an `Int32` parameter are not, because return value is not considered a part of a member's signature. The `Conversion` property also violates this requirement, because properties cannot have the same name as overloaded methods.

```
using System;

[assembly: CLSCompliant(true)]

public class Converter
{
    public double Conversion(int number)
    {
        return (double) number;
    }

    public float Conversion(int number)
    {
        return (float) number;
    }

    public double Conversion(long number)
    {
        return (double) number;
    }

    public bool Conversion
    {
        get { return true; }
    }
}

// Compilation produces a compiler error like the following:
// Naming3.cs(13,17): error CS0111: Type 'Converter' already defines a member called
//                 'Conversion' with the same parameter types
// Naming3.cs(8,18): (Location of symbol related to previous error)
// Naming3.cs(23,16): error CS0102: The type 'Converter' already contains a definition for
//                 'Conversion'
// Naming3.cs(8,18): (Location of symbol related to previous error)
```

```

<Assembly: CLSCompliant(True)>

Public Class Converter
    Public Function Conversion(number As Integer) As Double
        Return CDbl(number)
    End Function

    Public Function Conversion(number As Integer) As Single
        Return CSng(number)
    End Function

    Public Function Conversion(number As Long) As Double
        Return CDbl(number)
    End Function

    Public ReadOnly Property Conversion As Boolean
        Get
            Return True
        End Get
    End Property
End Class

' Compilation produces a compiler error like the following:
' Naming3.vb(8) : error BC30301: 'Public Function Conversion(number As Integer) As Double'
'                 and 'Public Function Conversion(number As Integer) As Single' cannot
'                 overload each other because they differ only by return types.
'

'     Public Function Conversion(number As Integer) As Double
'     ~~~~~
'
' Naming3.vb(20) : error BC30260: 'Conversion' is already declared as 'Public Function
'                 Conversion(number As Integer) As Single' in this class.
'

'     Public ReadOnly Property Conversion As Boolean
'     ~~~~~

```

Individual languages include unique keywords, so languages that target the common language runtime must also provide some mechanism for referencing identifiers (such as type names) that coincide with keywords. For example, `case` is a keyword in both C# and Visual Basic. However, the following Visual Basic example is able to disambiguate a class named `case` from the `case` keyword by using opening and closing braces. Otherwise, the example would produce the error message, "Keyword is not valid as an identifier," and fail to compile.

```

Public Class [case]
    Private _id As Guid
    Private name As String

    Public Sub New(name As String)
        _id = Guid.NewGuid()
        Me.name = name
    End Sub

    Public ReadOnly Property ClientName As String
        Get
            Return name
        End Get
    End Property
End Class

```

The following C# example is able to instantiate the `case` class by using the `@` symbol to disambiguate the identifier from the language keyword. Without it, the C# compiler would display two error messages, "Type expected" and "Invalid expression term 'case'."

```

using System;

public class Example
{
    public static void Main()
    {
        @case c = new @case("John");
        Console.WriteLine(c.ClientName);
    }
}

```

Type conversion

The Common Language Specification defines two conversion operators:

- `op_Implicit`, which is used for widening conversions that do not result in loss of data or precision. For example, the `Decimal` structure includes an overloaded `op_Implicit` operator to convert values of integral types and `Char` values to `Decimal` values.
- `op_Explicit`, which is used for narrowing conversions that can result in loss of magnitude (a value is converted to a value that has a smaller range) or precision. For example, the `Decimal` structure includes an overloaded `op_Explicit` operator to convert `Double` and `Single` values to `Decimal` and to convert `Decimal` values to integral values, `Double`, `Single`, and `Char`.

However, not all languages support operator overloading or the definition of custom operators. If you choose to implement these conversion operators, you should also provide an alternate way to perform the conversion. We recommend that you provide `From Xxx` and `To Xxx` methods.

The following example defines CLS-compliant implicit and explicit conversions. It creates a `UDouble` class that represents an signed double-precision, floating-point number. It provides for implicit conversions from `UDouble` to `Double` and for explicit conversions from `UDouble` to `Single`, `Double` to `UDouble`, and `Single` to `UDouble`. It also defines a `ToDouble` method as an alternative to the implicit conversion operator and the `ToSingle`, `FromDouble`, and `FromSingle` methods as alternatives to the explicit conversion operators.

```

using System;

public struct UDouble
{
    private double number;

    public UDouble(double value)
    {
        if (value < 0)
            throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

        number = value;
    }

    public UDouble(float value)
    {
        if (value < 0)
            throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

        number = value;
    }

    public static readonly UDouble MinValue = (UDouble) 0.0;
    public static readonly UDouble MaxValue = (UDouble) Double.MaxValue;

    public static explicit operator Double(UDouble value)
    {
        return value.number;
    }
}

```

```
}

public static implicit operator Single(UDouble value)
{
    if (value.number > (double) Single.MaxValue)
        throw new InvalidCastException("A UDouble value is out of range of the Single type.");

    return (float) value.number;
}

public static explicit operator UDouble(double value)
{
    if (value < 0)
        throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

    return new UDouble(value);
}

public static implicit operator UDouble(float value)
{
    if (value < 0)
        throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

    return new UDouble(value);
}

public static Double ToDouble(UDouble value)
{
    return (Double) value;
}

public static float ToSingle(UDouble value)
{
    return (float) value;
}

public static UDouble FromDouble(double value)
{
    return new UDouble(value);
}

public static UDouble FromSingle(float value)
{
    return new UDouble(value);
}
```

```

Public Structure UDouble
    Private number As Double

    Public Sub New(value As Double)
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        number = value
    End Sub

    Public Sub New(value As Single)
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        number = value
    End Sub

    Public Shared ReadOnly MinValue As UDouble = CType(0.0, UDouble)
    Public Shared ReadOnly MaxValue As UDouble = Double.MaxValue

    Public Shared Widening Operator CType(value As UDouble) As Double
        Return value.number
    End Operator

    Public Shared Narrowing Operator CType(value As UDouble) As Single
        If value.number > CDbl(Single.MaxValue) Then
            Throw New InvalidCastException("A UDouble value is out of range of the Single type.")
        End If
        Return CSng(value.number)
    End Operator

    Public Shared Narrowing Operator CType(value As Double) As UDouble
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        Return New UDouble(value)
    End Operator

    Public Shared Narrowing Operator CType(value As Single) As UDouble
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        Return New UDouble(value)
    End Operator

    Public Shared Function ToDouble(value As UDouble) As Double
        Return CType(value, Double)
    End Function

    Public Shared Function ToSingle(value As UDouble) As Single
        Return CType(value, Single)
    End Function

    Public Shared Function FromDouble(value As Double) As UDouble
        Return New UDouble(value)
    End Function

    Public Shared Function FromSingle(value As Single) As UDouble
        Return New UDouble(value)
    End Function
End Structure

```

Arrays

CLS-compliant arrays conform to the following rules:

- All dimensions of an array must have a lower bound of zero. The following example creates a non-CLS-

compliant array with a lower bound of one. Note that, despite the presence of the `CLSClaimAttribute` attribute, the compiler does not detect that the array returned by the `Numbers.GetTenPrimes` method is not CLS-compliant.

```
[assembly: CLSClaimAttribute(true)]  
  
public class Numbers  
{  
    public static Array GetTenPrimes()  
    {  
        Array arr = Array.CreateInstance(typeof(Int32), new int[] {10}, new int[] {1});  
        arr.SetValue(1, 1);  
        arr.SetValue(2, 2);  
        arr.SetValue(3, 3);  
        arr.SetValue(5, 4);  
        arr.SetValue(7, 5);  
        arr.SetValue(11, 6);  
        arr.SetValue(13, 7);  
        arr.SetValue(17, 8);  
        arr.SetValue(19, 9);  
        arr.SetValue(23, 10);  
  
        return arr;  
    }  
}
```

```
<Assembly: CLSClaimAttribute(True)>  
  
Public Class Numbers  
    Public Shared Function GetTenPrimes() As Array  
        Dim arr As Array = Array.CreateInstance(GetType(Int32), {10}, {1})  
        arr.SetValue(1, 1)  
        arr.SetValue(2, 2)  
        arr.SetValue(3, 3)  
        arr.SetValue(5, 4)  
        arr.SetValue(7, 5)  
        arr.SetValue(11, 6)  
        arr.SetValue(13, 7)  
        arr.SetValue(17, 8)  
        arr.SetValue(19, 9)  
        arr.SetValue(23, 10)  
        Return arr  
    End Function  
End Class
```

- All array elements must consist of CLS-compliant types. The following example defines two methods that return non-CLS-compliant arrays. The first returns an array of `UInt32` values. The second returns an `Object` array that includes `Int32` and `UInt32` values. Although the compiler identifies the first array as non-compliant because of its `UInt32` type, it fails to recognize that the second array includes non-CLS-compliant elements.

```

using System;

[assembly: CLSCompliant(true)]

public class Numbers
{
    public static UInt32[] GetTenPrimes()
    {
        uint[] arr = { 1u, 2u, 3u, 5u, 7u, 11u, 13u, 17u, 19u };
        return arr;
    }

    public static Object[] GetFivePrimes()
    {
        Object[] arr = { 1, 2, 3, 5u, 7u };
        return arr;
    }
}

// Compilation produces a compiler warning like the following:
//   Array2.cs(8,27): warning CS3002: Return type of 'Numbers.GetTenPrimes()' is not
//           CLS-compliant

```

```

<Assembly: CLSCompliant(True)>

Public Class Numbers
    Public Shared Function GetTenPrimes() As UInt32()
        Return { 1ui, 2ui, 3ui, 5ui, 7ui, 11ui, 13ui, 17ui, 19ui }
    End Function
    Public Shared Function GetFivePrimes() As Object()
        Dim arr() As Object = { 1, 2, 3, 5ui, 7ui }
        Return arr
    End Function
End Class
' Compilation produces a compiler warning like the following:
'   warning BC40027: Return type of function 'GetTenPrimes' is not CLS-compliant.

```

- Overload resolution for methods that have array parameters is based on the fact that they are arrays and on their element type. For this reason, the following definition of an overloaded `Getsquares` method is CLS-compliant.

```

using System;
using System.Numerics;

[assembly: CLSCompliant(true)]

public class Numbers
{
    public static byte[] GetSquares(byte[] numbers)
    {
        byte[] numbersOut = new byte[numbers.Length];
        for (int ctr = 0; ctr < numbers.Length; ctr++) {
            int square = ((int) numbers[ctr]) * ((int) numbers[ctr]);
            if (square <= Byte.MaxValue)
                numbersOut[ctr] = (byte) square;
            // If there's an overflow, assign MaxValue to the corresponding
            // element.
            else
                numbersOut[ctr] = Byte.MaxValue;

        }
        return numbersOut;
    }

    public static BigInteger[] GetSquares(BigInteger[] numbers)
    {
        BigInteger[] numbersOut = new BigInteger[numbers.Length];
        for (int ctr = 0; ctr < numbers.Length; ctr++)
            numbersOut[ctr] = numbers[ctr] * numbers[ctr];

        return numbersOut;
    }
}

```

```

Imports System.Numerics

<Assembly: CLSCompliant(True)>

Public Module Numbers
    Public Function GetSquares(numbers As Byte()) As Byte()
        Dim numbersOut(numbers.Length - 1) As Byte
        For ctr As Integer = 0 To numbers.Length - 1
            Dim square As Integer = (CInt(numbers(ctr)) * CInt(numbers(ctr)))
            If square <= Byte.MaxValue Then
                numbersOut(ctr) = CByte(square)
            ' If there's an overflow, assign MaxValue to the corresponding
            ' element.
            Else
                numbersOut(ctr) = Byte.MaxValue
            End If
        Next
        Return numbersOut
    End Function

    Public Function GetSquares(numbers As BigInteger()) As BigInteger()
        Dim numbersOut(numbers.Length - 1) As BigInteger
        For ctr As Integer = 0 To numbers.Length - 1
            numbersOut(ctr) = numbers(ctr) * numbers(ctr)
        Next
        Return numbersOut
    End Function
End Module

```

Interfaces

CLS-compliant interfaces can define properties, events, and virtual methods (methods with no implementation). A

CLS-compliant interface cannot have any of the following:

- Static methods or static fields. The C# compiler generates compiler errors if you define a static member in an interface.
- Fields. The C# compiler generates compiler errors if you define a field in an interface.
- Methods that are not CLS-compliant. For example, the following interface definition includes a method, `INumber.GetUnsigned`, that is marked as non-CLS-compliant. This example generates a compiler warning.

```
using System;

[assembly:CLSCCompliant(true)]

public interface INumber
{
    int Length();
    [CLSCCompliant(false)] ulong GetUnsigned();
}

// Attempting to compile the example displays output like the following:
//  Interface2.cs(8,32): warning CS3010: 'INumber.GetUnsigned()': CLS-compliant interfaces
//          must have only CLS-compliant members
```

```
<Assembly: CLSCCompliant(True)>

Public Interface INumber
    Function Length As Integer
        <CLSCCompliant(False)> Function GetUnsigned As ULong
    End Interface
    ' Attempting to compile the example displays output like the following:
    '  Interface2.vb(9) : warning BC40033: Non CLS-compliant 'function' is not allowed in a
    '  CLS-compliant interface.
    '
    '  <CLSCCompliant(False)> Function GetUnsigned As ULong
    '
```

Because of this rule, CLS-compliant types are not required to implement non-CLS-compliant members. If a CLS-compliant framework does expose a class that implements a non-CLS compliant interface, it should also provide concrete implementations of all non-CLS-compliant members.

CLS-compliant language compilers must also allow a class to provide separate implementations of members that have the same name and signature in multiple interfaces. C# supports explicit interface implementations to provide different implementations of identically named methods. The following example illustrates this scenario by defining a `Temperature` class that implements the `ICelsius` and `IFahrenheit` interfaces as explicit interface implementations.

```

using System;

[assembly: CLSCompliant(true)]

public interface IFahrenheit
{
    decimal GetTemperature();
}

public interface ICelsius
{
    decimal GetTemperature();
}

public class Temperature : ICelsius, IFahrenheit
{
    private decimal _value;

    public Temperature(decimal value)
    {
        // We assume that this is the Celsius value.
        _value = value;
    }

    decimal IFahrenheit.GetTemperature()
    {
        return _value * 9 / 5 + 32;
    }

    decimal ICelsius.GetTemperature()
    {
        return _value;
    }
}

public class Example
{
    public static void Main()
    {
        Temperature temp = new Temperature(100.0m);
        ICelsius cTemp = temp;
        IFahrenheit fTemp = temp;
        Console.WriteLine("Temperature in Celsius: {0} degrees",
                          cTemp.GetTemperature());
        Console.WriteLine("Temperature in Fahrenheit: {0} degrees",
                          fTemp.GetTemperature());
    }
}
// The example displays the following output:
//      Temperature in Celsius: 100.0 degrees
//      Temperature in Fahrenheit: 212.0 degrees

```

```

Assembly: CLSCompliant(True)>

Public Interface IFahrenheit
    Function GetTemperature() As Decimal
End Interface

Public Interface ICelsius
    Function GetTemperature() As Decimal
End Interface

Public Class Temperature : Implements ICelsius, IFahrenheit
    Private _value As Decimal

    Public Sub New(value As Decimal)
        ' We assume that this is the Celsius value.
        _value = value
    End Sub

    Public Function GetFahrenheit() As Decimal _
        Implements IFahrenheit.GetTemperature
        Return _value * 9 / 5 + 32
    End Function

    Public Function GetCelsius() As Decimal _
        Implements ICelsius.GetTemperature
        Return _value
    End Function
End Class

Module Example
    Public Sub Main()
        Dim temp As New Temperature(100.0d)
        Console.WriteLine("Temperature in Celsius: {0} degrees",
                          temp.GetCelsius())
        Console.WriteLine("Temperature in Fahrenheit: {0} degrees",
                          temp.GetFahrenheit())
    End Sub
End Module
' The example displays the following output:
'     Temperature in Celsius: 100.0 degrees
'     Temperature in Fahrenheit: 212.0 degrees

```

Enumerations

CLS-compliant enumerations must follow these rules:

- The underlying type of the enumeration must be an intrinsic CLS-compliant integer ([Byte](#), [Int16](#), [Int32](#), or [Int64](#)). For example, the following code tries to define an enumeration whose underlying type is [UInt32](#) and generates a compiler warning.

```

using System;

[assembly: CLSCompliant(true)]

public enum Size : uint {
    Unspecified = 0,
    XSmall = 1,
    Small = 2,
    Medium = 3,
    Large = 4,
    XLarge = 5
};

public class Clothing
{
    public string Name;
    public string Type;
    public string Size;
}

// The attempt to compile the example displays a compiler warning like the following:
//     Enum3.cs(6,13): warning CS3009: 'Size': base type 'uint' is not CLS-compliant

```

```

<Assembly: CLSCompliant(True)>

Public Enum Size As UInt32
    Unspecified = 0
    XSmall = 1
    Small = 2
    Medium = 3
    Large = 4
    XLarge = 5
End Enum

Public Class Clothing
    Public Name As String
    Public Type As String
    Public Size As Size
End Class
' The attempt to compile the example displays a compiler warning like the following:
'     Enum3.vb(6) : warning BC40032: Underlying type 'UInt32' of Enum is not CLS-compliant.
'
'     Public Enum Size As UInt32
'         ~~~~

```

- An enumeration type must have a single instance field named `value_` that is marked with the `FieldAttributes.RTSpecialName` attribute. This enables you to reference the field value implicitly.
- An enumeration includes literal static fields whose types match the type of the enumeration itself. For example, if you define a `State` enumeration with values of `State.On` and `State.Off`, `State.On` and `State.Off` are both literal static fields whose type is `State`.
- There are two kinds of enumerations:
 - An enumeration that represents a set of mutually exclusive, named integer values. This type of enumeration is indicated by the absence of the `System.FlagsAttribute` custom attribute.
 - An enumeration that represents a set of bit flags that can combine to generate an unnamed value. This type of enumeration is indicated by the presence of the `System.FlagsAttribute` custom attribute.

For more information, see the documentation for the [Enum](#) structure.

- The value of an enumeration is not limited to the range of its specified values. In other words, the range of

values in an enumeration is the range of its underlying value. You can use the `Enum.isDefined` method to determine whether a specified value is a member of an enumeration.

Type members in general

The Common Language Specification requires all fields and methods to be accessed as members of a particular class. Therefore, global static fields and methods (that is, static fields or methods that are defined apart from a type) are not CLS-compliant. If you try to include a global field or method in your source code, the C# compiler generates a compiler error.

The Common Language Specification supports only the standard managed calling convention. It doesn't support unmanaged calling conventions and methods with variable argument lists marked with the `varargs` keyword. For variable argument lists that are compatible with the standard managed calling convention, use the `ParamArrayAttribute` attribute or the individual language's implementation, such as the `params` keyword in C# and the `ParamArray` keyword in Visual Basic.

Member accessibility

Overriding an inherited member cannot change the accessibility of that member. For example, a public method in a base class cannot be overridden by a private method in a derived class. There is one exception: a `protected internal` (in C#) or `Protected Friend` (in Visual Basic) member in one assembly that is overridden by a type in a different assembly. In that case, the accessibility of the override is `Protected`.

The following example illustrates the error that is generated when the `CLSCompliantAttribute` attribute is set to `true`, and `Person`, which is a class derived from `Animal`, tries to change the accessibility of the `species` property from public to private. The example compiles successfully if its accessibility is changed to public.

```
using System;

[assembly: CLSCompliant(true)]

public class Animal
{
    private string _species;

    public Animal(string species)
    {
        _species = species;
    }

    public virtual string Species
    {
        get { return _species; }
    }

    public override string ToString()
    {
        return _species;
    }
}

public class Human : Animal
{
    private string _name;

    public Human(string name) : base("Homo Sapiens")
    {
        _name = name;
    }

    public string Name
    {
        get { return _name; }
    }

    private override string Species
    {
        get { return base.Species; }
    }

    public override string ToString()
    {
        return _name;
    }
}

public class Example
{
    public static void Main()
    {
        Human p = new Human("John");
        Console.WriteLine(p.Species);
        Console.WriteLine(p.ToString());
    }
}

// The example displays the following output:
//      error CS0621: 'Human.Species': virtual or abstract members cannot be private
```

```

<Assembly: CLSCompliant(True)>

Public Class Animal
    Private _species As String

    Public Sub New(species As String)
        _species = species
    End Sub

    Public Overridable ReadOnly Property Species As String
        Get
            Return _species
        End Get
    End Property

    Public Overrides Function ToString() As String
        Return _species
    End Function
End Class

Public Class Human : Inherits Animal
    Private _name As String

    Public Sub New(name As String)
        MyBase.New("Homo Sapiens")
        _name = name
    End Sub

    Public ReadOnly Property Name As String
        Get
            Return _name
        End Get
    End Property

    Private Overrides ReadOnly Property Species As String
        Get
            Return MyBase.Species
        End Get
    End Property

    Public Overrides Function ToString() As String
        Return _name
    End Function
End Class

Public Module Example
    Public Sub Main()
        Dim p As New Human("John")
        Console.WriteLine(p.Species)
        Console.WriteLine(p.ToString())
    End Sub
End Module

' The example displays the following output:
'     'Private Overrides ReadOnly Property Species As String' cannot override
'     'Public Overridable ReadOnly Property Species As String' because
'     they have different access levels.
'

'     Private Overrides ReadOnly Property Species As String

```

Types in the signature of a member must be accessible whenever that member is accessible. For example, this means that a public member cannot include a parameter whose type is private, protected, or internal. The following example illustrates the compiler error that results when a `StringWrapper` class constructor exposes an internal `StringOperationType` enumeration value that determines how a string value should be wrapped.

```

using System;
using System.Text;

public class StringWrapper
{
    string internalString;
    StringBuilder internalSB = null;
    bool useSB = false;

    public StringWrapper(StringOperationType type)
    {
        if (type == StringOperationType.Normal) {
            useSB = false;
        }
        else {
            useSB = true;
            internalSB = new StringBuilder();
        }
    }

    // The remaining source code...
}

internal enum StringOperationType { Normal, Dynamic }
// The attempt to compile the example displays the following output:
//     error CS0051: Inconsistent accessibility: parameter type
//           'StringOperationType' is less accessible than method
//           'StringWrapper.StringWrapper(StringOperationType)'

```

```

Imports System.Text

<Assembly:CLSCCompliant(True)>

Public Class StringWrapper

    Dim internalString As String
    Dim internalSB As StringBuilder = Nothing
    Dim useSB As Boolean = False

    Public Sub New(type As StringOperationType)
        If type = StringOperationType.Normal Then
            useSB = False
        Else
            internalSB = New StringBuilder()
            useSB = True
        End If
    End Sub

    ' The remaining source code...
End Class

Friend Enum StringOperationType As Integer
    Normal = 0
    Dynamic = 1
End Enum
' The attempt to compile the example displays the following output:
'     error BC30909: 'type' cannot expose type 'StringOperationType'
'     outside the project through class 'StringWrapper'.
'

'     Public Sub New(type As StringOperationType)
'             ~~~~~

```

Generic types and members

Nested types always have at least as many generic parameters as their enclosing type. These correspond by

position to the generic parameters in the enclosing type. The generic type can also include new generic parameters.

The relationship between the generic type parameters of a containing type and its nested types may be hidden by the syntax of individual languages. In the following example, a generic type `Outer<T>` contains two nested classes, `Inner1A` and `Inner1B<U>`. The calls to the `ToString` method, which each class inherits from `Object.ToString`, show that each nested class includes the type parameters of its containing class.

```
using System;

[assembly:CLSCompliant(true)]

public class Outer<T>
{
    T value;

    public Outer(T value)
    {
        this.value = value;
    }

    public class Inner1A : Outer<T>
    {
        public Inner1A(T value) : base(value)
        { }
    }

    public class Inner1B<U> : Outer<T>
    {
        U value2;

        public Inner1B(T value1, U value2) : base(value1)
        {
            this.value2 = value2;
        }
    }
}

public class Example
{
    public static void Main()
    {
        var inst1 = new Outer<String>("This");
        Console.WriteLine(inst1);

        var inst2 = new Outer<String>.Inner1A("Another");
        Console.WriteLine(inst2);

        var inst3 = new Outer<String>.Inner1B<int>("That", 2);
        Console.WriteLine(inst3);
    }
}

// The example displays the following output:
//      Outer`1[System.String]
//      Outer`1+Inner1A[System.String]
//      Outer`1+Inner1B`1[System.String,System.Int32]
```

```

<Assembly:CLSCompliant(True)>

Public Class Outer(Of T)
    Dim value As T

    Public Sub New(value As T)
        Me.value = value
    End Sub

    Public Class Inner1A : Inherits Outer(Of T)
        Public Sub New(value As T)
            MyBase.New(value)
        End Sub
    End Class

    Public Class Inner1B(Of U) : Inherits Outer(Of T)
        Dim value2 As U

        Public Sub New(value1 As T, value2 As U)
            MyBase.New(value1)
            Me.value2 = value2
        End Sub
    End Class
End Class

Public Module Example
    Public Sub Main()
        Dim inst1 As New Outer(Of String)("This")
        Console.WriteLine(inst1)

        Dim inst2 As New Outer(Of String).Inner1A("Another")
        Console.WriteLine(inst2)

        Dim inst3 As New Outer(Of String).Inner1B(Of Integer)("That", 2)
        Console.WriteLine(inst3)
    End Sub
End Module

' The example displays the following output:
'     Outer`1[System.String]
'     Outer`1+Inner1A[System.String]
'     Outer`1+Inner1B`1[System.String,System.Int32]

```

Generic type names are encoded in the form *name'n*, where *name* is the type name, ` is a character literal, and *n* is the number of parameters declared on the type, or, for nested generic types, the number of newly introduced type parameters. This encoding of generic type names is primarily of interest to developers who use reflection to access CLS-compliant generic types in a library.

If constraints are applied to a generic type, any types used as constraints must also be CLS-compliant. The following example defines a class named `BaseClass` that is not CLS-compliant and a generic class named `BaseCollection` whose type parameter must derive from `BaseClass`. But because `BaseClass` is not CLS-compliant, the compiler emits a warning.

```
using System;

[assembly:CLSCompliant(true)]

[CLSCompliant(false)] public class BaseClass
{}

public class BaseCollection<T> where T : BaseClass
{}
// Attempting to compile the example displays the following output:
//   warning CS3024: Constraint type 'BaseClass' is not CLS-compliant
```

```
Assembly: CLSCompliant(True)>

<CLSCompliant(False)> Public Class BaseClass
End Class

Public Class BaseCollection(Of T As BaseClass)
End Class
' Attempting to compile the example displays the following output:
'   warning BC40040: Generic parameter constraint type 'BaseClass' is not
'   CLS-compliant.
'
'   Public Class BaseCollection(Of T As BaseClass)
'   ~~~~~~
```

If a generic type is derived from a generic base type, it must redeclare any constraints so that it can guarantee that constraints on the base type are also satisfied. The following example defines a `Number<T>` that can represent any numeric type. It also defines a `FloatingPoint<T>` class that represents a floating point value. However, the source code fails to compile, because it does not apply the constraint on `Number<T>` (that `T` must be a value type) to `FloatingPoint<T>`.

```

using System;

[assembly:CLSCompliant(true)]

public class Number<T> where T : struct
{
    // use Double as the underlying type, since its range is a superset of
    // the ranges of all numeric types except BigInteger.
    protected double number;

    public Number(T value)
    {
        try {
            this.number = Convert.ToDouble(value);
        }
        catch (OverflowException e) {
            throw new ArgumentException("value is too large.", e);
        }
        catch (InvalidCastException e) {
            throw new ArgumentException("The value parameter is not numeric.", e);
        }
    }

    public T Add(T value)
    {
        return (T) Convert.ChangeType(number + Convert.ToDouble(value), typeof(T));
    }

    public T Subtract(T value)
    {
        return (T) Convert.ChangeType(number - Convert.ToDouble(value), typeof(T));
    }
}

public class FloatingPoint<T> : Number<T>
{
    public FloatingPoint(T number) : base(number)
    {
        if (typeof(float) == number.GetType() ||
            typeof(double) == number.GetType() ||
            typeof(decimal) == number.GetType())
            this.number = Convert.ToDouble(number);
        else
            throw new ArgumentException("The number parameter is not a floating-point number.");
    }
}

// The attempt to compile the example displays the following output:
//      error CS0453: The type 'T' must be a non-nullable value type in
//                      order to use it as parameter 'T' in the generic type or method 'Number<T>'
```

```

<Assembly:CLSCompliant(True)>

Public Class Number(Of T As Structure)
    ' Use Double as the underlying type, since its range is a superset of
    ' the ranges of all numeric types except BigInteger.
    Protected number As Double

    Public Sub New(value As T)
        Try
            Me.number = Convert.ToDouble(value)
        Catch e As OverflowException
            Throw New ArgumentException("value is too large.", e)
        Catch e As InvalidCastException
            Throw New ArgumentException("The value parameter is not numeric.", e)
        End Try
    End Sub

    Public Function Add(value As T) As T
        Return CType(Convert.ChangeType(number + Convert.ToDouble(value), GetType(T)), T)
    End Function

    Public Function Subtract(value As T) As T
        Return CType(Convert.ChangeType(number - Convert.ToDouble(value), GetType(T)), T)
    End Function
End Class

Public Class FloatingPoint(Of T) : Inherits Number(Of T)
    Public Sub New(number As T)
        MyBase.New(number)
        If TypeOf number Is Single Or
            TypeOf number Is Double Or
            TypeOf number Is Decimal Then
            Me.number = Convert.ToDouble(number)
        Else
            Throw New ArgumentException("The number parameter is not a floating-point number.")
        End If
    End Sub
End Class
' The attempt to compile the example displays the following output:
' error BC32105: Type argument 'T' does not satisfy the 'Structure'
' constraint for type parameter 'T'.
'
' Public Class FloatingPoint(Of T) : Inherits Number(Of T)
' ~

```

The example compiles successfully if the constraint is added to the `FloatingPoint<T>` class.

The Common Language Specification imposes a conservative per-instantiation model for nested types and protected members. Open generic types cannot expose fields or members with signatures that contain a specific instantiation of a nested, protected generic type. Non-generic types that extend a specific instantiation of a generic base class or interface cannot expose fields or members with signatures that contain a different instantiation of a nested, protected generic type.

The following example defines a generic type, `C1<T>`, and a protected class, `C1<T>.N`. `C1<T>` has two methods, `M1` and `M2`. However, `M1` is not CLS-compliant because it tries to return a `C1<int>.N` object from `C1<T>`. A second class, `C2`, is derived from `C1<long>`. It has two methods, `M3` and `M4`. `M3` is not CLS-compliant because it tries to return a `C1<int>.N` object from a subclass of `C1<long>`. Note that language compilers can be even more restrictive. In this example, Visual Basic displays an error when it tries to compile `M4`.

```
using System;

[assembly:CLSCompliant(true)]

public class C1<T>
{
    protected class N { }

    protected void M1(C1<int>.N n) { } // Not CLS-compliant - C1<int>.N not
                                         // accessible from within C1<T> in all
                                         // languages
    protected void M2(C1<T>.N n) { } // CLS-compliant - C1<T>.N accessible
                                         // inside C1<T>
}

public class C2 : C1<long>
{
    protected void M3(C1<int>.N n) { } // Not CLS-compliant - C1<int>.N is not
                                         // accessible in C2 (extends C1<long>)

    protected void M4(C1<long>.N n) { } // CLS-compliant, C1<long>.N is
                                         // accessible in C2 (extends C1<long>)
}
// Attempting to compile the example displays output like the following:
//     Generics4.cs(9,22): warning CS3001: Argument type 'C1<int>.N' is not CLS-compliant
//     Generics4.cs(18,22): warning CS3001: Argument type 'C1<int>.N' is not CLS-compliant
```

```

<Assembly:CLSCompliant(True)>

Public Class C1(Of T)
    Protected Class N
        End Class

        Protected Sub M1(n As C1(Of Integer).N)      ' Not CLS-compliant - C1<int>.N not
            ' accessible from within C1(Of T) in all
            ' languages

        Protected Sub M2(n As C1(Of T).N)          ' CLS-compliant - C1(Of T).N accessible
            ' inside C1(Of T)
        End Sub
    End Class

        ' ~~~~~
        ' Protected Sub M4(n As C1(Of Long).N)
        ' ~~~~~

```

Constructors

Constructors in CLS-compliant classes and structures must follow these rules:

- A constructor of a derived class must call the instance constructor of its base class before it accesses inherited instance data. This requirement is due to the fact that base class constructors are not inherited by their derived classes. This rule does not apply to structures, which do not support direct inheritance.

Typically, compilers enforce this rule independently of CLS compliance, as the following example shows. It creates a `Doctor` class that is derived from a `Person` class, but the `Doctor` class fails to call the `Person` class constructor to initialize inherited instance fields.

```
using System;

[assembly: CLSCompliant(true)]

public class Person
{
    private string fName, lName, _id;

    public Person(string firstName, string lastName, string id)
    {
        if (String.IsNullOrEmpty(firstName + lastName))
            throw new ArgumentNullException("Either a first name or a last name must be provided.");

        fName = firstName;
        lName = lastName;
        _id = id;
    }

    public string FirstName
    {
        get { return fName; }
    }

    public string LastName
    {
        get { return lName; }
    }

    public string Id
    {
        get { return _id; }
    }

    public override string ToString()
    {
        return String.Format("{0}{1}{2}", fName,
                             String.IsNullOrEmpty(fName) ? "" : " ",
                             lName);
    }
}

public class Doctor : Person
{
    public Doctor(string firstName, string lastName, string id)
    {

    }

    public override string ToString()
    {
        return "Dr. " + base.ToString();
    }
}

// Attempting to compile the example displays output like the following:
//   ctor1.cs(45,11): error CS1729: 'Person' does not contain a constructor that takes 0
//   arguments
//   ctor1.cs(10,11): (Location of symbol related to previous error)
```

```

<Assembly: CLSCompliant(True)>

Public Class Person
    Private fName, lName, _id As String

    Public Sub New(firstName As String, lastName As String, id As String)
        If String.IsNullOrEmpty(firstName + lastName) Then
            Throw New ArgumentNullException("Either a first name or a last name must be provided.")
        End If

        fName = firstName
        lName = lastName
        _id = id
    End Sub

    Public ReadOnly Property FirstName As String
        Get
            Return fName
        End Get

            Return lName
        End Get
    End Property

    Public ReadOnly Property Id As String
        Get
            Return _id
        End Get
    End Property

    Public Overrides Function ToString() As String
        Return String.Format("{0}{1}{2}", fName,
            If(String.IsNullOrEmpty(fName), "", " "),
            lName)
    End Function
End Class

Public Class Doctor : Inherits Person
    Public Sub New(firstName As String, lastName As String, id As String)
    End Sub

    Public Overrides Function ToString() As String
        Return "Dr. " + MyBase.ToString()
    End Function
End Class

' Attempting to compile the example displays output like the following:
'   Ctor1.vb(46) : error BC30148: First statement of this 'Sub New' must be a call
'   to 'MyBase.New' or 'MyClass.New' because base class 'Person' of 'Doctor' does
'   not have an accessible 'Sub New' that can be called with no arguments.
'
'   Public Sub New()
'       ~~~

```

- An object constructor cannot be called except to create an object. In addition, an object cannot be initialized twice. For example, this means that `Object.MemberwiseClone` must not call constructors.

Properties

Properties in CLS-compliant types must follow these rules:

- A property must have a setter, a getter, or both. In an assembly, these are implemented as special methods, which means that they will appear as separate methods (the getter is named `get_PropertyName` and the setter is `set_PropertyName`) marked as `SpecialName` in the assembly's metadata. The C# compiler enforces

this rule automatically without the need to apply the [CLSCompliantAttribute](#) attribute.

- A property's type is the return type of the property getter and the last argument of the setter. These types must be CLS compliant, and arguments cannot be assigned to the property by reference (that is, they cannot be managed pointers).
- If a property has both a getter and a setter, they must both be virtual, both static, or both instance. The C# compiler automatically enforces this rule through property definition syntax.

Events

An event is defined by its name and its type. The event type is a delegate that is used to indicate the event. For example, the `DbConnection.StateChange` event is of type `StateChangeEventHandler`. In addition to the event itself, three methods with names based on the event name provide the event's implementation and are marked as `SpecialName` in the assembly's metadata:

- A method for adding an event handler, named `add_EventName`. For example, the event subscription method for the `DbConnection.StateChange` event is named `add_StateChange`.
- A method for removing an event handler, named `remove_EventName`. For example, the removal method for the `DbConnection.StateChange` event is named `remove_StateChange`.
- A method for indicating that the event has occurred, named `raise_EventName`.

NOTE

Most of the Common Language Specification's rules regarding events are implemented by language compilers and are transparent to component developers.

The methods for adding, removing, and raising the event must have the same accessibility. They must also all be static, instance, or virtual. The methods for adding and removing an event have one parameter whose type is the event delegate type. The add and remove methods must both be present or both be absent.

The following example defines a CLS-compliant class named `Temperature` that raises a `TemperatureChangedEventArgs` event if the change in temperature between two readings equals or exceeds a threshold value. The `Temperature` class explicitly defines a `raise_TemperatureChanged` method so that it can selectively execute event handlers.

```
using System;
using System.Collections;
using System.Collections.Generic;

[assembly: CLSCompliant(true)]

public class TemperatureChangedEventArgs : EventArgs
{
    private Decimal originalTemp;
    private Decimal newTemp;
    private DateTimeOffset when;

    public TemperatureChangedEventArgs(Decimal original, Decimal @new, DateTimeOffset time)
    {
        originalTemp = original;
        newTemp = @new;
        when = time;
    }

    public Decimal OldTemperature
    {
        get { return originalTemp; }
    }
}
```

```

public Decimal CurrentTemperature
{
    get { return newTemp; }
}

public DateTimeOffset Time
{
    get { return when; }
}
}

public delegate void TemperatureChanged(Object sender, TemperatureChangedEventArgs e);

public class Temperature

```

Overloads

The Common Language Specification imposes the following requirements on overloaded members:

- Members can be overloaded based on the number of parameters and the type of any parameter. Calling convention, return type, custom modifiers applied to the method or its parameter, and whether parameters are passed by value or by reference are not considered when differentiating between overloads. For an example, see the code for the requirement that names must be unique within a scope in the [Naming conventions](#) section.
- Only properties and methods can be overloaded. Fields and events cannot be overloaded.
- Generic methods can be overloaded based on the number of their generic parameters.

NOTE

The `op_Explicit` and `op_Implicit` operators are exceptions to the rule that return value is not considered part of a method signature for overload resolution. These two operators can be overloaded based on both their parameters and their return value.

Exceptions

Exception objects must derive from `System.Exception` or from another type derived from `System.Exception`. The following example illustrates the compiler error that results when a custom class named `ErrorClass` is used for exception handling.

```
using System;

[assembly: CLSCompliant(true)]

public class ErrorClass
{
    string msg;

    public ErrorClass(string errorMessage)
    {
        msg = errorMessage;
    }

    public string Message
    {
        get { return msg; }
    }
}

public static class StringUtilities
{
    public static string[] SplitString(this string value, int index)
    {
        if (index < 0 | index > value.Length) {
            ErrorClass badIndex = new ErrorClass("The index is not within the string.");
            throw badIndex;
        }
        string[] retVal = { value.Substring(0, index - 1),
                           value.Substring(index) };
        return retVal;
    }
}

// Compilation produces a compiler error like the following:
//     Exceptions1.cs(26,16): error CS0155: The type caught or thrown must be derived from
//         System.Exception
```

```

Imports System.Runtime.CompilerServices

<Assembly: CLSCompliant(True)>

    Dim msg As String

    Public Sub New(errorMessage As String)
        msg = errorMessage
    End Sub

    Public ReadOnly Property Message As String
        Get
            Return msg
        End Get
    End Property
End Class

Public Module StringUtilities
    <Extension()> Public Function SplitString(value As String, index As Integer) As String()
        If index < 0 Or index > value.Length Then
            Dim BadIndex As New ErrorClass("The index is not within the string.")
            Throw BadIndex
        End If
        Dim retVal() As String = { value.Substring(0, index - 1),
                                  value.Substring(index) }
        Return retVal
    End Function
End Module

' Compilation produces a compiler error like the following:
'   Exceptions1.vb(27) : error BC30665: 'Throw' operand must derive from 'System.Exception'.
'
'           Throw BadIndex
' ~~~~~

```

To correct this error, the `ErrorClass` class must inherit from `System.Exception`. In addition, the `Message` property must be overridden. The following example corrects these errors to define an `ErrorClass` class that is CLS-compliant.

```

using System;

[assembly: CLSCompliant(true)]

public class ErrorClass : Exception
{
    string msg;

    public ErrorClass(string errorMessage)
    {
        msg = errorMessage;
    }

    public override string Message
    {
        get { return msg; }
    }
}

public static class StringUtilities
{
    public static string[] SplitString(this string value, int index)
    {
        if (index < 0 | index > value.Length) {
            ErrorClass badIndex = new ErrorClass("The index is not within the string.");
            throw badIndex;
        }
        string[] retVal = { value.Substring(0, index - 1),
                           value.Substring(index) };
        return retVal;
    }
}

```

```

Imports System.Runtime.CompilerServices

<Assembly: CLSCompliant(True)>

Public Class ErrorClass : Inherits Exception
    Dim msg As String

    Public Sub New(errorMessage As String)
        msg = errorMessage
    End Sub

    Public Overrides ReadOnly Property Message As String
        Get
            Return msg
        End Get
    End Property
End Class

Public Module StringUtilities
    <Extension()> Public Function SplitString(value As String, index As Integer) As String()
        If index < 0 Or index > value.Length Then
            Dim BadIndex As New ErrorClass("The index is not within the string.")
            Throw BadIndex
        End If
        Dim retVal() As String = { value.Substring(0, index - 1),
                                  value.Substring(index) }
        Return retVal
    End Function
End Module

```

Attributes

In .NET Framework assemblies, custom attributes provide an extensible mechanism for storing custom attributes and retrieving metadata about programming objects, such as assemblies, types, members, and method parameters. Custom attributes must derive from [System.Attribute](#) or from a type derived from [System.Attribute](#).

The following example violates this rule. It defines a `NumericAttribute` class that does not derive from `System.Attribute`. Note that a compiler error results only when the non-CLS-compliant attribute is applied, not when the class is defined.

```
using System;

[assembly: CLSCompliant(true)]

[AttributeUsageAttribute(AttributeTargets.Class | AttributeTargets.Struct)]
public class NumericAttribute
{
    private bool _isNumeric;

    public NumericAttribute(bool isNumeric)
    {
        _isNumeric = isNumeric;
    }

    public bool IsNumeric
    {
        get { return _isNumeric; }
    }
}

[Numeric(true)] public struct UDouble
{
    double Value;
}

// Compilation produces a compiler error like the following:
//   Attribute1.cs(22,2): error CS0616: 'NumericAttribute' is not an attribute class
//   Attribute1.cs(7,14): (Location of symbol related to previous error)
```

```
<Assembly: CLSCompliant(True)>

<AttributeUsageAttribute(AttributeTargets.Class Or AttributeTargets.Struct)> _
Public Class NumericAttribute
    Private _isNumeric As Boolean

    Public Sub New(isNumeric As Boolean)
        _isNumeric = isNumeric
    End Sub

    Public ReadOnly Property IsNumeric As Boolean
        Get
            Return _isNumeric
        End Get
    End Property
End Class

<Numeric(True)> Public Structure UDouble
    Dim Value As Double
End Structure

' Compilation produces a compiler error like the following:
'   error BC31504: 'NumericAttribute' cannot be used as an attribute because it
'   does not inherit from 'System.Attribute'.
'

'   <Numeric(True)> Public Structure UDouble
'       ~~~~~~
```

The constructor or the properties of a CLS-compliant attribute can expose only the following types:

- `Boolean`
- `Byte`
- `Char`
- `Double`
- `Int16`
- `Int32`
- `Int64`
- `Single`
- `String`
- `Type`
- Any enumeration type whose underlying type is `Byte`, `Int16`, `Int32`, or `Int64`.

The following example defines a `DescriptionAttribute` class that derives from `Attribute`. The class constructor has a parameter of type `Descriptor`, so the class is not CLS-compliant. Note that the C# compiler emits a warning but compiles successfully.

```
using System;

[assembly:CLSClaimedAttribute(true)]

public enum DescriptorType { type, member };

public class Descriptor
{
    public DescriptorType Type;
    public String Description;
}

[AttributeUsage(AttributeTargets.All)]
public class DescriptionAttribute : Attribute
{
    private Descriptor desc;

    public DescriptionAttribute(Descriptor d)
    {
        desc = d;
    }

    public Descriptor Descriptor
    { get { return desc; } }
}

// Attempting to compile the example displays output like the following:
//      warning CS3015: 'DescriptionAttribute' has no accessible
//                      constructors which use only CLS-compliant types
```

```

<Assembly:CLSCCompliantAttribute(True)>

Public Enum DescriptorType As Integer
    Type = 0
    Member = 1
End Enum

Public Class Descriptor
    Public Type As DescriptorType
    Public Description As String
End Class

<AttributeUsage(AttributeTargets.All)> _
Public Class DescriptionAttribute : Inherits Attribute
    Private desc As Descriptor

    Public Sub New(d As Descriptor)
        desc = d
    End Sub

    Public ReadOnly Property Descriptor As Descriptor
        Get
            Return desc
        End Get
    End Property
End Class

```

The CLSCCompliantAttribute attribute

The [CLSCCompliantAttribute](#) attribute is used to indicate whether a program element complies with the Common Language Specification. The `CLSCCompliantAttribute(CLSCCompliantAttribute(Boolean))` constructor includes a single required parameter, *isCompliant*, that indicates whether the program element is CLS-compliant.

At compile time, the compiler detects non-compliant elements that are presumed to be CLS-compliant and emits a warning. The compiler does not emit warnings for types or members that are explicitly declared to be non-compliant.

Component developers can use the `CLSCCompliantAttribute` attribute in two ways:

- To define the parts of the public interface exposed by a component that are CLS-compliant and the parts that are not CLS-compliant. When the attribute is used to mark particular program elements as CLS-compliant, its use guarantees that those elements are accessible from all languages and tools that target the .NET Framework.
- To ensure that the component library's public interface exposes only program elements that are CLS-compliant. If elements are not CLS-compliant, compilers will generally issue a warning.

WARNING

In some cases, language compilers enforce CLS-compliant rules regardless of whether the `CLSCCompliantAttribute` attribute is used. For example, defining a `*static` member in an interface violates a CLS rule. However, if you define a `*static` member in an interface, the C# compiler displays an error message and fails to compile the app.

The `CLSCCompliantAttribute` attribute is marked with an [AttributeUsageAttribute](#) attribute that has a value of `AttributeTargets.All`. This value allows you to apply the `CLSCCompliantAttribute` attribute to any program element, including assemblies, modules, types (classes, structures, enumerations, interfaces, and delegates), type members (constructors, methods, properties, fields, and events), parameters, generic parameters, and return values. However, in practice, you should apply the attribute only to assemblies, types, and type members. Otherwise, compilers

ignore the attribute and continue to generate compiler warnings whenever they encounter a non-compliant parameter, generic parameter, or return value in your library's public interface.

The value of the `CLSCompliantAttribute` attribute is inherited by contained program elements. For example, if an assembly is marked as CLS-compliant, its types are also CLS-compliant. If a type is marked as CLS-compliant, its nested types and members are also CLS-compliant.

You can explicitly override the inherited compliance by applying the `CLSCompliantAttribute` attribute to a contained program element. For example, you can use the `CLSCompliantAttribute` attribute with an `isCompliant` value of `false` to define a non-compliant type in a compliant assembly, and you can use the attribute with an `isCompliant` value of `true` to define a compliant type in a non-compliant assembly. You can also define non-compliant members in a compliant type. However, a non-compliant type cannot have compliant members, so you cannot use the attribute with an `isCompliant` value of `true` to override inheritance from a non-compliant type.

When you are developing components, you should always use the `CLSCompliantAttribute` attribute to indicate whether your assembly, its types, and its members are CLS-compliant.

To create CLS-compliant components:

1. Use the `CLSCompliantAttribute` to mark your assembly as CLS-compliant.
2. Mark any publicly exposed types in the assembly that are not CLS-compliant as non-compliant.
3. Mark any publicly exposed members in CLS-compliant types as non-compliant.
4. Provide a CLS-compliant alternative for non-CLS-compliant members.

If you've successfully marked all your non-compliant types and members, your compiler should not emit any non-compliance warnings. However, you should indicate which members are not CLS-compliant and list their CLS-compliant alternatives in your product documentation.

The following example uses the `CLSCompliantAttribute` attribute to define a CLS-compliant assembly and a type, `CharacterUtilities`, that has two non-CLS-compliant members. Because both members are tagged with the `CLSCompliant(false)` attribute, the compiler produces no warnings. The class also provides a CLS-compliant alternative for both methods. Ordinarily, we would just add two overloads to the `ToUTF16` method to provide CLS-compliant alternatives. However, because methods cannot be overloaded based on return value, the names of the CLS-compliant methods are different from the names of the non-compliant methods.

```
using System;
using System.Text;

[assembly:CLSCompliant(true)]

public class CharacterUtilities
{
    [CLSCompliant(false)] public static ushort ToUTF16(String s)
    {
        s = s.Normalize(NormalizationForm.FormC);
        return Convert.ToInt16(s[0]);
    }

    [CLSCompliant(false)] public static ushort ToUTF16(Char ch)
    {
        return Convert.ToInt16(ch);
    }

    // CLS-compliant alternative for ToUTF16(String).
    public static int ToUTF16CodeUnit(String s)
    {
        s = s.Normalize(NormalizationForm.FormC);
        return (int) Convert.ToInt16(s[0]);
    }

    // CLS-compliant alternative for ToUTF16(Char).
    public static int ToUTF16CodeUnit(Char ch)
    {
        return Convert.ToInt32(ch);
    }

    public bool HasMultipleRepresentations(String s)
    {
        String s1 = s.Normalize(NormalizationForm.FormC);
        return s.Equals(s1);
    }

    public int GetUnicodeCodePoint(Char ch)
    {
        if (Char.IsSurrogate(ch))
            throw new ArgumentException("ch cannot be a high or low surrogate.");

        return Char.ConvertToUtf32(ch.ToString(), 0);
    }

    public int GetUnicodeCodePoint(Char[] chars)
    {
        if (chars.Length > 2)
            throw new ArgumentException("The array has too many characters.");

        if (chars.Length == 2) {
            if (! Char.IsSurrogatePair(chars[0], chars[1]))
                throw new ArgumentException("The array must contain a low and a high surrogate.");
            else
                return Char.ConvertToUtf32(chars[0], chars[1]);
        }
        else {
            return Char.ConvertToUtf32(chars.ToString(), 0);
        }
    }
}
```

```

Imports System.Text

<Assembly:CLSCompliant(True)>

Public Class CharacterUtilities
    <CLSCompliant(False)> Public Shared Function ToUTF16(s As String) As UShort
        s = s.Normalize(NormalizationForm.FormC)
        Return Convert.ToInt16(s(0))
    End Function

    <CLSCompliant(False)> Public Shared Function ToUTF16(ch As Char) As UShort
        Return Convert.ToInt16(ch)
    End Function

    ' CLS-compliant alternative for ToUTF16(String).
    Public Shared Function ToUTF16CodeUnit(s As String) As Integer
        s = s.Normalize(NormalizationForm.FormC)
        Return CInt(Convert.ToInt16(s(0)))
    End Function

    ' CLS-compliant alternative for ToUTF16(Char).
    Public Shared Function ToUTF16CodeUnit(ch As Char) As Integer
        Return Convert.ToInt32(ch)
    End Function

    Public Function HasMultipleRepresentations(s As String) As Boolean
        Dim s1 As String = s.Normalize(NormalizationForm.FormC)
        Return s.Equals(s1)
    End Function

    Public Function GetUnicodeCodePoint(ch As Char) As Integer
        If Char.IsSurrogate(ch) Then
            Throw New ArgumentException("ch cannot be a high or low surrogate.")
        End If
        Return Char.ConvertToUtf32(ch.ToString(), 0)
    End Function

    Public Function GetUnicodeCodePoint(chars() As Char) As Integer
        If chars.Length > 2 Then
            Throw New ArgumentException("The array has too many characters.")
        End If
        If chars.Length = 2 Then
            If Not Char.IsSurrogatePair(chars(0), chars(1)) Then
                Throw New ArgumentException("The array must contain a low and a high surrogate.")
            Else
                Return Char.ConvertToUtf32(chars(0), chars(1))
            End If
        Else
            Return Char.ConvertToUtf32(chars.ToString(), 0)
        End If
    End Function
End Class

```

If you are developing an app rather than a library (that is, if you aren't exposing types or members that can be consumed by other app developers), the CLS compliance of the program elements that your app consumes are of interest only if your language does not support them. In that case, your language compiler will generate an error when you try to use a non-CLS-compliant element.

Cross-Language Interoperability

Language independence has a number of possible meanings. One meaning involves seamlessly consuming types written in one language from an app written in another language. A second meaning, which is the focus of this article, involves combining code written in multiple languages into a single .NET Framework assembly.

The following example illustrates cross-language interoperability by creating a class library named Utilities.dll that includes two classes, `NumericLib` and `StringLib`. The `NumericLib` class is written in C#, and the `StringLib` class is written in Visual Basic. Here's the source code for `StringUtil.vb`, which includes a single member, `ToTitleCase`, in its `StringLib` class.

```
Imports System.Collections.Generic
Imports System.Runtime.CompilerServices

Public Module StringLib
    Private exclusions As List(Of String)

    Sub New()
        Dim words() As String = { "a", "an", "and", "of", "the" }
        exclusions = New List(Of String)
        exclusions.AddRange(words)
    End Sub

    <Extension()> _
    Public Function ToTitleCase(title As String) As String
        Dim words() As String = title.Split()
        Dim result As String = String.Empty

        For ctr As Integer = 0 To words.Length - 1
            Dim word As String = words(ctr)
            If ctr = 0 OrElse Not exclusions.Contains(word.ToLower()) Then
                result += word.Substring(0, 1).ToUpper() + _
                          word.Substring(1).ToLower()
            Else
                result += word.ToLower()
            End If
            If ctr <= words.Length - 1 Then
                result += " "
            End If
        Next
        Return result
    End Function
End Module
```

Here's the source code for NumberUtil.cs, which defines a `NumericLib` class that has two members, `IsEven` and `NearZero`.

```

using System;

public static class NumericLib
{
    public static bool IsEven(this IConvertible number)
    {
        if (number is Byte ||
            number is SByte ||
            number is Int16 ||
            number is UInt16 ||
            number is Int32 ||
            number is UInt32 ||
            number is Int64)
            return ((long) number) % 2 == 0;
        else if (number is UInt64)
            return ((ulong) number) % 2 == 0;
        else
            throw new NotSupportedException("IsEven called for a non-integer value.");
    }

    public static bool NearZero(double number)
    {
        return number < .00001;
    }
}

```

To package the two classes in a single assembly, you must compile them into modules. To compile the Visual Basic source code file into a module, use this command:

```
vbc /t:module StringUtil.vb
```

To compile the C# source code file into a module, use this command:

```
csc /t:module NumberUtil.cs
```

You then use the Link tool (Link.exe) to compile the two modules into an assembly:

```
link numberutil.netmodule stringutil.netmodule /out:UtilityLib.dll /dll
```

The following example then calls the `NumericLib.NearZero` and `StringLib.ToTitleCase` methods. Note that both the Visual Basic code and the C# code are able to access the methods in both classes.

```

using System;

public class Example
{
    public static void Main()
    {
        Double dbl = 0.0 - Double.Epsilon;
        Console.WriteLine(NumericLib.NearZero(dbl));

        string s = "war and peace";
        Console.WriteLine(s.ToTitleCase());
    }
}
// The example displays the following output:
//      True
//      War and Peace

```

```
Module Example
    Public Sub Main()
        Dim dbl As Double = 0.0 - Double.Epsilon
        Console.WriteLine(NumericLib.NearZero(dbl))

        Dim s As String = "war and peace"
        Console.WriteLine(s.ToTitleCase())
    End Sub
End Module
' The example displays the following output:
'      True
'      War and Peace
```

To compile the Visual Basic code, use this command:

```
vbc example.vb /r:UtilityLib.dll
```

To compile with C#, change the name of the compiler from vbc to csc, and change the file extension from .vb to .cs:

```
csc example.cs /r:UtilityLib.dll
```

Language Independence and Language-Independent Components

3/14/2019 • 68 minutes to read • [Edit Online](#)

The .NET Framework is language independent. This means that, as a developer, you can develop in one of the many languages that target the .NET Framework, such as C#, C++/CLI, Eiffel, F#, IronPython, IronRuby, PowerBuilder, Visual Basic, Visual COBOL, and Windows PowerShell. You can access the types and members of class libraries developed for the .NET Framework without having to know the language in which they were originally written and without having to follow any of the original language's conventions. If you are a component developer, your component can be accessed by any .NET Framework app regardless of its language.

NOTE

This first part of this article discusses creating language-independent components—that is, components that can be consumed by apps that are written in any language. You can also create a single component or app from source code written in multiple languages; see [Cross-Language Interoperability](#) in the second part of this article.

To fully interact with other objects written in any language, objects must expose to callers only those features that are common to all languages. This common set of features is defined by the Common Language Specification (CLS), which is a set of rules that apply to generated assemblies. The Common Language Specification is defined in Partition I, Clauses 7 through 11 of the [ECMA-335 Standard: Common Language Infrastructure](#).

If your component conforms to the Common Language Specification, it is guaranteed to be CLS-compliant and can be accessed from code in assemblies written in any programming language that supports the CLS. You can determine whether your component conforms to the Common Language Specification at compile time by applying the [CLSCompliantAttribute](#) attribute to your source code. For more information, see [The CLSCompliantAttribute attribute](#).

CLS compliance rules

This section discusses the rules for creating a CLS-compliant component. For a complete list of rules, see Partition I, Clause 11 of the [ECMA-335 Standard: Common Language Infrastructure](#).

NOTE

The Common Language Specification discusses each rule for CLS compliance as it applies to consumers (developers who are programmatically accessing a component that is CLS-compliant), frameworks (developers who are using a language compiler to create CLS-compliant libraries), and extenders (developers who are creating a tool such as a language compiler or a code parser that creates CLS-compliant components). This article focuses on the rules as they apply to frameworks. Note, though, that some of the rules that apply to extenders may also apply to assemblies that are created using `Reflection.Emit`.

To design a component that is language independent, you only need to apply the rules for CLS compliance to your component's public interface. Your private implementation does not have to conform to the specification.

IMPORTANT

The rules for CLS compliance apply only to a component's public interface, not to its private implementation.

For example, unsigned integers other than `Byte` are not CLS-compliant. Because the `Person` class in the following example exposes an `Age` property of type `UInt16`, the following code displays a compiler warning.

```
using System;

[assembly: CLSCompliant(true)]

public class Person
{
    private UInt16 personAge = 0;

    public UInt16 Age
    { get { return personAge; } }

}

// The attempt to compile the example displays the following compiler warning:
//    Public1.cs(10,18): warning CS3003: Type of 'Person.Age' is not CLS-compliant
```

```

<Assembly: CLSCompliant(True)>

Public Class Person
    Private personAge As UInt16

    Public ReadOnly Property Age As UInt16
        Get
            Return personAge
        End Get
    End Property
End Class
' The attempt to compile the example displays the following compiler warning:
'   Public1.vb(9) : warning BC40027: Return type of function 'Age' is not CLS-compliant.
'
'   Public ReadOnly Property Age As UInt16
'       ~~~

```

You can make the `Person` class CLS-compliant by changing the type of `Age` property from `UInt16` to `Int16`, which is a CLS-compliant, 16-bit signed integer. You do not have to change the type of the private `personAge` field.

```

using System;

[assembly: CLSCompliant(true)]

public class Person
{
    private Int16 personAge = 0;

    public Int16 Age
    { get { return personAge; } }
}

```

```

<Assembly: CLSCompliant(True)>

Public Class Person
    Private personAge As UInt16

    Public ReadOnly Property Age As Int16
        Get
            Return CType(personAge, Int16)
        End Get
    End Property
End Class

```

A library's public interface consists of the following:

- Definitions of public classes.
- Definitions of the public members of public classes, and definitions of members accessible to derived classes (that is, protected members).
- Parameters and return types of public methods of public classes, and parameters and return types of methods accessible to derived classes.

The rules for CLS compliance are listed in the following table. The text of the rules is taken verbatim from the [ECMA-335 Standard: Common Language Infrastructure](#), which is Copyright 2012 by Ecma International. More detailed information about these rules is found in the following sections.

CATEGORY	SEE	RULE	RULE NUMBER
Accessibility	Member accessibility	Accessibility shall not be changed when overriding inherited methods, except when overriding a method inherited from a different assembly with accessibility <code>family-or-assembly</code> . In this case, the override shall have accessibility <code>family</code> .	10
Accessibility	Member accessibility	The visibility and accessibility of types and members shall be such that types in the signature of any member shall be visible and accessible whenever the member itself is visible and accessible. For example, a public method that is visible outside its assembly shall not have an argument whose type is visible only within the assembly. The visibility and accessibility of types composing an instantiated generic type used in the signature of any member shall be visible and accessible whenever the member itself is visible and accessible. For example, an instantiated generic type present in the signature of a member that is visible outside its assembly shall not have a generic argument whose type is visible only within the assembly.	12
Arrays	Arrays	Arrays shall have elements with a CLS-compliant type, and all dimensions of the array shall have lower bounds of zero. Only the fact that an item is an array and the element type of the array shall be required to distinguish between overloads. When overloading is based on two or more array types the element types shall be named types.	16
Attributes	Attributes	Attributes shall be of type <code>System.Attribute</code> , or a type inheriting from it.	41

CATEGORY	SEE	RULE	RULE NUMBER
Attributes	Attributes	The CLS only allows a subset of the encodings of custom attributes. The only types that shall appear in these encodings are (see Partition IV): System.Type , System.String , System.Char , System.Boolean , System.Byte , System.Int16 , System.Int32 , System.Int64 , System.Single , System.Double , and any enumeration type based on a CLS-compliant base integer type.	34
Attributes	Attributes	The CLS does not allow publicly visible required modifiers (<code>modreq</code> , see Partition II), but does allow optional modifiers (<code>modopt</code> , see Partition II) it does not understand.	35
Constructors	Constructors	An object constructor shall call some instance constructor of its base class before any access occurs to inherited instance data. (This does not apply to value types, which need not have constructors.)	21
Constructors	Constructors	An object constructor shall not be called except as part of the creation of an object, and an object shall not be initialized twice.	22
Enumerations	Enumerations	The underlying type of an enum shall be a built-in CLS integer type, the name of the field shall be "value_ ", and that field shall be marked <code>RTSpecialName</code> .	7
Enumerations	Enumerations	There are two distinct kinds of enums, indicated by the presence or absence of the System.FlagsAttribute (see Partition IV Library) custom attribute. One represents named integer values; the other represents named bit flags that can be combined to generate an unnamed value. The value of an <code>enum</code> is not limited to the specified values.	8

CATEGORY	SEE	RULE	RULE NUMBER
Enumerations	Enumerations	Literal static fields of an enum shall have the type of the enum itself.	9
Events	Events	The methods that implement an event shall be marked <code>SpecialName</code> in the metadata.	29
Events	Events	The accessibility of an event and of its accessors shall be identical.	30
Events	Events	The <code>add</code> and <code>remove</code> methods for an event shall both either be present or absent.	31
Events	Events	The <code>add</code> and <code>remove</code> methods for an event shall each take one parameter whose type defines the type of the event and that shall be derived from System.Delegate .	32
Events	Events	Events shall adhere to a specific naming pattern. The <code>SpecialName</code> attribute referred to in CLS rule 29 shall be ignored in appropriate name comparisons and shall adhere to identifier rules.	33
Exceptions	Exceptions	Objects that are thrown shall be of type System.Exception or a type inheriting from it. Nonetheless, CLS-compliant methods are not required to block the propagation of other types of exceptions.	40
General	CLS compliance: the Rules	CLS rules apply only to those parts of a type that are accessible or visible outside of the defining assembly.	1
General	CLS compliance: the Rules	Members of non-CLS compliant types shall not be marked CLS-compliant.	2

CATEGORY	SEE	RULE	RULE NUMBER
Generics	Generic types and members	Nested types shall have at least as many generic parameters as the enclosing type. Generic parameters in a nested type correspond by position to the generic parameters in its enclosing type.	42
Generics	Generic types and members	The name of a generic type shall encode the number of type parameters declared on the non-nested type, or newly introduced to the type if nested, according to the rules defined above.	43
Generics	Generic types and members	A generic type shall redeclare sufficient constraints to guarantee that any constraints on the base type, or interfaces would be satisfied by the generic type constraints.	4444
Generics	Generic types and members	Types used as constraints on generic parameters shall themselves be CLS-compliant.	45
Generics	Generic types and members	The visibility and accessibility of members (including nested types) in an instantiated generic type shall be considered to be scoped to the specific instantiation rather than the generic type declaration as a whole. Assuming this, the visibility and accessibility rules of CLS rule 12 still apply.	46
Generics	Generic types and members	For each abstract or virtual generic method, there shall be a default concrete (non-abstract) implementation.	47
Interfaces	Interfaces	CLS-compliant interfaces shall not require the definition of non-CLS compliant methods in order to implement them.	18
Interfaces	Interfaces	CLS-compliant interfaces shall not define static methods, nor shall they define fields.	19

CATEGORY	SEE	RULE	RULE NUMBER
Members	Type members in general	Global static fields and methods are not CLS-compliant.	36
Members	--	The value of a literal static is specified through the use of field initialization metadata. A CLS-compliant literal must have a value specified in field initialization metadata that is of exactly the same type as the literal (or of the underlying type, if that literal is an <code>enum</code>).	13
Members	Type members in general	The vararg constraint is not part of the CLS, and the only calling convention supported by the CLS is the standard managed calling convention.	15
Naming conventions	Naming conventions	Assemblies shall follow Annex 7 of Technical Report 15 of the Unicode Standard3.0 governing the set of characters permitted to start and be included in identifiers, available online at https://www.unicode.org/unicode/reports/tr15/tr15-18.html . Identifiers shall be in the canonical format defined by Unicode Normalization Form C. For CLS purposes, two identifiers are the same if their lowercase mappings (as specified by the Unicode locale-insensitive, one-to-one lowercase mappings) are the same. That is, for two identifiers to be considered different under the CLS they shall differ in more than simply their case. However, in order to override an inherited definition the CLI requires the precise encoding of the original declaration be used.	4

CATEGORY	SEE	RULE	RULE NUMBER
Overloading	Naming conventions	All names introduced in a CLS-compliant scope shall be distinct independent of kind, except where the names are identical and resolved via overloading. That is, while the CTS allows a single type to use the same name for a method and a field, the CLS does not.	5
Overloading	Naming conventions	Fields and nested types shall be distinct by identifier comparison alone, even though the CTS allows distinct signatures to be distinguished. Methods, properties, and events that have the same name (by identifier comparison) shall differ by more than just the return type, except as specified in CLS Rule 39.	6
Overloading	Overloads	Only properties and methods can be overloaded.	37
Overloading	Overloads	Properties and methods can be overloaded based only on the number and types of their parameters, except the conversion operators named <code>op_Implicit</code> and <code>op_Explicit</code> , which can also be overloaded based on their return type.	38
Overloading	--	If two or more CLS-compliant methods declared in a type have the same name and, for a specific set of type instantiations, they have the same parameter and return types, then all these methods shall be semantically equivalent at those type instantiations.	48
Types	Type and type member signatures	<code>System.Object</code> is CLS-compliant. Any other CLS-compliant class shall inherit from a CLS-compliant class.	23

CATEGORY	SEE	RULE	RULE NUMBER
Properties	Properties	The methods that implement the getter and setter methods of a property shall be marked <code>SpecialName</code> in the metadata.	24
Properties	Properties	A property's accessors shall all be static, all be virtual, or all be instance.	26
Properties	Properties	The type of a property shall be the return type of the getter and the type of the last argument of the setter. The types of the parameters of the property shall be the types of the parameters to the getter and the types of all but the final parameter of the setter. All of these types shall be CLS-compliant, and shall not be managed pointers (i.e., shall not be passed by reference).	27
Properties	Properties	Properties shall adhere to a specific naming pattern. The <code>SpecialName</code> attribute referred to in CLS rule 24 shall be ignored in appropriate name comparisons and shall adhere to identifier rules. A property shall have a getter method, a setter method, or both.	28
Type conversion	Type conversion	If either <code>op_Implicit</code> or <code>op_Explicit</code> is provided, an alternate means of providing the coercion shall be provided.	39
Types	Type and type member signatures	Boxed value types are not CLS-compliant.	3
Types	Type and type member signatures	All types appearing in a signature shall be CLS-compliant. All types composing an instantiated generic type shall be CLS-compliant.	11
Types	Type and type member signatures	Typed references are not CLS-compliant.	14

Category	See	Rule	Rule Number
Types	Type and type member signatures	Unmanaged pointer types are not CLS-compliant.	17
Types	Type and type member signatures	CLS-compliant classes, value types, and interfaces shall not require the implementation of non-CLS-compliant members.	20

Types and type member signatures

The [System.Object](#) type is CLS-compliant and is the base type of all object types in the .NET Framework type system. Inheritance in the .NET Framework is either implicit (for example, the [String](#) class implicitly inherits from the [Object](#) class) or explicit (for example, the [CultureNotFoundException](#) class explicitly inherits from the [ArgumentException](#) class, which explicitly inherits from the [SystemException](#) class, which explicitly inherits from the [Exception](#) class). For a derived type to be CLS compliant, its base type must also be CLS-compliant.

The following example shows a derived type whose base type is not CLS-compliant. It defines a base [Counter](#) class that uses an unsigned 32-bit integer as a counter. Because the class provides counter functionality by wrapping an unsigned integer, the class is marked as non-CLS-compliant. As a result, a derived class, [NonZeroCounter](#), is also not CLS-compliant.

```
using System;

[assembly: CLSCompliant(true)]

[CLSCompliant(false)]
public class Counter
{
    UInt32 ctr;

    public Counter()
    {
        ctr = 0;
    }

    protected Counter(UInt32 ctr)
    {
        this.ctr = ctr;
    }

    public override string ToString()
    {
        return String.Format("{0}"). , ctr);
    }

    public UInt32 Value
    {
        get { return ctr; }
    }

    public void Increment()
    {
        ctr += (uint) 1;
    }
}

public class NonZeroCounter : Counter
{
    public NonZeroCounter(int startIndex) : this((uint) startIndex)
    {

    }

    private NonZeroCounter(UInt32 startIndex) : base(startIndex)
    {
    }
}

// Compilation produces a compiler warning like the following:
// Type3.cs(37,14): warning CS3009: 'NonZeroCounter': base type 'Counter' is not
//           CLS-compliant
// Type3.cs(7,14): (Location of symbol related to previous warning)
```

```

<Assembly: CLSCompliant(True)>

<CLSCompliant(False)> _
Public Class Counter
    Dim ctr As UInt32

    Public Sub New
        ctr = 0
    End Sub

    Protected Sub New(ctr As UInt32)
        This ctr
    End Sub

    Public Overrides Function ToString() As String
        Return String.Format("{0}", ctr)
    End Function

    Public ReadOnly Property Value As UInt32
        Get
            Return ctr
        End Get
    End Property

    Public Sub Increment()
        ctr += CType(1, UInt32)
    End Sub
End Class

Public Class NonZeroCounter : Inherits Counter
    Public Sub New(startIndex As Integer)
        MyBase.New(CType(startIndex, UInt32))
    End Sub

    Private Sub New(startIndex As UInt32)
        MyBase.New(CType(startIndex, UInt32))
    End Sub
End Class

' Compilation produces a compiler warning like the following:
' Type3.vb(34) : warning BC40026: 'NonZeroCounter' is not CLS-compliant
' because it derives from 'Counter', which is not CLS-compliant.
'

' Public Class NonZeroCounter : Inherits Counter
' ~~~~~

```

All types that appear in member signatures, including a method's return type or a property type, must be CLS-compliant. In addition, for generic types:

- All types that compose an instantiated generic type must be CLS-compliant.
- All types used as constraints on generic parameters must be CLS-compliant.

The .NET Framework [common type system](#) includes a number of built-in types that are supported directly by the common language runtime and are specially encoded in an assembly's metadata. Of these intrinsic types, the types listed in the following table are CLS-compliant.

CLS-COMPLIANT TYPE	DESCRIPTION
Byte	8-bit unsigned integer
Int16	16-bit signed integer

CLS-COMPLIANT TYPE	DESCRIPTION
Int32	32-bit signed integer
Int64	64-bit signed integer
Single	Single-precision floating-point value
Double	Double-precision floating-point value
Boolean	<code>true</code> or <code>false</code> value type
Char	UTF-16 encoded code unit
Decimal	Non-floating-point decimal number
IntPtr	Pointer or handle of a platform-defined size
String	Collection of zero, one, or more Char objects

The intrinsic types listed in the following table are not CLS-Compliant.

NON-COMPLIANT TYPE	DESCRIPTION	CLS-COMPLIANT ALTERNATIVE
SByte	8-bit signed integer data type	Int16
TypedReference	Pointer to an object and its runtime type	None
UInt16	16-bit unsigned integer	Int32
UInt32	32-bit unsigned integer	Int64
UInt64	64-bit unsigned integer	Int64 (may overflow), BigInteger , or Double
IntPtr	Unsigned pointer or handle	IntPtr

The .NET Framework Class Library or any other class library may include other types that aren't CLS-compliant; for example:

- Boxed value types. The following C# example creates a class that has a public property of type `int*` named `Value`. Because an `int*` is a boxed value type, the compiler flags it as non-CLS-compliant.

```
using System;

[assembly:CLSClaimed(true)]

public unsafe class TestClass
{
    private int* val;

    public TestClass(int number)
    {
        val = (int*) number;
    }

    public int* Value {
        get { return val; }
    }
}

// The compiler generates the following output when compiling this example:
//     warning CS3003: Type of 'TestClass.Value' is not CLS-compliant
```

- Typed references, which are special constructs that contain a reference to an object and a reference to a type. Typed references are represented in the .NET Framework by the [TypedReference](#) class.

If a type is not CLS-compliant, you should apply the [CLSClaimedAttribute](#) attribute with an `isCompliant` value of `false` to it. For more information, see [The CLSClaimedAttribute attribute](#) section.

The following example illustrates the problem of CLS compliance in a method signature and in generic type instantiation. It defines an `InvoiceItem` class with a property of type `UInt32`, a property of type `Nullable(Of UInt32)`, and a constructor with parameters of type `UInt32` and `Nullable(Of UInt32)`. You get four compiler warnings when you try to compile this example.

```
using System;

[assembly: CLSCompliant(true)]

public class InvoiceItem
{
    private uint invId = 0;
    private uint itemId = 0;
    private Nullable<uint> qty;

    public InvoiceItem(uint sku, Nullable<uint> quantity)
    {
        itemId = sku;
        qty = quantity;
    }

    public Nullable<uint> Quantity
    {
        get { return qty; }
        set { qty = value; }
    }

    public uint InvoiceId
    {
        get { return invId; }
        set { invId = value; }
    }
}

// The attempt to compile the example displays the following output:
//  Type1.cs(13,23): warning CS3001: Argument type 'uint' is not CLS-compliant
//  Type1.cs(13,33): warning CS3001: Argument type 'uint?' is not CLS-compliant
//  Type1.cs(19,26): warning CS3003: Type of 'InvoiceItem.Quantity' is not CLS-compliant
//  Type1.cs(25,16): warning CS3003: Type of 'InvoiceItem.InvoiceId' is not CLS-compliant
```

```

<Assembly: CLSCompliant(True)>

Public Class InvoiceItem

    Private invId As UInteger = 0
    Private itemId As UInteger = 0
    Private qty AS Nullable(Of UInteger)

    Public Sub New(sku As UInteger, quantity As Nullable(Of UInteger))
        itemId = sku
        qty = quantity
    End Sub

    Public Property Quantity As Nullable(Of UInteger)
        Get
            Return qty
        End Get
        Set
            qty = value
        End Set
    End Property

    Public Property InvoiceId As UInteger
        Get
            Return invId
        End Get
        Set
            invId = value
        End Set
    End Property
End Class

' The attempt to compile the example displays output similar to the following:
' Type1.vb(13) : warning BC40028: Type of parameter 'sku' is not CLS-compliant.
'
'     Public Sub New(sku As UInteger, quantity As Nullable(Of UInteger))
'     ~~~
'
' Type1.vb(13) : warning BC40041: Type 'UInteger' is not CLS-compliant.
'
'     Public Sub New(sku As UInteger, quantity As Nullable(Of UInteger))
'     ~~~~~
'
' Type1.vb(18) : warning BC40041: Type 'UInteger' is not CLS-compliant.
'
'     Public Property Quantity As Nullable(Of UInteger)
'     ~~~~~
'
' Type1.vb(27) : warning BC40027: Return type of function 'InvoiceId' is not CLS-compliant.
'
'     Public Property InvoiceId As UInteger
'     ~~~~~

```

To eliminate the compiler warnings, replace the non-CLS-compliant types in the `InvoiceItem` public interface with compliant types:

```
using System;

[assembly: CLSCompliant(true)]

public class InvoiceItem
{
    private uint invId = 0;
    private uint itemId = 0;
    private Nullable<int> qty;

    public InvoiceItem(int sku, Nullable<int> quantity)
    {
        if (sku <= 0)
            throw new ArgumentOutOfRangeException("The item number is zero or negative.");
        itemId = (uint) sku;

        qty = quantity;
    }

    public Nullable<int> Quantity
    {
        get { return qty; }
        set { qty = value; }
    }

    public int InvoiceId
    {
        get { return (int) invId; }
        set {
            if (value <= 0)
                throw new ArgumentOutOfRangeException("The invoice number is zero or negative.");
            invId = (uint) value; }
    }
}
```

```

<Assembly: CLSCompliant(True)>

Public Class InvoiceItem

    Private invId As UInteger = 0
    Private itemId As UInteger = 0
    Private qty AS Nullable(Of Integer)

    Public Sub New(sku As Integer, quantity As Nullable(Of Integer))
        If sku <= 0 Then
            Throw New ArgumentOutOfRangeException("The item number is zero or negative.")
        End If
        itemId = CUInt(sku)
        qty = quantity
    End Sub

    Public Property Quantity As Nullable(Of Integer)
        Get
            Return qty
        End Get
        Set
            qty = value
        End Set
    End Property

    Public Property InvoiceId As Integer
        Get
            Return CInt(invId)
        End Get
        Set
            invId = CUInt(value)
        End Set
    End Property
End Class

```

In addition to the specific types listed, some categories of types are not CLS compliant. These include unmanaged pointer types and function pointer types. The following example generates a compiler warning because it uses a pointer to an integer to create an array of integers.

```

using System;

[assembly: CLSCompliant(true)]

public class ArrayHelper
{
    unsafe public static Array CreateInstance(Type type, int* ptr, int items)
    {
        Array arr = Array.CreateInstance(type, items);
        int* addr = ptr;
        for (int ctr = 0; ctr < items; ctr++) {
            int value = *addr;
            arr.SetValue(value, ctr);
            addr++;
        }
        return arr;
    }
}

// The attempt to compile this example displays the following output:
//     UnmanagedType1.cs(8,57): warning CS3001: Argument type 'int*' is not CLS-compliant

```

For CLS-compliant abstract classes (that is, classes marked as `abstract` in C# or as `MustInherit` in Visual Basic), all members of the class must also be CLS-compliant.

Naming conventions

Because some programming languages are case-insensitive, identifiers (such as the names of namespaces, types, and members) must differ by more than case. Two identifiers are considered equivalent if their lowercase mappings are the same. The following C# example defines two public classes, `Person` and `person`. Because they differ only by case, the C# compiler flags them as not CLS-compliant.

```
using System;

[assembly: CLSCompliant(true)]

public class Person : person
{
}

public class person
{
}

// Compilation produces a compiler warning like the following:
//   Naming1.cs(11,14): warning CS3005: Identifier 'person' differing
//                     only in case is not CLS-compliant
//   Naming1.cs(6,14): (Location of symbol related to previous warning)
```

Programming language identifiers, such as the names of namespaces, types, and members, must conform to the [Unicode Standard 3.0, Technical Report 15, Annex 7](#). This means that:

- The first character of an identifier can be any Unicode uppercase letter, lowercase letter, title case letter, modifier letter, other letter, or letter number. For information on Unicode character categories, see the [System.Globalization.UnicodeCategory](#) enumeration.
- Subsequent characters can be from any of the categories as the first character, and can also include non-spacing marks, spacing combining marks, decimal numbers, connector punctuations, and formatting codes.

Before you compare identifiers, you should filter out formatting codes and convert the identifiers to Unicode Normalization Form C, because a single character can be represented by multiple UTF-16-encoded code units. Character sequences that produce the same code units in Unicode Normalization Form C are not CLS-compliant. The following example defines a property named `Å`, which consists of the character ANGSTROM SIGN (U+212B), and a second property named `Å`, which consists of the character LATIN CAPITAL LETTER A WITH RING ABOVE (U+00C5). Both the C# and Visual Basic compilers flag the source code as non-CLS-compliant.

```

public class Size
{
    private double a1;
    private double a2;

    public double A
    {
        get { return a1; }
        set { a1 = value; }
    }

    public double A
    {
        get { return a2; }
        set { a2 = value; }
    }
}

// Compilation produces a compiler warning like the following:
//   Naming2a.cs(16,18): warning CS3005: Identifier 'Size.A' differing only in case is not
//       CLS-compliant
//   Naming2a.cs(10,18): (Location of symbol related to previous warning)
//   Naming2a.cs(18,8): warning CS3005: Identifier 'Size.A.get' differing only in case is not
//       CLS-compliant
//   Naming2a.cs(12,8): (Location of symbol related to previous warning)
//   Naming2a.cs(19,8): warning CS3005: Identifier 'Size.A.set' differing only in case is not
//       CLS-compliant
//   Naming2a.cs(13,8): (Location of symbol related to previous warning)

```

```

<Assembly: CLSCompliant(True)>
Public Class Size
    Private a1 As Double
    Private a2 As Double

    Public Property A As Double
        Get
            Return a1
        End Get
        Set
            a1 = value
        End Set
    End Property

    Public Property A As Double
        Get
            Return a2
        End Get
        Set
            a2 = value
        End Set
    End Property
End Class

' Compilation produces a compiler warning like the following:
'   Naming1.vb(9) : error BC30269: 'Public Property A As Double' has multiple definitions
'       with identical signatures.
'
'   Public Property A As Double
'       ~

```

Member names within a particular scope (such as the namespaces within an assembly, the types within a namespace, or the members within a type) must be unique except for names that are resolved through overloading. This requirement is more stringent than that of the common type system, which allows multiple members within a scope to have identical names as long as they are different kinds of members (for example, one is a method and one is a field). In particular, for type members:

- Fields and nested types are distinguished by name alone.
- Methods, properties, and events that have the same name must differ by more than just return type.

The following example illustrates the requirement that member names must be unique within their scope. It defines a class named `Converter` that includes four members named `Conversion`. Three are methods, and one is a property. The method that includes an `Int64` parameter is uniquely named, but the two methods with an `Int32` parameter are not, because return value is not considered a part of a member's signature. The `Conversion` property also violates this requirement, because properties cannot have the same name as overloaded methods.

```
using System;

[assembly: CLSCompliant(true)]

public class Converter
{
    public double Conversion(int number)
    {
        return (double) number;
    }

    public float Conversion(int number)
    {
        return (float) number;
    }

    public double Conversion(long number)
    {
        return (double) number;
    }

    public bool Conversion
    {
        get { return true; }
    }
}

// Compilation produces a compiler error like the following:
// Naming3.cs(13,17): error CS0111: Type 'Converter' already defines a member called
//           'Conversion' with the same parameter types
// Naming3.cs(8,18): (Location of symbol related to previous error)
// Naming3.cs(23,16): error CS0102: The type 'Converter' already contains a definition for
//           'Conversion'
// Naming3.cs(8,18): (Location of symbol related to previous error)
```

```

<Assembly: CLSCompliant(True)>

'                 and 'Public Function Conversion(number As Integer) As Single' cannot
'                 overload each other because they differ only by return types.
'

'     Public Function Conversion(number As Integer) As Double
'     ~~~~~
' Naming3.vb(20) : error BC30260: 'Conversion' is already declared as 'Public Function
'                 Conversion(number As Integer) As Single' in this class.
'

'     Public ReadOnly Property Conversion As Boolean
'     ~~~~~

```

Individual languages include unique keywords, so languages that target the common language runtime must also provide some mechanism for referencing identifiers (such as type names) that coincide with keywords. For example, `case` is a keyword in both C# and Visual Basic. However, the following Visual Basic example is able to disambiguate a class named `case` from the `case` keyword by using opening and closing braces. Otherwise, the example would produce the error message, "Keyword is not valid as an identifier," and fail to compile.

```

Public Class [case]
    Private _id As Guid
    Private name As String

    Public Sub New(name As String)
        _id = Guid.NewGuid()
        Me.name = name
    End Sub

    Public ReadOnly Property ClientName As String
        Get
            Return name
        End Get
    End Property
End Class

```

The following C# example is able to instantiate the `case` class by using the `@` symbol to disambiguate the identifier from the language keyword. Without it, the C# compiler would display two error messages, "Type expected" and "Invalid expression term 'case'."

```

using System;

public class Example
{
    public static void Main()
    {
        @case c = new @case("John");
        Console.WriteLine(c.ClientName);
    }
}

```

Type conversion

The Common Language Specification defines two conversion operators:

- `op_Implicit`, which is used for widening conversions that do not result in loss of data or precision. For example, the `Decimal` structure includes an overloaded `op_Implicit` operator to convert values of integral types and `Char` values to `Decimal` values.
- `op_Explicit`, which is used for narrowing conversions that can result in loss of magnitude (a value is converted to a value that has a smaller range) or precision. For example, the `Decimal` structure includes an overloaded `op_Explicit` operator to convert `Double` and `Single` values to `Decimal` and to convert `Decimal` values to integral values, `Double`, `Single`, and `Char`.

However, not all languages support operator overloading or the definition of custom operators. If you choose to implement these conversion operators, you should also provide an alternate way to perform the conversion. We recommend that you provide `From Xxx` and `To Xxx` methods.

The following example defines CLS-compliant implicit and explicit conversions. It creates a `UDouble` class that represents an signed double-precision, floating-point number. It provides for implicit conversions from `UDouble` to `Double` and for explicit conversions from `UDouble` to `Single`, `Double` to `UDouble`, and `Single` to `UDouble`. It also defines a `ToDouble` method as an alternative to the implicit conversion operator and the `ToSingle`, `FromDouble`, and `FromSingle` methods as alternatives to the explicit conversion operators.

```

using System;

public struct UDouble
{
    private double number;

    public UDouble(double value)
    {
        if (value < 0)
            throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

        number = value;
    }

    public UDouble(float value)
    {
        if (value < 0)
            throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

        number = value;
    }

    public static readonly UDouble MinValue = (UDouble) 0.0;
    public static readonly UDouble MaxValue = (UDouble) Double.MaxValue;

    public static explicit operator Double(UDouble value)
    {
        return value.number;
    }
}

```

```
}

public static implicit operator Single(UDouble value)
{
    if (value.number > (double) Single.MaxValue)
        throw new InvalidCastException("A UDouble value is out of range of the Single type.");

    return (float) value.number;
}

public static explicit operator UDouble(double value)
{
    if (value < 0)
        throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

    return new UDouble(value);
}

public static implicit operator UDouble(float value)
{
    if (value < 0)
        throw new InvalidCastException("A negative value cannot be converted to a UDouble.");

    return new UDouble(value);
}

public static Double ToDouble(UDouble value)
{
    return (Double) value;
}

public static float ToSingle(UDouble value)
{
    return (float) value;
}

public static UDouble FromDouble(double value)
{
    return new UDouble(value);
}

public static UDouble FromSingle(float value)
{
    return new UDouble(value);
}
}
```

```

Public Structure UDouble
    Private number As Double

    Public Sub New(value As Double)
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        number = value
    End Sub

    Public Sub New(value As Single)
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        number = value
    End Sub

    Public Shared ReadOnly MinValue As UDouble = CType(0.0, UDouble)
    Public Shared ReadOnly MaxValue As UDouble = Double.MaxValue

    Public Shared Widening Operator CType(value As UDouble) As Double
        Return value.number
    End Operator

    Public Shared Narrowing Operator CType(value As UDouble) As Single
        If value.number > CDbl(Single.MaxValue) Then
            Throw New InvalidCastException("A UDouble value is out of range of the Single type.")
        End If
        Return CSng(value.number)
    End Operator

    Public Shared Narrowing Operator CType(value As Double) As UDouble
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        Return New UDouble(value)
    End Operator

    Public Shared Narrowing Operator CType(value As Single) As UDouble
        If value < 0 Then
            Throw New InvalidCastException("A negative value cannot be converted to a UDouble.")
        End If
        Return New UDouble(value)
    End Operator

    Public Shared Function ToDouble(value As UDouble) As Double
        Return CType(value, Double)
    End Function

    Public Shared Function ToSingle(value As UDouble) As Single

    End Function

    Public Shared Function FromDouble(value As Double) As UDouble
        Return New UDouble(value)
    End Function

    Public Shared Function FromSingle(value As Single) As UDouble
        Return New UDouble(value)
    End Function
End Structure

```

Arrays

CLS-compliant arrays conform to the following rules:

- All dimensions of an array must have a lower bound of zero. The following example creates a non-CLS-

compliant array with a lower bound of one. Note that, despite the presence of the `CLSCompliantAttribute` attribute, the compiler does not detect that the array returned by the `Numbers.GetTenPrimes` method is not CLS-compliant.

```
[assembly: CLSCompliant(true)]  
  
public class Numbers  
{  
    public static Array GetTenPrimes()  
    {  
        Array arr = Array.CreateInstance(typeof(Int32), new int[] {10}, new int[] {1});  
        arr.SetValue(1, 1);  
        arr.SetValue(2, 2);  
        arr.SetValue(3, 3);  
        arr.SetValue(5, 4);  
        arr.SetValue(7, 5);  
        arr.SetValue(11, 6);  
        arr.SetValue(13, 7);  
        arr.SetValue(17, 8);  
        arr.SetValue(19, 9);  
        arr.SetValue(23, 10);  
  
        return arr;  
    }  
}
```

```
<Assembly: CLSCompliant(True)>  
  
Public Class Numbers  
    Public Shared Function GetTenPrimes() As Array  
        Dim arr As Array = Array.CreateInstance(GetType(Int32), {10}, {1})  
        arr.SetValue(1, 1)  
        arr.SetValue(2, 2)  
        arr.SetValue(3, 3)  
        arr.SetValue(5, 4)  
        arr.SetValue(7, 5)  
        arr.SetValue(11, 6)  
        arr.SetValue(13, 7)  
        arr.SetValue(17, 8)  
        arr.SetValue(19, 9)  
        arr.SetValue(23, 10)  
  
        Return arr  
    End Function  
End Class
```

- All array elements must consist of CLS-compliant types. The following example defines two methods that return non-CLS-compliant arrays. The first returns an array of `UInt32` values. The second returns an `Object` array that includes `Int32` and `UInt32` values. Although the compiler identifies the first array as non-compliant because of its `UInt32` type, it fails to recognize that the second array includes non-CLS-compliant elements.

```

using System;

[assembly: CLSCompliant(true)]

public class Numbers
{
    public static UInt32[] GetTenPrimes()
    {
        uint[] arr = { 1u, 2u, 3u, 5u, 7u, 11u, 13u, 17u, 19u };
        return arr;
    }

    public static Object[] GetFivePrimes()
    {
        Object[] arr = { 1, 2, 3, 5, 7 };
        return arr;
    }
}

// Compilation produces a compiler warning like the following:
//   Array2.cs(8,27): warning CS3002: Return type of 'Numbers.GetTenPrimes()' is not
//       CLS-compliant

```

```

<Assembly: CLSCompliant(True)>

Public Class Numbers
    Public Shared Function GetTenPrimes() As UInt32()
        Return { 1ui, 2ui, 3ui, 5ui, 7ui, 11ui, 13ui, 17ui, 19ui }
    End Function

    Public Shared Function GetFivePrimes() As Object()
        Dim arr() As Object = { 1, 2, 3, 5ui, 7ui }
        Return arr
    End Function
End Class
' Compilation produces a compiler warning like the following:
'   warning BC40027: Return type of function 'GetTenPrimes' is not CLS-compliant.
'
'       Public Shared Function GetTenPrimes() As UInt32()
'           ~~~~~

```

- Overload resolution for methods that have array parameters is based on the fact that they are arrays and on their element type. For this reason, the following definition of an overloaded `GetSquares` method is CLS-compliant.

```

using System;
using System.Numerics;

[assembly: CLSCompliant(true)]

public class Numbers
{
    public static byte[] GetSquares(byte[] numbers)
    {
        byte[] numbersOut = new byte[numbers.Length];
        for (int ctr = 0; ctr < numbers.Length; ctr++) {
            int square = ((int) numbers[ctr]) * ((int) numbers[ctr]);
            if (square <= Byte.MaxValue)
                numbersOut[ctr] = (byte) square;
            // If there's an overflow, assign MaxValue to the corresponding
            // element.
            else
                numbersOut[ctr] = Byte.MaxValue;
        }
        return numbersOut;
    }

    public static BigInteger[] GetSquares(BigInteger[] numbers)
    {
        BigInteger[] numbersOut = new BigInteger[numbers.Length];
        for (int ctr = 0; ctr < numbers.Length; ctr++)
            numbersOut[ctr] = numbers[ctr] * numbers[ctr];

        return numbersOut;
    }
}

```

```

Imports System.Numerics

<Assembly: CLSCompliant(True)>

Public Module Numbers
    Public Function GetSquares(numbers As Byte()) As Byte()
        Dim numbersOut(numbers.Length - 1) As Byte
        For ctr As Integer = 0 To numbers.Length - 1
            Dim square As Integer = (CInt(numbers(ctr)) * CInt(numbers(ctr)))
            If square <= Byte.MaxValue Then
                numbersOut(ctr) = CByte(square)
            ' If there's an overflow, assign MaxValue to the corresponding
            ' element.
            Else
                numbersOut(ctr) = Byte.MaxValue
            End If
        Next
        Return numbersOut
    End Function

    Public Function GetSquares(numbers As BigInteger()) As BigInteger()
        Dim numbersOut(numbers.Length - 1) As BigInteger
        For ctr As Integer = 0 To numbers.Length - 1
            numbersOut(ctr) = numbers(ctr) * numbers(ctr)
        Next
        Return numbersOut
    End Function
End Module

```

Interfaces

CLS-compliant interfaces can define properties, events, and virtual methods (methods with no implementation).

A CLS-compliant interface cannot have any of the following:

- Static methods or static fields. Both the C# and Visual Basic compilers generate compiler errors if you define a static member in an interface.
- Fields. Both the C# and Visual Basic compilers generate compiler errors if you define a field in an interface.
- Methods that are not CLS-compliant. For example, the following interface definition includes a method, `INumber.GetUnsigned`, that is marked as non-CLS-compliant. This example generates a compiler warning.

```
using System;

[assembly:CLSCompliant(true)]

public interface INumber
{
    int Length();
    [CLSCompliant(false)] ulong GetUnsigned();
}

// Attempting to compile the example displays output like the following:
//   Interface2.cs(8,32): warning CS3010: 'INumber.GetUnsigned()': CLS-compliant interfaces
//       must have only CLS-compliant members
```

```
<Assembly: CLSCompliant(True)>

Public Interface INumber
    Function Length As Integer

        <CLSCompliant(False)> Function GetUnsigned As ULong
    End Interface

    ' Attempting to compile the example displays output like the following:
    '   Interface2.vb(9) : warning BC40033: Non CLS-compliant 'function' is not allowed in a
    '   CLS-compliant interface.

    '   <CLSCompliant(False)> Function GetUnsigned As ULong
    '   ~~~~~~
```

Because of this rule, CLS-compliant types are not required to implement non-CLS-compliant members. If a CLS-compliant framework does expose a class that implements a non-CLS compliant interface, it should also provide concrete implementations of all non-CLS-compliant members.

CLS-compliant language compilers must also allow a class to provide separate implementations of members that have the same name and signature in multiple interfaces. Both C# and Visual Basic support [explicit interface implementations](#) to provide different implementations of identically named methods. Visual Basic also supports the `Implements` keyword, which enables you to explicitly designate which interface and member a particular member implements. The following example illustrates this scenario by defining a `Temperature` class that implements the `ICelsius` and `IFahrenheit` interfaces as explicit interface implementations.

```
using System;

[assembly: CLSCompliant(true)]

public interface IFahrenheit
{
    decimal GetTemperature();
}

public interface ICelsius
{
    decimal GetTemperature();
}

public class Temperature : ICelsius, IFahrenheit
{
    private decimal _value;

    public Temperature(decimal value)
    {
        // We assume that this is the Celsius value.
        _value = value;
    }

    decimal IFahrenheit.GetTemperature()
    {
        return _value * 9 / 5 + 32;
    }

    decimal ICelsius.GetTemperature()
    {
        return _value;
    }
}

public class Example
{
    public static void Main()
    {
        Temperature temp = new Temperature(100.0m);
        ICelsius cTemp = temp;
        IFahrenheit fTemp = temp;
        Console.WriteLine("Temperature in Celsius: {0} degrees",
                          cTemp.GetTemperature());
        Console.WriteLine("Temperature in Fahrenheit: {0} degrees",
                          fTemp.GetTemperature());
    }
}

// The example displays the following output:
//      Temperature in Celsius: 100.0 degrees
//      Temperature in Fahrenheit: 212.0 degrees
```

```

<Assembly: CLSCompliant(True)>

Public Interface IFahrenheit
    Function GetTemperature() As Decimal
End Interface

Public Interface ICelsius
    Function GetTemperature() As Decimal
End Interface

Public Class Temperature : Implements ICelsius, IFahrenheit
    Private _value As Decimal

    Public Sub New(value As Decimal)
        ' We assume that this is the Celsius value.
        _value = value
    End Sub

    Public Function GetFahrenheit() As Decimal _
        Implements IFahrenheit.GetTemperature
        Return _value * 9 / 5 + 32
    End Function

    Public Function GetCelsius() As Decimal _
        Implements ICelsius.GetTemperature
        Return _value
    End Function
End Class

Module Example
    Public Sub Main()
        Dim temp As New Temperature(100.0d)
        Console.WriteLine("Temperature in Celsius: {0} degrees",
                          temp.GetCelsius())
        Console.WriteLine("Temperature in Fahrenheit: {0} degrees",
                          temp.GetFahrenheit())
    End Sub
End Module
' The example displays the following output:
'     Temperature in Celsius: 100.0 degrees
'     Temperature in Fahrenheit: 212.0 degrees

```

Enumerations

CLS-compliant enumerations must follow these rules:

- The underlying type of the enumeration must be an intrinsic CLS-compliant integer ([Byte](#), [Int16](#), [Int32](#), or [Int64](#)). For example, the following code tries to define an enumeration whose underlying type is [UInt32](#) and generates a compiler warning.

```

using System;

[assembly: CLSCompliant(true)]

public enum Size : uint {
    Unspecified = 0,
    XSmall = 1,
    Small = 2,
    Medium = 3,
    Large = 4,
    XLarge = 5
};

public class Clothing
{
    public string Name;
    public string Type;
    public string Size;
}
// The attempt to compile the example displays a compiler warning like the following:
//     Enum3.cs(6,13): warning CS3009: 'Size': base type 'uint' is not CLS-compliant

```

```

<Assembly: CLSCompliant(True)>

Public Enum Size As UInt32
    Unspecified = 0
    XSmall = 1
    Small = 2
    Medium = 3
    Large = 4
    XLarge = 5
End Enum

Public Class Clothing
    Public Name As String
    Public Type As String
    Public Size As Size
End Class
' The attempt to compile the example displays a compiler warning like the following:
'     Enum3.vb(6) : warning BC40032: Underlying type 'UInt32' of Enum is not CLS-compliant.
'
'     Public Enum Size As UInt32
'         ~~~~

```

- An enumeration type must have a single instance field named `Value__` that is marked with the [FieldAttributes.RTSpecialName](#) attribute. This enables you to reference the field value implicitly.
- An enumeration includes literal static fields whose types match the type of the enumeration itself. For example, if you define a `State` enumeration with values of `State.On` and `State.Off`, `State.On` and `State.Off` are both literal static fields whose type is `State`.
- There are two kinds of enumerations:
 - An enumeration that represents a set of mutually exclusive, named integer values. This type of enumeration is indicated by the absence of the [System.FlagsAttribute](#) custom attribute.
 - An enumeration that represents a set of bit flags that can combine to generate an unnamed value. This type of enumeration is indicated by the presence of the [System.FlagsAttribute](#) custom attribute.

For more information, see the documentation for the [Enum](#) structure.

- The value of an enumeration is not limited to the range of its specified values. In other words, the range of values in an enumeration is the range of its underlying value. You can use the [Enum.IsDefined](#) method to determine whether a specified value is a member of an enumeration.

Type members in general

The Common Language Specification requires all fields and methods to be accessed as members of a particular class. Therefore, global static fields and methods (that is, static fields or methods that are defined apart from a type) are not CLS-compliant. If you try to include a global field or method in your source code, both the C# and Visual Basic compilers generate a compiler error.

The Common Language Specification supports only the standard managed calling convention. It doesn't support unmanaged calling conventions and methods with variable argument lists marked with the `varargs` keyword. For variable argument lists that are compatible with the standard managed calling convention, use the [ParamArrayAttribute](#) attribute or the individual language's implementation, such as the `params` keyword in C# and the `ParamArray` keyword in Visual Basic.

Member accessibility

Overriding an inherited member cannot change the accessibility of that member. For example, a public method in a base class cannot be overridden by a private method in a derived class. There is one exception: a `protected internal` (in C#) or `Protected Friend` (in Visual Basic) member in one assembly that is overridden by a type in a different assembly. In that case, the accessibility of the override is `Protected`.

The following example illustrates the error that is generated when the [CLSCompliantAttribute](#) attribute is set to `true`, and `Human`, which is a class derived from `Animal`, tries to change the accessibility of the `Species` property from public to private. The example compiles successfully if its accessibility is changed to public.

```
using System;

[assembly: CLSCompliant(true)]

public class Animal
{
    private string _species;

    public Animal(string species)
    {
        _species = species;
    }

    public virtual string Species
    {
        get { return _species; }
    }

    public override string ToString()
    {
        return _species;
    }
}

public class Human : Animal
{
    private string _name;

    public Human(string name) : base("Homo Sapiens")
    {
        _name = name;
    }

    public string Name
    {
        get { return _name; }
    }

    private override string Species
    {
        get { return base.Species; }
    }

    public override string ToString()
    {
        return _name;
    }
}

public class Example
{
    public static void Main()
    {
        Human p = new Human("John");
        Console.WriteLine(p.Species);
        Console.WriteLine(p.ToString());
    }
}

// The example displays the following output:
//      error CS0621: 'Human.Species': virtual or abstract members cannot be private
```

```

<Assembly: CLSCompliant(True)>

Public Class Animal
    Private _species As String

    Public Sub New(species As String)
        _species = species
    End Sub

    Public Overridable ReadOnly Property Species As String
        Get
            Return _species
        End Get
    End Property

    Public Overrides Function ToString() As String
        Return _species
    End Function
End Class

Public Class Human : Inherits Animal
    Private _name As String

    Public Sub New(name As String)
        MyBase.New("Homo Sapiens")
        _name = name
    End Sub

    Public ReadOnly Property Name As String
        Get
            Return _name
        End Get
    End Property

    Private Overrides ReadOnly Property Species As String
        Get
            Return MyBase.Species
        End Get
    End Property

    Public Overrides Function ToString() As String
        Return _name
    End Function
End Class

Public Module Example
    Public Sub Main()
        Dim p As New Human("John")
        Console.WriteLine(p.Species)
        Console.WriteLine(p.ToString())
    End Sub
End Module

' The example displays the following output:
'     'Private Overrides ReadOnly Property Species As String' cannot override
'     'Public Overridable ReadOnly Property Species As String' because
'     they have different access levels.
'

'     Private Overrides ReadOnly Property Species As String

```

Types in the signature of a member must be accessible whenever that member is accessible. For example, this means that a public member cannot include a parameter whose type is private, protected, or internal. The following example illustrates the compiler error that results when a `StringWrapper` class constructor exposes an internal `StringOperationType` enumeration value that determines how a string value should be wrapped.

```

using System;
using System.Text;

public class StringWrapper
{
    string internalString;

Generic types and members

Nested types always have at least as many generic parameters as their enclosing type. These correspond by

position to the generic parameters in the enclosing type. The generic type can also include new generic parameters.

The relationship between the generic type parameters of a containing type and its nested types may be hidden by the syntax of individual languages. In the following example, a generic type `Outer<T>` contains two nested classes, `Inner1A` and `Inner1B<U>`. The calls to the `Tostring` method, which each class inherits from `Object.ToString`, show that each nested class includes the type parameters of its containing class.

```
using System;

[assembly:CLSCCompliant(true)]

public class Outer<T>
{
    T value;

    public Outer(T value)
    {
        this.value = value;
    }

    public class Inner1A : Outer<T>
    {
        public Inner1A(T value) : base(value)
        { }

    }

    public class Inner1B<U> : Outer<T>
    {
        U value2;

        public Inner1B(T value1, U value2) : base(value1)
        {
            this.value2 = value2;
        }
    }
}

public class Example
{
    public static void Main()
    {
        var inst1 = new Outer<String>("This");
        Console.WriteLine(inst1);

        var inst2 = new Outer<String>.Inner1A("Another");
        Console.WriteLine(inst2);

        var inst3 = new Outer<String>.Inner1B<int>("That", 2);
        Console.WriteLine(inst3);
    }
}

// The example displays the following output:
//      Outer`1[System.String]
//      Outer`1+Inner1A[System.String]
//      Outer`1+Inner1B`1[System.String,System.Int32]
```

```

<Assembly:CLSCompliant(True)>

Public Class Outer(Of T)
    Dim value As T

    Public Sub New(value As T)
        Me.value = value
    End Sub

'     Outer`1+Inner1A[System.String]
'     Outer`1+Inner1B`1[System.String,System.Int32]

```

Generic type names are encoded in the form *name`n*, where *name* is the type name, ` is a character literal, and *n* is the number of parameters declared on the type, or, for nested generic types, the number of newly introduced type parameters. This encoding of generic type names is primarily of interest to developers who use reflection to access CLS-compliant generic types in a library.

If constraints are applied to a generic type, any types used as constraints must also be CLS-compliant. The following example defines a class named `BaseClass` that is not CLS-compliant and a generic class named `BaseCollection` whose type parameter must derive from `BaseClass`. But because `BaseClass` is not CLS-compliant, the compiler emits a warning.

```
using System;

[assembly:CLSCCompliant(true)]

[CLSCCompliant(false)] public class BaseClass
{}

public class BaseCollection<T> where T : BaseClass
{}
// Attempting to compile the example displays the following output:
//   warning CS3024: Constraint type 'BaseClass' is not CLS-compliant
```

```
<Assembly: CLSCCompliant(True)>

<CLSCCompliant(False)> Public Class BaseClass
End Class

Public Class BaseCollection(Of T As BaseClass)
End Class
' Attempting to compile the example displays the following output:
'   warning BC40040: Generic parameter constraint type 'BaseClass' is not
'   CLS-compliant.
'
'   Public Class BaseCollection(Of T As BaseClass)
'   ~~~~~~
```

If a generic type is derived from a generic base type, it must redeclare any constraints so that it can guarantee that constraints on the base type are also satisfied. The following example defines a `Number<T>` that can represent any numeric type. It also defines a `FloatingPoint<T>` class that represents a floating point value. However, the source code fails to compile, because it does not apply the constraint on `Number<T>` (that T must be a value type) to `FloatingPoint<T>`.

```

using System;

[assembly:CLSCCompliant(true)]

public class Number<T> where T : struct
{
    // use Double as the underlying type, since its range is a superset of
    // the ranges of all numeric types except BigInteger.
    protected double number;

    public Number(T value)
    {
        try {
            this.number = Convert.ToDouble(value);
        }
        catch (OverflowException e) {
            throw new ArgumentException("value is too large.", e);
        }
        catch (InvalidCastException e) {
            throw new ArgumentException("The value parameter is not numeric.", e);
        }
    }

    public T Add(T value)
    {
        return (T) Convert.ChangeType(number + Convert.ToDouble(value), typeof(T));
    }

    public T Subtract(T value)
    {
        return (T) Convert.ChangeType(number - Convert.ToDouble(value), typeof(T));
    }
}

public class FloatingPoint<T> : Number<T>
{
    public FloatingPoint(T number) : base(number)
    {
        if (typeof(float) == number.GetType() ||
            typeof(double) == number.GetType() ||
            typeof(decimal) == number.GetType())
            this.number = Convert.ToDouble(number);
        else
            throw new ArgumentException("The number parameter is not a floating-point number.");
    }
}

// The attempt to compile the example displays the following output:
//      error CS0453: The type 'T' must be a non-nullable value type in
//                      order to use it as parameter 'T' in the generic type or method 'Number<T>'
```

```

<Assembly:CLSCompliant(True)>

Public Class Number(Of T As Structure)
    ' Use Double as the underlying type, since its range is a superset of
    ' the ranges of all numeric types except BigInteger.
    Protected number As Double

    Public Sub New(value As T)
        Try
            Me.number = Convert.ToDouble(value)
        Catch e As OverflowException
            Throw New ArgumentException("value is too large.", e)
        Catch e As InvalidCastException
            Throw New ArgumentException("The value parameter is not numeric.", e)
        End Try
    End Sub

    Public Function Add(value As T) As T
        Return CType(Convert.ChangeType(number + Convert.ToDouble(value), GetType(T)), T)
    End Function

    Public Function Subtract(value As T) As T
        Return CType(Convert.ChangeType(number - Convert.ToDouble(value), GetType(T)), T)
    End Function
End Class

Public Class FloatingPoint(Of T) : Inherits Number(Of T)
    Public Sub New(number As T)
        MyBase.New(number)
        If TypeOf number Is Single Or
            TypeOf number Is Double Or
            TypeOf number Is Decimal Then
            Me.number = Convert.ToDouble(number)
        Else
            throw new ArgumentException("The number parameter is not a floating-point number.")
        End If
    End Sub
End Class
' The attempt to compile the example displays the following output:
'   error BC32105: Type argument 'T' does not satisfy the 'Structure'
'   constraint for type parameter 'T'.
'
'   Public Class FloatingPoint(Of T) : Inherits Number(Of T)
'   ~

```

The example compiles successfully if the constraint is added to the `FloatingPoint<T>` class.

```

```

The Common Language Specification imposes a conservative per-instantiation model for nested types and protected members. Open generic types cannot expose fields or members with signatures that contain a specific instantiation of a nested, protected generic type. Non-generic types that extend a specific instantiation of a generic base class or interface cannot expose fields or members with signatures that contain a different instantiation of a nested, protected generic type.

The following example defines a generic type, `C1<T>` (or `C1(of T)` in Visual Basic), and a protected class, `C1<T>.N` (or `C1(of T).N` in Visual Basic). `C1<T>` has two methods, `M1` and `M2`. However, `M1` is not CLS-compliant because it tries to return a `C1<int>.N` (or `C1(of Integer).N`) object from `C1<T>` (or `C1(of T)`). A second class, `C2`, is derived from `C1<long>` (or `C1(of Long)`). It has two methods, `M3` and `M4`. `M3` is not CLS-compliant because it tries to return a `C1<int>.N` (or `C1(of Integer).N`) object from a subclass of `C1<long>`. Note that language compilers can be even more restrictive. In this example, Visual Basic displays an error when it tries to compile `M4`.

```
using System;

[assembly:CLSCompliant(true)]

public class C1<T>
{
    protected class N { }

    protected void M1(C1<int>.N n) { } // Not CLS-compliant - C1<int>.N not
                                         // accessible from within C1<T> in all
                                         // languages
    protected void M2(C1<T>.N n) { } // CLS-compliant - C1<T>.N accessible
                                         // inside C1<T>
}

public class C2 : C1<long>
{
    protected void M3(C1<int>.N n) { } // Not CLS-compliant - C1<int>.N is not
                                         // accessible in C2 (extends C1<long>)

    protected void M4(C1<long>.N n) { } // CLS-compliant, C1<long>.N is
                                         // accessible in C2 (extends C1<long>)
}
// Attempting to compile the example displays output like the following:
//      Generics4.cs(9,22): warning CS3001: Argument type 'C1<int>.N' is not CLS-compliant
//      Generics4.cs(18,22): warning CS3001: Argument type 'C1<int>.N' is not CLS-compliant
```

```

```

Constructors

Constructors in CLS-compliant classes and structures must follow these rules:

- A constructor of a derived class must call the instance constructor of its base class before it accesses inherited instance data. This requirement is due to the fact that base class constructors are not inherited by their derived classes. This rule does not apply to structures, which do not support direct inheritance.

Typically, compilers enforce this rule independently of CLS compliance, as the following example shows. It creates a `Doctor` class that is derived from a `Person` class, but the `Doctor` class fails to call the `Person` class constructor to initialize inherited instance fields.

```
using System;

[assembly: CLSCompliant(true)]

public class Person
{
    private string fName, lName, _id;

    public Person(string firstName, string lastName, string id)
    {
        if (String.IsNullOrEmpty(firstName + lastName))
            throw new ArgumentNullException("Either a first name or a last name must be provided.");

        fName = firstName;
        lName = lastName;
        _id = id;
    }

    public string FirstName
    {
        get { return fName; }
    }

    public string LastName
    {
        get { return lName; }
    }

    public string Id
    {
        get { return _id; }
    }

    public override string ToString()
    {
        return String.Format("{0}{1}{2}", fName,
                             String.IsNullOrEmpty(fName) ? "" : " ",
                             lName);
    }
}

public class Doctor : Person
{
    public Doctor(string firstName, string lastName, string id)
    {

    }

    public override string ToString()
    {
        return "Dr. " + base.ToString();
    }
}

// Attempting to compile the example displays output like the following:
//  ctor1.cs(45,11): error CS1729: 'Person' does not contain a constructor that takes 0
//      arguments
//  ctor1.cs(10,11): (Location of symbol related to previous error)
```

```

<Assembly: CLSCompliant(True)>

Public Class Person
    Private fName, lName, _id As String

    Public Sub New(firstName As String, lastName As String, id As String)
        If String.IsNullOrEmpty(firstName + lastName) Then
            Throw New ArgumentNullException("Either a first name or a last name must be provided.")
        End If

        fName = firstName
        lName = lastName
        _id = id
    End Sub

    Public ReadOnly Property FirstName As String
        Get
            Return fName
        End Get
    End Property

    Public ReadOnly Property LastName As String
        Get
            Return lName
        End Get
    End Property

    Public ReadOnly Property Id As String
        Get
            Return _id
        End Get
    End Property

    Public Overrides Function ToString() As String
        Return String.Format("{0}{1}{2}", fName,
            If(String.IsNullOrEmpty(fName), "", " "),
            lName)
    End Function
End Class

Public Class Doctor : Inherits Person
    Public Sub New(firstName As String, lastName As String, id As String)
    End Sub

    Public Overrides Function ToString() As String
        Return "Dr. " + MyBase.ToString()
    End Function
End Class

' Attempting to compile the example displays output like the following:
'   Ctor1.vb(46) : error BC30148: First statement of this 'Sub New' must be a call
'   to 'MyBase.New' or 'MyClass.New' because base class 'Person' of 'Doctor' does
'   not have an accessible 'Sub New' that can be called with no arguments.
'

'   Public Sub New()
'       ~~~

```

- An object constructor cannot be called except to create an object. In addition, an object cannot be initialized twice. For example, this means that [Object.MemberwiseClone](#) and deserialization methods such as [BinaryFormatter.Deserialize](#) must not call constructors.

Properties

Properties in CLS-compliant types must follow these rules:

- A property must have a setter, a getter, or both. In an assembly, these are implemented as special methods, which means that they will appear as separate methods (the getter is named `get_`

propertyname and the setter is `set_ propertyname)` marked as `SpecialName` in the assembly's metadata.

The C# and Visual Basic compilers enforce this rule automatically without the need to apply the `CLSCompliantAttribute` attribute.

- A property's type is the return type of the property getter and the last argument of the setter. These types must be CLS compliant, and arguments cannot be assigned to the property by reference (that is, they cannot be managed pointers).
- If a property has both a getter and a setter, they must both be virtual, both static, or both instance. The C# and Visual Basic compilers automatically enforce this rule through their property definition syntax.

Events

An event is defined by its name and its type. The event type is a delegate that is used to indicate the event. For example, the `AppDomain.AssemblyResolve` event is of type `ResolveEventHandler`. In addition to the event itself, three methods with names based on the event name provide the event's implementation and are marked as `SpecialName` in the assembly's metadata:

- A method for adding an event handler, named `add_EventName`. For example, the event subscription method for the `AppDomain.AssemblyResolve` event is named `add_AssemblyResolve`.
- A method for removing an event handler, named `remove_EventName`. For example, the removal method for the `AppDomain.AssemblyResolve` event is named `remove_AssemblyResolve`.
- A method for indicating that the event has occurred, named `raise_EventName`.

NOTE

Most of the Common Language Specification's rules regarding events are implemented by language compilers and are transparent to component developers.

The methods for adding, removing, and raising the event must have the same accessibility. They must also all be static, instance, or virtual. The methods for adding and removing an event have one parameter whose type is the event delegate type. The add and remove methods must both be present or both be absent.

The following example defines a CLS-compliant class named `Temperature` that raises a `TemperatureChangedEventArgs` event if the change in temperature between two readings equals or exceeds a threshold value. The `Temperature` class explicitly defines a `raise_TemperatureChanged` method so that it can selectively execute event handlers.

```
using System;
using System.Collections;

```

Overloads

The Common Language Specification imposes the following requirements on overloaded members:

- Members can be overloaded based on the number of parameters and the type of any parameter. Calling convention, return type, custom modifiers applied to the method or its parameter, and whether parameters are passed by value or by reference are not considered when differentiating between overloads. For an example, see the code for the requirement that names must be unique within a scope in the [Naming conventions](#) section.
- Only properties and methods can be overloaded. Fields and events cannot be overloaded.
- Generic methods can be overloaded based on the number of their generic parameters.

NOTE

The `op_Explicit` and `op_Implicit` operators are exceptions to the rule that return value is not considered part of a method signature for overload resolution. These two operators can be overloaded based on both their parameters and their return value.

Exceptions

Exception objects must derive from [System.Exception](#) or from another type derived from [System.Exception](#). The following example illustrates the compiler error that results when a custom class named `ErrorClass` is used for exception handling.

```
using System;

[assembly: CLSCompliant(true)]

public class ErrorClass
{
    string msg;

    public ErrorClass(string errorMessage)
    {
        msg = errorMessage;
    }

    public string Message
    {
        get { return msg; }
    }
}

public static class StringUtils
{
    public static string[] SplitString(this string value, int index)
    {
        if (index < 0 | index > value.Length) {
            ErrorClass badIndex = new ErrorClass("The index is not within the string.");
            throw badIndex;
        }
        string[] retVal = { value.Substring(0, index - 1),
                           value.Substring(index) };
        return retVal;
    }
}

// Compilation produces a compiler error like the following:
//   Exceptions1.cs(26,16): error CS0155: The type caught or thrown must be derived from
//       System.Exception
```

```

Imports System.Runtime.CompilerServices

<Assembly: CLSCompliant(True)>

Public Class ErrorClass
    Dim msg As String

    Public Sub New(errorMessage As String)
        msg = errorMessage
    End Sub

    Public ReadOnly Property Message As String
        Get
            Return msg
        End Get
    End Property
End Class

Public Module StringUtilities
    <Extension()> Public Function SplitString(value As String, index As Integer) As String()
        If index < 0 Or index > value.Length Then
            Dim BadIndex As New ErrorClass("The index is not within the string.")
            Throw BadIndex
        End If
        Dim retVal() As String = { value.Substring(0, index - 1),
                                  value.Substring(index) }
        Return retVal
    End Function
End Module

' Compilation produces a compiler error like the following:
'   Exceptions1.vb(27) : error BC30665: 'Throw' operand must derive from 'System.Exception'.
'

'       Throw BadIndex
'
~~~~~
```

To correct this error, the `ErrorClass` class must inherit from `System.Exception`. In addition, the `Message` property must be overridden. The following example corrects these errors to define an `ErrorClass` class that is CLS-compliant.

```

using System;

[assembly: CLSCompliant(true)]

public class ErrorClass : Exception
{
    string msg;

    public ErrorClass(string errorMessage)
    {
        msg = errorMessage;
    }

    public override string Message
    {
        get { return msg; }
    }
}

public static class StringUtils
{
    public static string[] SplitString(this string value, int index)
    {
        if (index < 0 | index > value.Length) {
            ErrorClass badIndex = new ErrorClass("The index is not within the string.");
            throw badIndex;
        }
        string[] retVal = { value.Substring(0, index - 1),
                           value.Substring(index) };
        return retVal;
    }
}

```

```

Imports System.Runtime.CompilerServices

<Assembly: CLSCompliant(True)>

Public Class ErrorClass : Inherits Exception
    Dim msg As String

    Public Sub New(errorMessage As String)
        msg = errorMessage
    End Sub

    Public Overrides ReadOnly Property Message As String
        Get
            Return msg
        End Get
    End Property
End Class

Public Module StringUtils
    <Extension()> Public Function SplitString(value As String, index As Integer) As String()
        If index < 0 Or index > value.Length Then
            Dim BadIndex As New ErrorClass("The index is not within the string.")
            Throw BadIndex
        End If
        Dim retVal() As String = { value.Substring(0, index - 1),
                                  value.Substring(index) }
        Return retVal
    End Function
End Module

```

Attributes

In .NET Framework assemblies, custom attributes provide an extensible mechanism for storing custom attributes and retrieving metadata about programming objects, such as assemblies, types, members, and method parameters. Custom attributes must derive from [System.Attribute](#) or from a type derived from [System.Attribute](#).

The following example violates this rule. It defines a `NumericAttribute` class that does not derive from [System.Attribute](#). Note that a compiler error results only when the non-CLS-compliant attribute is applied, not when the class is defined.

```
using System;

[assembly: CLSCompliant(true)]

[AttributeUsageAttribute(AttributeTargets.Class | AttributeTargets.Struct)]
public class NumericAttribute
{
    private bool _isNumeric;

    public NumericAttribute(bool isNumeric)
    {
        _isNumeric = isNumeric;
    }

    public bool IsNumeric
    {
        get { return _isNumeric; }
    }
}

[Numeric(true)] public struct UDouble
{
    double Value;
}
// Compilation produces a compiler error like the following:
//   Attribute1.cs(22,2): error CS0616: 'NumericAttribute' is not an attribute class
//   Attribute1.cs(7,14): (Location of symbol related to previous error)
```

```
<Assembly: CLSCompliant(True)>

<AttributeUsageAttribute(AttributeTargets.Class Or AttributeTargets.Struct)> _
Public Class NumericAttribute
    Private _isNumeric As Boolean

    Public Sub New(isNumeric As Boolean)
        _isNumeric = isNumeric
    End Sub

    Public ReadOnly Property IsNumeric As Boolean
        Get
            Return _isNumeric
        End Get
    End Property
End Class

<Numeric(True)> Public Structure UDouble
    Dim Value As Double
End Structure
' Compilation produces a compiler error like the following:
'   error BC31504: 'NumericAttribute' cannot be used as an attribute because it
'   does not inherit from 'System.Attribute'.
'
'   <Numeric(True)> Public Structure UDouble
'   ~~~~~~
```

The constructor or the properties of a CLS-compliant attribute can expose only the following types:

- [Boolean](#)
- [Byte](#)
- [Char](#)
- [Double](#)
- [Int16](#)
- [Int32](#)
- [Int64](#)
- [Single](#)
- [String](#)
- [Type](#)
- Any enumeration type whose underlying type is [Byte](#), [Int16](#), [Int32](#), or [Int64](#).

The following example defines a `DescriptionAttribute` class that derives from [Attribute](#). The class constructor has a parameter of type `Descriptor`, so the class is not CLS-compliant. Note that the C# compiler emits a warning but compiles successfully, whereas the Visual Basic compiler emits neither a warning nor an error.

```
using System;

[assembly:CLSCCompliantAttribute(true)]

public enum DescriptorType { type, member };

public class Descriptor
{
    public DescriptorType Type;
    public String Description;
}

[AttributeUsage(AttributeTargets.All)]
public class DescriptionAttribute : Attribute
{
    private Descriptor desc;

    public DescriptionAttribute(Descriptor d)
    {
        desc = d;
    }

    public Descriptor Descriptor
    { get { return desc; } }
}

// Attempting to compile the example displays output like the following:
//      warning CS3015: 'DescriptionAttribute' has no accessible
//                      constructors which use only CLS-compliant types
```

```

<Assembly:CLSCCompliantAttribute(True)>

Public Enum DescriptorType As Integer
    Type = 0
    Member = 1
End Enum

Public Class Descriptor
    Public Type As DescriptorType
    Public Description As String
End Class

<AttributeUsage(AttributeTargets.All)> _
Public Class DescriptionAttribute : Inherits Attribute
    Private desc As Descriptor

    Public Sub New(d As Descriptor)
        desc = d
    End Sub

    Public ReadOnly Property Descriptor As Descriptor
        Get
            Return desc
        End Get
    End Property
End Class

```

The CLSCCompliantAttribute attribute

The [CLSCCompliantAttribute](#) attribute is used to indicate whether a program element complies with the Common Language Specification. The [CLSCCompliantAttribute.CLSCompliantAttribute\(Boolean\)](#) constructor includes a single required parameter, `isCompliant`, that indicates whether the program element is CLS-compliant.

At compile time, the compiler detects non-compliant elements that are presumed to be CLS-compliant and emits a warning. The compiler does not emit warnings for types or members that are explicitly declared to be non-compliant.

Component developers can use the [CLSCCompliantAttribute](#) attribute in two ways:

- To define the parts of the public interface exposed by a component that are CLS-compliant and the parts that are not CLS-compliant. When the attribute is used to mark particular program elements as CLS-compliant, its use guarantees that those elements are accessible from all languages and tools that target the .NET Framework.
- To ensure that the component library's public interface exposes only program elements that are CLS-compliant. If elements are not CLS-compliant, compilers will generally issue a warning.

WARNING

In some cases, language compilers enforce CLS-compliant rules regardless of whether the [CLSCCompliantAttribute](#) attribute is used. For example, defining a static member in an interface violates a CLS rule. In this regard, if you define a `static` (in C#) or `Shared` (in Visual Basic) member in an interface, both the C# and Visual Basic compilers display an error message and fail to compile the app.

The [CLSCCompliantAttribute](#) attribute is marked with an [AttributeUsageAttribute](#) attribute that has a value of [AttributeTargets.All](#). This value allows you to apply the [CLSCCompliantAttribute](#) attribute to any program element, including assemblies, modules, types (classes, structures, enumerations, interfaces, and delegates), type

members (constructors, methods, properties, fields, and events), parameters, generic parameters, and return values. However, in practice, you should apply the attribute only to assemblies, types, and type members. Otherwise, compilers ignore the attribute and continue to generate compiler warnings whenever they encounter a non-compliant parameter, generic parameter, or return value in your library's public interface.

The value of the [CLSCompliantAttribute](#) attribute is inherited by contained program elements. For example, if an assembly is marked as CLS-compliant, its types are also CLS-compliant. If a type is marked as CLS-compliant, its nested types and members are also CLS-compliant.

You can explicitly override the inherited compliance by applying the [CLSCompliantAttribute](#) attribute to a contained program element. For example, you can use the [CLSCompliantAttribute](#) attribute with an `isCompliant` value of `false` to define a non-compliant type in a compliant assembly, and you can use the attribute with an `isCompliant` value of `true` to define a compliant type in a non-compliant assembly. You can also define non-compliant members in a compliant type. However, a non-compliant type cannot have compliant members, so you cannot use the attribute with an `isCompliant` value of `true` to override inheritance from a non-compliant type.

When you are developing components, you should always use the [CLSCompliantAttribute](#) attribute to indicate whether your assembly, its types, and its members are CLS-compliant.

To create CLS-compliant components:

1. Use the [CLSCompliantAttribute](#) to mark your assembly as CLS-compliant.
2. Mark any publicly exposed types in the assembly that are not CLS-compliant as non-compliant.
3. Mark any publicly exposed members in CLS-compliant types as non-compliant.
4. Provide a CLS-compliant alternative for non-CLS-compliant members.

If you've successfully marked all your non-compliant types and members, your compiler should not emit any non-compliance warnings. However, you should indicate which members are not CLS-compliant and list their CLS-compliant alternatives in your product documentation.

The following example uses the [CLSCompliantAttribute](#) attribute to define a CLS-compliant assembly and a type, `CharacterUtilities`, that has two non-CLS-compliant members. Because both members are tagged with the `CLSCompliant(false)` attribute, the compiler produces no warnings. The class also provides a CLS-compliant alternative for both methods. Ordinarily, we would just add two overloads to the `ToUTF16` method to provide CLS-compliant alternatives. However, because methods cannot be overloaded based on return value, the names of the CLS-compliant methods are different from the names of the non-compliant methods.

```

using System;
using System.Text;

[assembly:CLSCompliant(true)]

public class CharacterUtilities
{
    [CLSCompliant(false)] public static ushort ToUTF16(String s)
    {
        s = s.Normalize(NormalizationForm.FormC);
        return Convert.ToInt16(s[0]);
    }

    [CLSCompliant(false)] public static ushort ToUTF16(Char ch)
    {
        return Convert.ToInt16(ch);
    }

    // CLS-compliant alternative for ToUTF16(String).
    public static int ToUTF16CodeUnit(String s)
    {
        s = s.Normalize(NormalizationForm.FormC);
        return (int) Convert.ToInt16(s[0]);
    }

    // CLS-compliant alternative for ToUTF16(Char).
    public static int ToUTF16CodeUnit(Char ch)
    {
        return Convert.ToInt32(ch);
    }

End Class

```

If you are developing an app rather than a library (that is, if you aren't exposing types or members that can be consumed by other app developers), the CLS compliance of the program elements that your app consumes are of interest only if your language does not support them. In that case, your language compiler will generate an error when you try to use a non-CLS-compliant element.

Cross-Language Interoperability

Language independence has a number of possible meanings. One meaning, which is discussed in the article [Language Independence and Language-Independent Components](#), involves seamlessly consuming types written in one language from an app written in another language. A second meaning, which is the focus of this article, involves combining code written in multiple languages into a single .NET Framework assembly.

The following example illustrates cross-language interoperability by creating a class library named Utilities.dll that includes two classes, `NumericLib` and `StringLib`. The `NumericLib` class is written in C#, and the `StringLib` class is written in Visual Basic. Here's the source code for StringUtil.vb, which includes a single member, `ToTitleCase`, in its `StringLib` class.

```
Imports System.Collections.Generic
Imports System.Runtime.CompilerServices

Public Module StringLib
    Private exclusions As List(Of String)

    Sub New()
        Dim words() As String = { "a", "an", "and", "of", "the" }
        exclusions = New List(Of String)
        exclusions.AddRange(words)
    End Sub

    <Extension()> _
    Public Function ToTitleCase(title As String) As String
        Dim words() As String = title.Split()
        Dim result As String = String.Empty

        For ctr As Integer = 0 To words.Length - 1
            Dim word As String = words(ctr)
            If ctr = 0 OrElse Not exclusions.Contains(word.ToLower()) Then
                result += word.Substring(0, 1).ToUpper() + _
                          word.Substring(1).ToLower()
            Else
                result += word.ToLower()
            End If
            If ctr <= words.Length - 1 Then
                result += " "
            End If
        Next
        Return result
    End Function
End Module
```

Here's the source code for NumberUtil.cs, which defines a `NumericLib` class that has two members, `IsEven` and `NearZero`.

```

using System;

public static class NumericLib
{
    public static bool IsEven(this IConvertible number)
    {
        if (number is Byte ||
            number is SByte ||
            number is Int16 ||
            number is UInt16 ||
            number is Int32 ||
            number is UInt32 ||
            number is Int64)
            return Convert.ToInt64(number) % 2 == 0;
        else if (number is UInt64)
            return ((ulong) number) % 2 == 0;
        else
            throw new NotSupportedException("IsEven called for a non-integer value.");
    }

    public static bool NearZero(double number)
    {
        return Math.Abs(number) < .00001;
    }
}

```

To package the two classes in a single assembly, you must compile them into modules. To compile the Visual Basic source code file into a module, use this command:

```
vbc /t:module StringUtil.vb
```

For more information about the command-line syntax of the Visual Basic compiler, see [Building from the Command Line](#).

To compile the C# source code file into a module, use this command:

```
csc /t:module NumberUtil.cs
```

For more information about the command-line syntax of the C# compiler, see [Command-line Building With csc.exe](#).

You then use the [Linker options](#) to compile the two modules into an assembly:

```
link numberutil.netmodule stringutil.netmodule /out:UtilityLib.dll /dll
```

The following example then calls the `NumericLib.NearZero` and `StringLib.ToTitleCase` methods. Note that both the Visual Basic code and the C# code are able to access the methods in both classes.

```
using System;

public class Example
{
    public static void Main()
    {
        Double dbl = 0.0 - Double.Epsilon;
        Console.WriteLine(NumericLib.NearZero(dbl));

        string s = "war and peace";
        Console.WriteLine(s.ToTitleCase());
    }
}

// The example displays the following output:
//      True
//      War and Peace
```

```
Module Example
    Public Sub Main()
        Dim dbl As Double = 0.0 - Double.Epsilon
        Console.WriteLine(NumericLib.NearZero(dbl))

        Dim s As String = "war and peace"
        Console.WriteLine(s.ToTitleCase())
    End Sub
End Module

' The example displays the following output:
'      True
'      War and Peace
```

To compile the Visual Basic code, use this command:

```
vbc example.vb /r:UtilityLib.dll
```

To compile with C#, change the name of the compiler from **vbc** to **csc**, and change the file extension from .vb to .cs:

```
csc example.cs /r:UtilityLib.dll
```

Framework Libraries

11/16/2018 • 2 minutes to read • [Edit Online](#)

.NET has an expansive standard set of class libraries, referred to as either the base class libraries (core set) or framework class libraries (complete set). These libraries provide implementations for many general and app-specific types, algorithms and utility functionality. Both commercial and community libraries build on top of the framework class libraries, providing easy to use off-the-shelf libraries for a wide set of computing tasks.

A subset of these libraries are provided with each .NET implementation. Base Class Library (BCL) APIs are expected with any .NET implementation, both because developers will want them and because popular libraries will need them to run. App-specific libraries above the BCL, such as ASP.NET, will not be available on all .NET implementations.

Base Class Libraries

The BCL provides the most foundational types and utility functionality and are the base of all other .NET class libraries. They aim to provide very general implementations without any bias to any workload. Performance is always an important consideration, since apps might prefer a particular policy, such as low-latency to high-throughput or low-memory to low-CPU usage. These libraries are intended to be high-performance generally, and take a middle-ground approach according to these various performance concerns. For most apps, this approach has been quite successful.

Primitive Types

.NET includes a set of primitive types, which are used (to varying degrees) in all programs. These types contain data, such as numbers, strings, bytes and arbitrary objects. The C# language includes keywords for these types. A sample set of these types is listed below, with the matching C# keywords.

- [System.Object \(object\)](#) - The ultimate base class in the CLR type system. It is the root of the type hierarchy.
- [System.Int16 \(short\)](#) - A 16-bit signed integer type. The unsigned [UInt16](#) also exists.
- [System.Int32 \(int\)](#) - A 32-bit signed integer type. The unsigned [UInt32](#) also exists.
- [System.Single \(float\)](#) - A 32-bit floating-point type.
- [System.Decimal \(decimal\)](#) - A 128-bit decimal type.
- [System.Byte \(byte\)](#) - An unsigned 8-bit integer that represents a byte of memory.
- [System.Boolean \(bool\)](#) - A boolean type that represents `true` or `false`.
- [System.Char \(char\)](#) - A 16-bit numeric type that represents a Unicode character.
- [System.String \(string\)](#) - Represents a series of characters. Different than a `char[]`, but enables indexing into each individual `char` in the `string`.

Data Structures

.NET includes a set of data structures that are the workhorses of almost any .NET apps. These are mostly collections, but also include other types.

- [Array](#) - Represents an array of strongly typed objects that can be accessed by index. Has a fixed size, per its construction.
- [List<T>](#) - Represents a strongly typed list of objects that can be accessed by index. Is automatically resized as needed.
- [Dictionary< TKey, TValue >](#) - Represents a collection of values that are indexed by a key. Values can be accessed

via key. Is automatically resized as needed.

- [Uri](#) - Provides an object representation of a uniform resource identifier (URI) and easy access to the parts of the URI.
- [DateTime](#) - Represents an instant in time, typically expressed as a date and time of day.

Utility APIs

.NET includes a set of utility APIs that provide functionality for many important tasks.

- [HttpClient](#) - An API for sending HTTP requests and receiving HTTP responses from a resource identified by a URI.
- [XDocument](#) - An API for loading, and querying XML documents with LINQ.
- [StreamReader](#) - An API for reading files.
- [StreamWriter](#) - An API for writing files.

App-Model APIs

There are many app-models that can be used with .NET, provided by several companies.

- [ASP.NET](#) - Provides a web framework for building Web sites and services. Supported on Windows, Linux and macOS (depends on ASP.NET version).

.NET class library overview

2/28/2019 • 4 minutes to read • [Edit Online](#)

.NET implementations include classes, interfaces, delegates, and value types that expedite and optimize the development process and provide access to system functionality. To facilitate interoperability between languages, most .NET types are CLS-compliant and can therefore be used from any programming language whose compiler conforms to the common language specification (CLS).

.NET types are the foundation on which .NET applications, components, and controls are built. .NET implementations include types that perform the following functions:

- Represent base data types and exceptions.
- Encapsulate data structures.
- Perform I/O.
- Access information about loaded types.
- Invoke .NET Framework security checks.
- Provide data access, rich client-side GUI, and server-controlled, client-side GUI.

.NET provides a rich set of interfaces, as well as abstract and concrete (non-abstract) classes. You can use the concrete classes as is or, in many cases, derive your own classes from them. To use the functionality of an interface, you can either create a class that implements the interface or derive a class from one of the .NET classes that implements the interface.

Naming conventions

.NET types use a dot syntax naming scheme that connotes a hierarchy. This technique groups related types into namespaces so they can be searched and referenced more easily. The first part of the full name — up to the rightmost dot — is the namespace name. The last part of the name is the type name. For example,

`System.Collections.Generic.List<T>` represents the `List<T>` type, which belongs to the `System.Collections.Generic` namespace. The types in `System.Collections.Generic` can be used to work with generic collections.

This naming scheme makes it easy for library developers extending the .NET Framework to create hierarchical groups of types and name them in a consistent, informative manner. It also allows types to be unambiguously identified by their full name (that is, by their namespace and type name), which prevents type name collisions. Library developers are expected to use the following convention when creating names for their namespaces:

CompanyName.TechnologyName

For example, the namespace `Microsoft.Word` conforms to this guideline.

The use of naming patterns to group related types into namespaces is a very useful way to build and document class libraries. However, this naming scheme has no effect on visibility, member access, inheritance, security, or binding. A namespace can be partitioned across multiple assemblies and a single assembly can contain types from multiple namespaces. The assembly provides the formal structure for versioning, deployment, security, loading, and visibility in the common language runtime.

For more information on namespaces and type names, see [Common Type System](#).

System namespace

The [System](#) namespace is the root namespace for fundamental types in .NET. This namespace includes classes that represent the base data types used by all applications: [Object](#) (the root of the inheritance hierarchy), [Byte](#), [Char](#), [Array](#), [Int32](#), [String](#), and so on. Many of these types correspond to the primitive data types that your programming language uses. When you write code using .NET Framework types, you can use your language's corresponding keyword when a .NET Framework base data type is expected.

The following table lists the base types that .NET supplies, briefly describes each type, and indicates the corresponding type in Visual Basic, C#, C++, and F#.

CATEGORY	CLASS NAME	DESCRIPTION	VISUAL BASIC DATA TYPE	C# DATA TYPE	C++/CLI DATA TYPE	F# DATA TYPE
Integer	Byte	An 8-bit unsigned integer.	Byte	byte	unsigned char	byte
	SByte	An 8-bit signed integer. Not CLS-compliant.	SByte	sbyte	char -or- signed char	sbyte
	Int16	A 16-bit signed integer.	Short	short	short	int16
	Int32	A 32-bit signed integer.	Integer	int	int -or- long	int
	Int64	A 64-bit signed integer.	Long	long	_int64	int64
	UInt16	A 16-bit unsigned integer. Not CLS-compliant.	UShort	ushort	unsigned short	uint16
	UInt32	A 32-bit unsigned integer. Not CLS-compliant.	UInteger	uint	unsigned int -or- unsigned long	uint32
	UInt64	A 64-bit unsigned integer. Not CLS-compliant.	ULong	ulong	unsigned int64	uint64

Category	Class Name	Description	Visual Basic Data Type	C# Data Type	C++/CLI Data Type	F# Data Type
Floating point	Single	A single-precision (32-bit) floating-point number.	Single	float	float	float32 or single
	Double	A double-precision (64-bit) floating-point number.	Double	double	double	float or double
Logical	Boolean	A Boolean value (true or false).	Boolean	bool	bool	bool
Other	Char	A Unicode (16-bit) character.	Char	char	wchar_t	char
	Decimal	A decimal (128-bit) value.	Decimal	decimal	Decimal	decimal
	IntPtr	A signed integer whose size depends on the underlying platform (a 32-bit value on a 32-bit platform and a 64-bit value on a 64-bit platform).	IntPtr No built-in type.	IntPtr No built-in type.	IntPtr No built-in type.	unativeint
	UIntPtr	An unsigned integer whose size depends on the underlying platform (a 32-bit value on a 32-bit platform and a 64-bit value on a 64-bit platform). Not CLS-compliant.	UIntPtr No built-in type.	UIntPtr No built-in type.	UIntPtr No built-in type.	unativeint
	Object	The root of the object hierarchy.	Object	object	Object^	obj

Category	Class Name	Description	Visual Basic Data Type	C# Data Type	C++/CLI Data Type	F# Data Type
	String	An immutable, fixed-length string of Unicode characters.	String	string	String^	string

In addition to the base data types, the [System](#) namespace contains over 100 classes, ranging from classes that handle exceptions to classes that deal with core runtime concepts, such as application domains and the garbage collector. The [System](#) namespace also contains many second-level namespaces.

For more information about namespaces, use the [.NET API Browser](#) to browse the .NET Class Library. The API reference documentation provides documentation on each namespace, its types, and each of their members.

[Dates, Times, and Time Zones](#)

Describes how to work with time zones and time zone conversions in time zone-aware applications.

.NET class libraries

2/23/2019 • 3 minutes to read • [Edit Online](#)

Class libraries are the [shared library](#) concept for .NET. They enable you to componentize useful functionality into modules that can be used by multiple applications. They can also be used as a means of loading functionality that is not needed or not known at application startup. Class libraries are described using the [.NET Assembly file format](#).

There are three types of class libraries that you can use:

- **Platform-specific** class libraries have access to all the APIs in a given platform (for example, .NET Framework, Xamarin iOS), but can only be used by apps and libraries that target that platform.
- **Portable** class libraries have access to a subset of APIs, and can be used by apps and libraries that target multiple platforms.
- **.NET Standard** class libraries are a merger of the platform-specific and portable library concept into a single model that provides the best of both.

Platform-specific class libraries

Platform-specific libraries are bound to a single .NET implementation (for example, .NET Framework on Windows) and can therefore take significant dependencies on a known execution environment. Such an environment will expose a known set of APIs (.NET and OS APIs) and will maintain and expose expected state (for example, Windows registry).

Developers who create platform specific libraries can fully exploit the underlying platform. The libraries will only ever run on that given platform, making platform checks or other forms of conditional code unnecessary (modulo single sourcing code for multiple platforms).

Platform-specific libraries have been the primary class library type for the .NET Framework. Even as other .NET implementations emerged, platform-specific libraries remained the dominant library type.

Portable class libraries

Portable libraries are supported on multiple .NET implementations. They can still take dependencies on a known execution environment, however, the environment is a synthetic one that is generated by the intersection of a set of concrete .NET implementations. This means that exposed APIs and platform assumptions are a subset of what would be available to a platform-specific library.

You choose a platform configuration when you create a portable library. These are the set of platforms that you need to support (for example, .NET Framework 4.5+, Windows Phone 8.0+). The more platforms you opt to support, the fewer APIs and fewer platform assumptions you can make, the lowest common denominator. This characteristic can be confusing at first, since people often think "more is better", but find that more supported platforms results in fewer available APIs.

Many library developers have switched from producing multiple platform-specific libraries from one source (using conditional compilation directives) to portable libraries. There are [several approaches](#) for accessing platform-specific functionality within portable libraries, with [bait-and-switch](#) being the most widely accepted technique at this point.

.NET Standard class libraries

.NET Standard libraries are a replacement of the platform-specific and portable libraries concepts. They are

platform-specific in the sense that they expose all functionality from the underlying platform (no synthetic platforms or platform intersections). They are portable in the sense that they work on all supporting platforms.

The .NET Standard exposes a set of library *contracts*. .NET implementations must support each contract fully or not at all. Each implementation, therefore, supports a set of .NET Standard contracts. The corollary is that each .NET Standard class library is supported on the platforms that support its contract dependencies.

The .NET Standard does not expose the entire functionality of the .NET Framework (nor is that a goal), however, they do expose many more APIs than Portable Class Libraries. More APIs will be added over time.

The following platforms support .NET Standard libraries:

- .NET Core
- .NET Framework
- Mono
- Xamarin.iOS, Xamarin.Mac, Xamarin.Android
- Universal Windows Platform (UWP)
- Windows
- Windows Phone
- Windows Phone Silverlight

For more information, see the [.NET Standard](#) topic.

Mono class libraries

Class libraries are supported on Mono, including the three types of libraries described above. Mono has often been seen (correctly) as a cross-platform implementation of the Microsoft .NET Framework. In part, this was because platform-specific .NET Framework libraries could run on the Mono runtime without modification or recompilation. This characteristic was in place before the creation of portable class libraries, so was an obvious choice to enable binary portability between the .NET Framework and Mono (although it only worked in one direction).

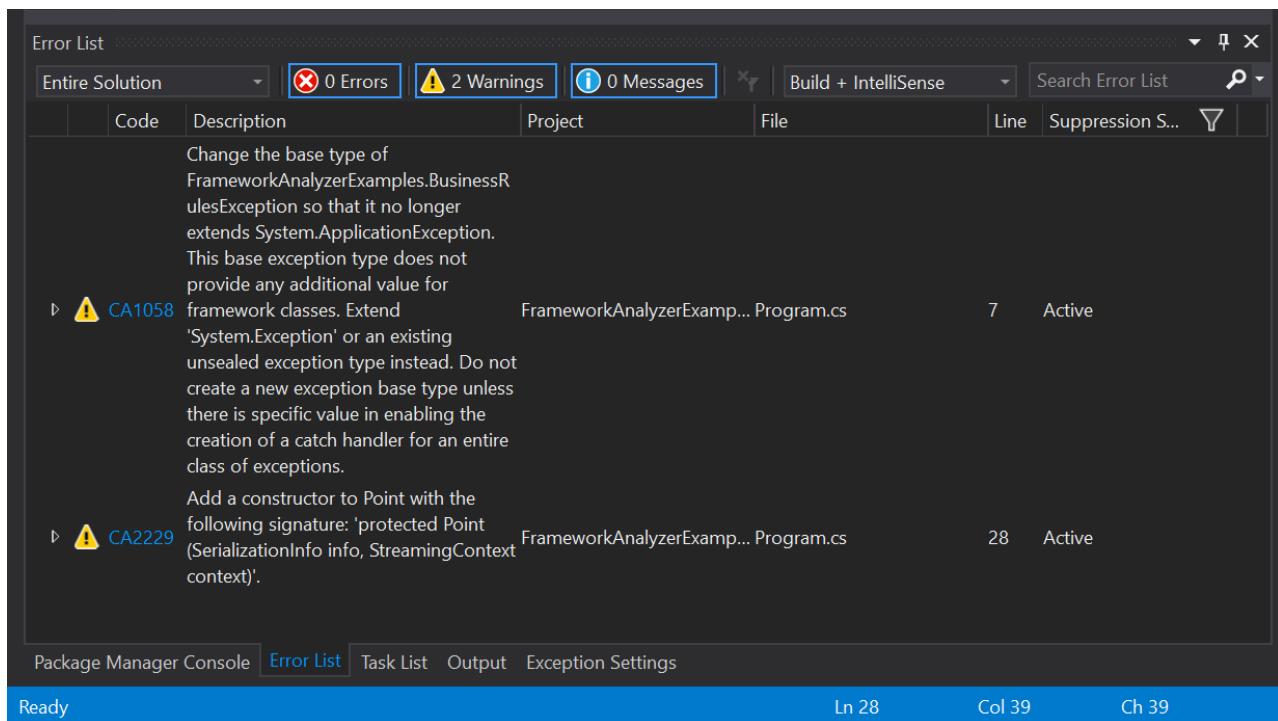

The Roslyn based Analyzers

3/5/2019 • 2 minutes to read • [Edit Online](#)

Roslyn-based analyzers use the .NET Compiler SDK (Roslyn APIs) to analyze your project's source code to find issues and suggest corrections. Different analyzers look for different classes of issues, ranging from practices that are likely to cause bugs to security concerns to API compatibility.

Roslyn-based analyzers work both interactively and during builds. The analyzer provides different guidance when in Visual Studio or in command-line builds.

While you edit code in Visual Studio, the analyzers run as you make changes, catching possible issues as soon as you create code that trigger concerns. Any issues are highlighted with squiggles under any issue. Visual Studio displays a light bulb, and when you click on it the analyzer will suggest possible fixes for that issue. When you build the project, either in Visual Studio or from the command line, all the source code is analyzed and the analyzer provides a full list of potential issues. The following figure shows one example.

Roslyn-based analyzers report potential issues as errors, warnings, or information based on the severity of the issue.

You install Roslyn-based analyzers as NuGet packages in your project. The configured analyzers and any settings for each analyzer are restored and run on any developer's machine for that project.

NOTE

The user experience for Roslyn-based analyzers is different than that of the Code Analysis libraries like the older versions of FxCop and the security analysis tools. You don't need to explicitly run the Roslyn-based analyzers. There's no need to use the "Run Code Analysis" menu items on the "Analyze" menu in Visual Studio. Roslyn-based analyzers run asynchronously as you work.

[More information on specific analyzers](#)

The following analyzers are covered in this section:

- [API Analyzer](#): This analyzer examines your code for potential compatibility risks or uses of deprecated APIs.
- [Framework Analyzer](#): This analyzer examines your code to ensure it follows the guidelines for .NET Framework applications. These rules include several security-based recommendations.
- [.NET Portability Analyzer](#): This analyzer examines your code to see how much work is required to make your application compatible with other .NET implementations and profiles, including .NET Core, .NET Standard, UWP, and Xamarin for iOS, Android, and Mac.

.NET API analyzer

3/8/2019 • 4 minutes to read • [Edit Online](#)

The .NET API Analyzer is a Roslyn analyzer that discovers potential compatibility risks for C# APIs on different platforms and detects calls to deprecated APIs. It can be useful for all C# developers at any stage of development.

API Analyzer comes as a NuGet package [Microsoft.DotNet.Analyzers.Compatibility](#). After you reference it in a project, it automatically monitors the code and indicates problematic API usage. You can also get suggestions on possible fixes by clicking on the light bulb. The drop-down menu includes an option to suppress the warnings.

NOTE

The .NET API analyzer is still a pre-release version.

Prerequisites

- Visual Studio 2017 or Visual Studio for Mac (all versions).

Discovering deprecated APIs

What are deprecated APIs?

The .NET family is a set of large products that are constantly upgraded to better serve customer needs. It's natural to deprecate some APIs and replace them with new ones. An API is considered deprecated when a better alternative exists. One way to inform that an API is deprecated and shouldn't be used is to mark it with the [ObsoleteAttribute](#) attribute. The disadvantage of this approach is that there is only one diagnostic ID for all obsolete APIs (for C#, [CS0612](#)). This means that:

- It's impossible to have dedicated documents for each case.
- It's impossible to suppress certain category of warnings. You can suppress either all or none of them.
- To inform users of a new deprecation, a referenced assembly or targeting package has to be updated.

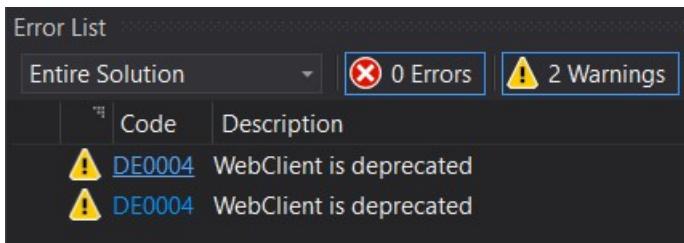

The API Analyzer uses API-specific error codes that begin with DE (which stands for Deprecation Error), which allows control over the display of individual warnings. The deprecated APIs identified by the analyzer are defined in the [dotnet/platform-compat](#) repo.

Using the API Analyzer

When a deprecated API, such as [WebClient](#), is used in a code, API Analyzer highlights it with a green squiggly line. When you hover over the API call, a light bulb is displayed with information about the API deprecation, as in the following example:

The **Error List** window contains warnings with a unique ID per deprecated API, as shown in the following example (DE004):

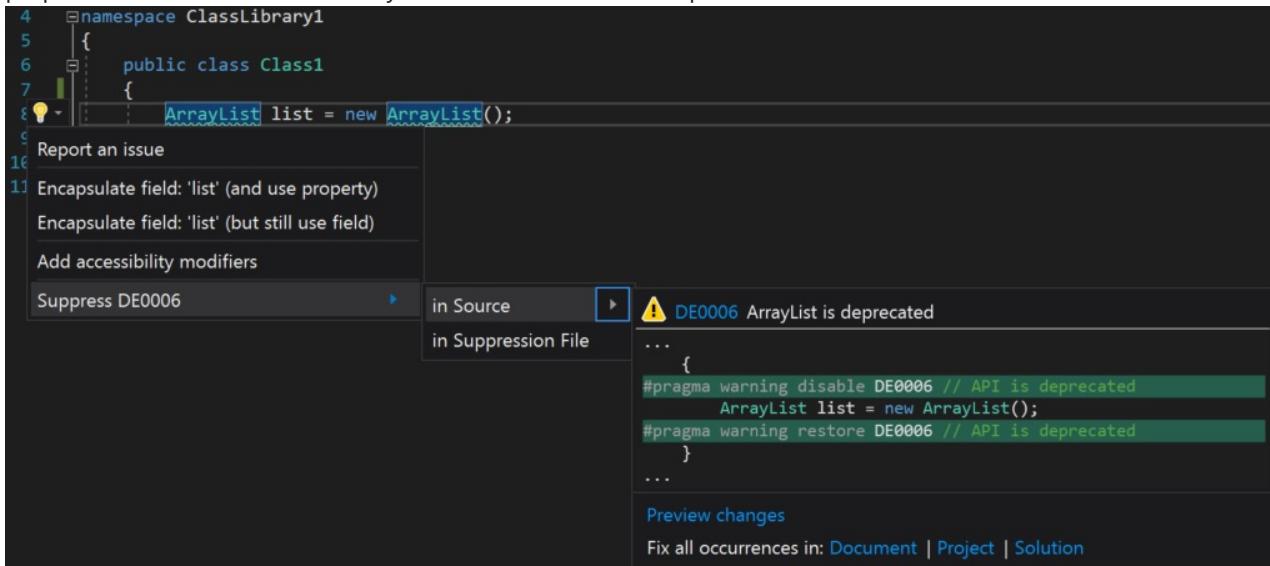

By clicking on the ID, you go to a webpage with detailed information about why the API was deprecated and suggestions regarding alternative APIs that can be used.

Any warnings can be suppressed by right-clicking on the highlighted member and selecting **Suppress <diagnostic ID>**. There are two ways to suppress warnings:

- [locally \(in source\)](#)
- [globally \(in a suppression file\)](#) - recommended

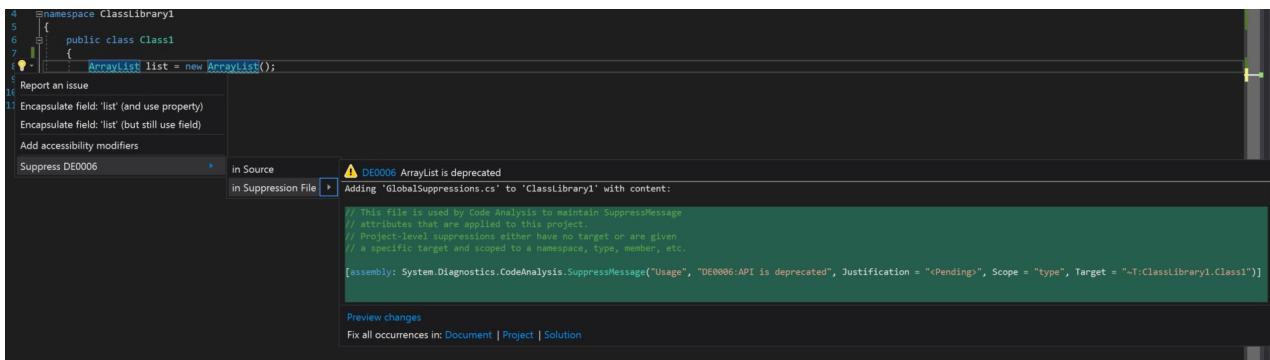

Suppressing warnings locally

To suppress warnings locally, right-click on the member you want to suppress warnings for and then select **Quick Actions and Refactorings > Suppress diagnostic ID<diagnostic ID> > in Source**. The `#pragma` warning preprocessor directive is added to your source code in the scope defined:

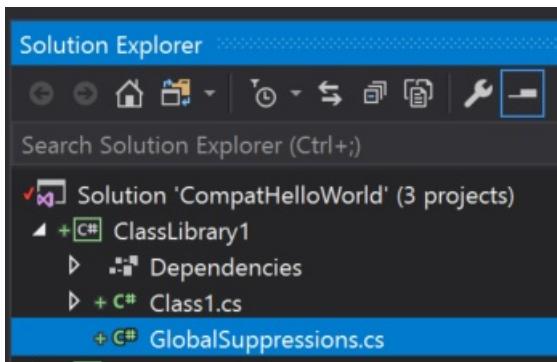

Suppressing warnings globally

To suppress warnings globally, right-click on the member you want to suppress warnings for and then select **Quick Actions and Refactorings > Suppress diagnostic ID<diagnostic ID> > in Suppression File**.

A `GlobalSuppressions.cs` file is added to your project after the first suppression. New global suppressions are appended to this file.

Global suppression is the recommended way to ensure consistency of API usage across projects.

Discovering cross-platform issues

Similar to deprecated APIs, the analyzer identifies all APIs that are not cross-platform. For example, `Console.WindowWidth` works on Windows but not on Linux and macOS. The diagnostic ID is shown in the **Error List** window. You can suppress that warning by right-clicking and selecting **Quick Actions and Refactorings**. Unlike deprecation cases where you have two options (either keep using the deprecated member and suppress warnings or not use it at all), here if you're developing your code only for certain platforms, you can suppress all warnings for all other platforms you don't plan to run your code on. To do so, you just need to edit your project file and add the `PlatformCompatIgnore` property that lists all platforms to be ignored. The accepted values are: `Linux`, `macOS`, and `Windows`.

```
<PropertyGroup>
  <PlatformCompatIgnore>Linux;macOS</PlatformCompatIgnore>
</PropertyGroup>
```

If your code targets multiple platforms and you want to take advantage of an API not supported on some of them, you can guard that part of the code with an `if` statement:

```
if (RuntimeInformation.IsOSPlatform(OSPlatform.Windows))
{
    var w = Console.WindowWidth;
    // More code
}
```

You can also conditionally compile per target framework/operating system, but you currently need to do that [manually](#).

Supported diagnostics

Currently, the analyzer handles the following cases:

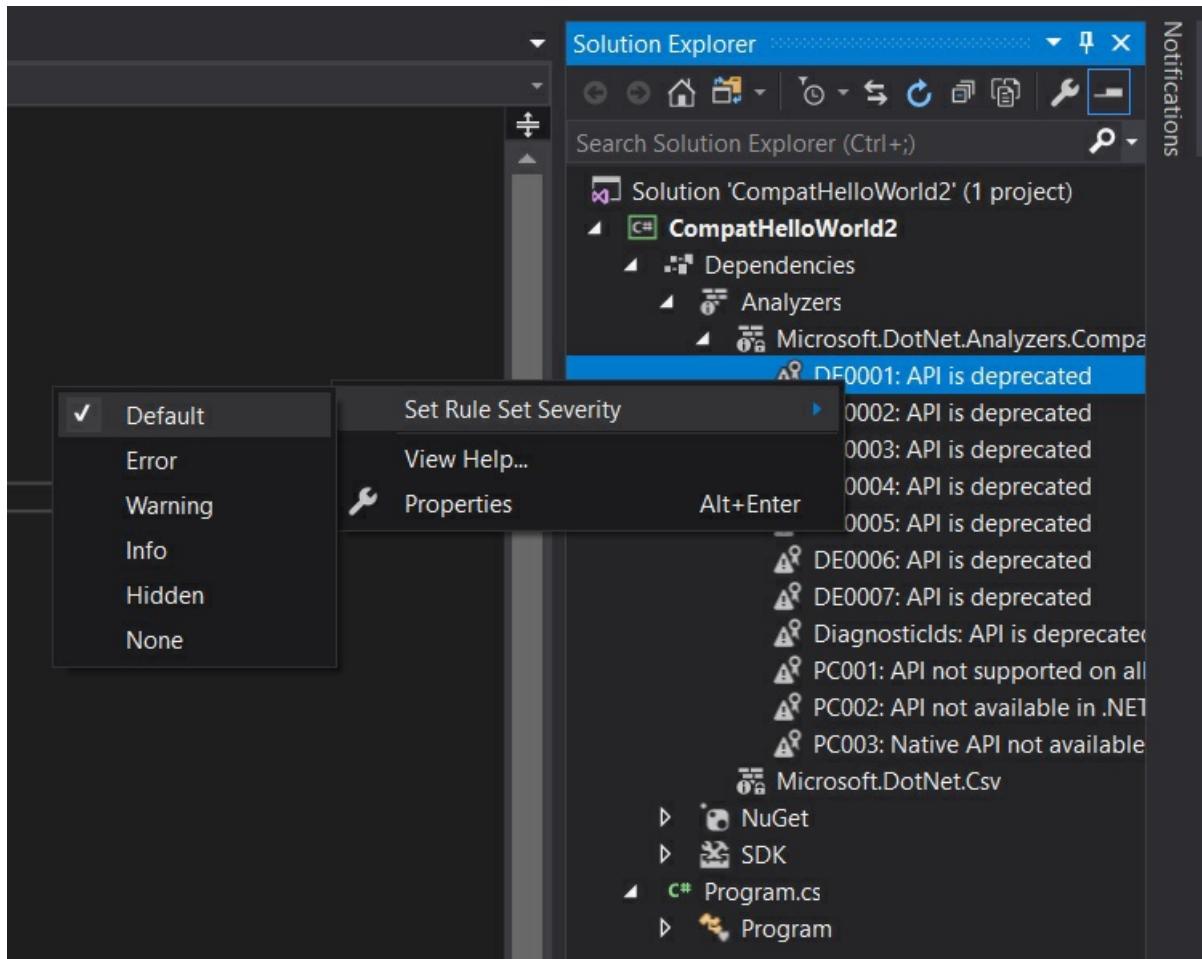

- Usage of a .NET Standard API that throws `PlatformNotSupportedException` (PC001).
- Usage of a .NET Standard API that isn't available on the .NET Framework 4.6.1 (PC002).
- Usage of a native API that doesn't exist in UWP (PC003).
- Usage of an API that is marked as deprecated (DEXXXX).

CI machine

All these diagnostics are available not only in the IDE, but also on the command line as part of building your project, which includes the CI server.

Configuration

The user decides how the diagnostics should be treated: as warnings, errors, suggestions, or to be turned off. For example, as an architect, you can decide that compatibility issues should be treated as errors, calls to some deprecated APIs generate warnings, while others only generate suggestions. You can configure this separately by diagnostic ID and by project. To do so in **Solution Explorer**, navigate to the **Dependencies** node under your project. Expand the nodes **Dependencies** > **Analyzers** > **Microsoft.DotNet.Analyzers.Compatibility**. Right click on the diagnostic ID, select **Set Rule Set Severity** and pick the desired option.

The .NET Portability Analyzer

3/9/2019 • 2 minutes to read • [Edit Online](#)

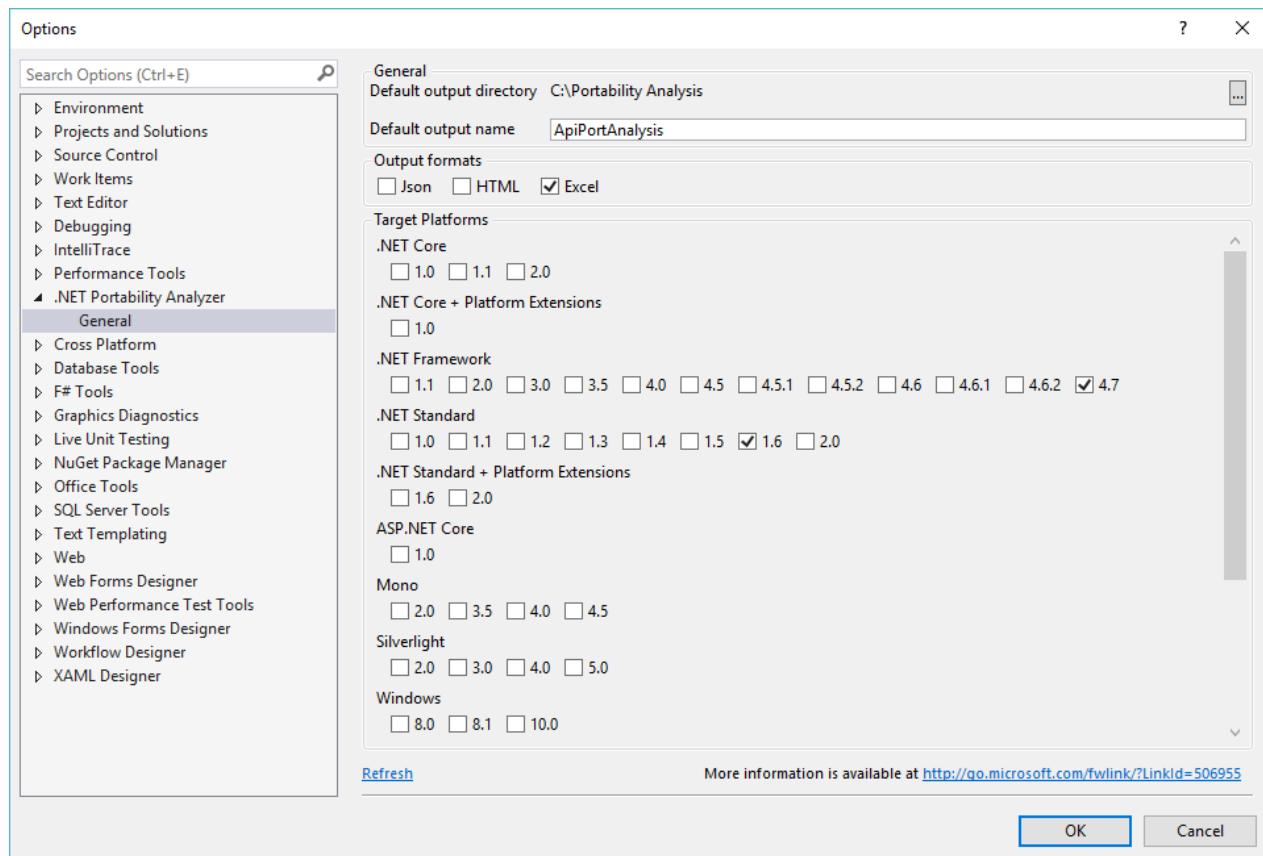

Want to make your libraries multi-platform? Want to see how much work is required to make your application compatible with other .NET implementations and profiles, including .NET Core, .NET Standard, UWP, and Xamarin for iOS, Android, and Mac? The [.NET Portability Analyzer](#) is a tool that provides you with a detailed report on how flexible your program is across .NET implementations by analyzing assemblies. The Portability Analyzer is offered as a Visual Studio Extension and as a console app.

New targets

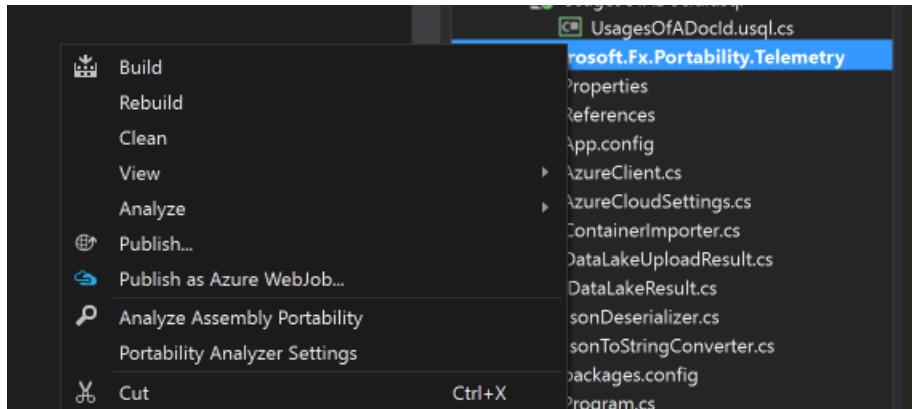

- [.NET Core](#): Has a modular design, employs side-by-side, and targets cross-platform scenarios. Side-by-side allows you to adopt new .NET Core versions without breaking other apps.
- [ASP.NET Core](#): is a modern web-framework built on .NET Core thus giving developers the same benefits.
- [Universal Windows Platform](#): Improve performance of your Windows Store apps that run on x64 and ARM machines by using .NET Native's static compilation.
- .NET Core + Platform Extensions: Includes the .NET Core APIs in addition to other APIs in the .NET ecosystem such as WCF, ASP.NET Core, FSharp, and Azure.
- .NET Standard + Platform Extensions: Includes the .NET Standard APIs in addition to other .NET ecosystem such as WCF, ASP.NET Core, FSharp, and Azure.

How to use Portability Analyzer

To begin using the .NET Portability Analyzer, you first need to download and install the extension from the [Visual Studio Marketplace](#). It works on Visual Studio 2015 and Visual Studio 2017. You can configure it in Visual Studio via **Analyze > Portability Analyzer Settings** and select your Target Platforms.

To analyze your entire project, right-click on your project in **Solution Explorer** and select **Analyze Assembly Portability**. Otherwise, go to the **Analyze** menu and select **Analyze Assembly Portability**. From there, select your project's executable or DLL.

After running the analysis, you will see your .NET Portability Report. Only types that are unsupported by a target platform appear in the list and you can review recommendations in the **Messages** tab in the **Error List**. You can also jump to problem areas directly from the **Messages** tab.

The screenshot shows the .NET Portability Report window. At the top, it says 'Assembly Mono 4.5' and 'HubApp1.Windows 94.84%'. Below that is the 'HubApp1.Windows' section with a 'Missing assemblies' table. Under 'Target type', there is a table comparing Windows.Foundation.Rect methods across Mono 4.5 and recommended changes. The 'Error List' tab is selected, showing 0 Errors, 0 Warnings, and 25 Messages. One message is expanded, showing code related to System.Runtime.InteropServices.WindowsRuntime.WindowsRuntimeMarshal.

Don't want to use Visual Studio? You can also use the Portability Analyzer from the command prompt. Just download the [API Portability Analyzer](#).

- Type the following command to analyze the current directory: `\...\ApiPort.exe analyze -f .`
- To analyze a specific list of .dll files, type the following command:
`\...\ApiPort.exe analyze -f first.dll -f second.dll -f third.dll`

Your .NET Portability Report is saved as an Excel file (.xlsx) in your current directory. The **Details** tab in the Excel Workbook contains more information.

For more information on the .NET Portability Analyzer, visit the [GitHub documentation](#) and [A Brief Look at the .NET Portability Analyzer Channel 9 video](#).

The .NET Framework Analyzer

5/2/2018 • 4 minutes to read • [Edit Online](#)

You can use the .NET Framework Analyzer to find potential issues in your .NET Framework-based application code. This analyzer finds potential issues and suggests fixes to them.

The analyzer runs interactively in Visual Studio as you write your code or as part of a CI build. You should add the analyzer to your project as early as possible in your development. The sooner you find any potential issues in your code, the easier they are to fix. However, you can add it at any time in the development cycle. It finds any issues with the existing code and warns about new issues as you keep developing.

Installing and configuring the .NET Framework Analyzer

The .NET Security Analyzers must be installed as a NuGet package on every project where you want them to run. Only one developer needs to add them to the project. The analyzer package is a project dependency and will run on every developer's machine once it has the updated solution.

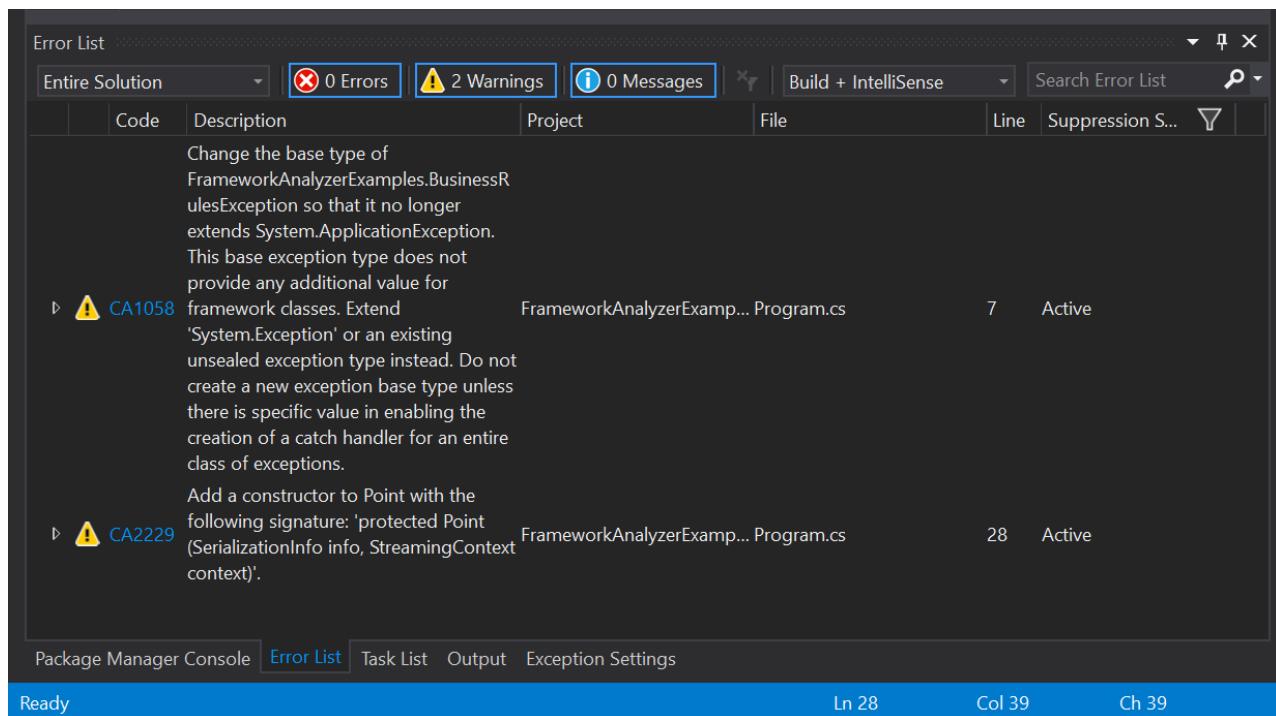

The .NET Framework Analyzer is delivered in the [Microsoft.NetFramework.Analyzers](#) NuGet package. This package provides only the analyzers specific to the .NET Framework, which includes security analyzers. In most cases, you'll want the [Microsoft.CodeAnalysis.FxCopAnalyzers](#) NuGet package. The FxCopAnalyzers aggregate package contains all the framework analyzers included in the Framework.Analyzers package as well as the following analyzers:

- [Microsoft.CodeQuality.Analyzers](#): Provides general guidance and guidance for .NET Standard APIs
- [Microsoft.NetCore.Analyzers](#): Provides analyzers specific to .NET Core APIs.
- [Text.Analyzers](#): Provides guidance for text included as code, including comments.

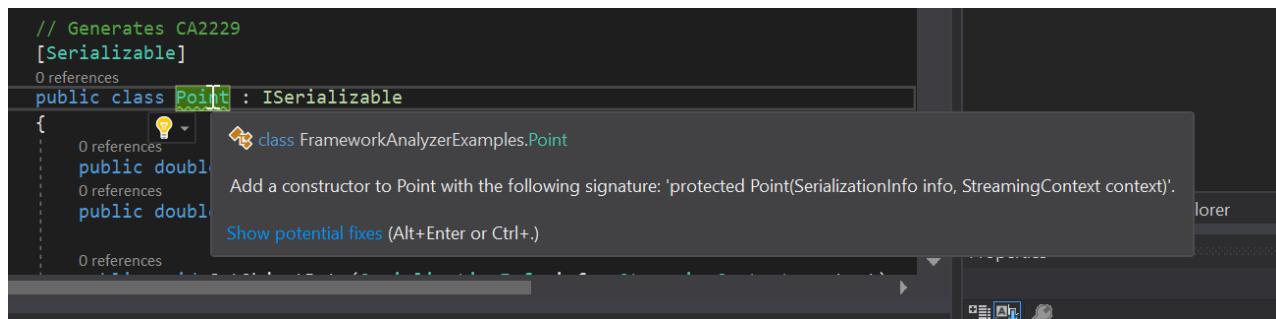

To install it, right-click on the project, and select "Manage Dependencies". From the NuGet explorer, search for "NetFramework Analyzer", or if you prefer, "Fx Cop Analyzer". Install the latest stable version in all projects in your solution.

Using the .NET Framework Analyzer

Once the NuGet package is installed, build your solution. The analyzer will report any issues it locates in your codebase. The issues are reported as warnings in the Visual Studio Error List window, as shown in the following image:

As you write code, you see squiggles underneath any potential issue in your code. Hover over any issue and you see details about the issue, and suggestions for any possible fix, as shown in the following image:

The analyzers examine the code in your solution and provide you with a list of warnings for any of these issues:

CA1058: Types should not extend certain base types

There are a small number of types in the .NET Framework that you should not derive from directly.

Category: Design

Severity: Warning

Additional information: [CA1058: Types should not extend certain base types](#)

CA2153: Do not catch corrupted state exceptions

Catching corrupted state exceptions could mask errors (such as access violations), resulting in an inconsistent state of execution or making it easier for attackers to compromise a system. Instead, catch and handle a more specific set of exception type(s) or re-throw the exception

Category: Security

Severity: Warning

Additional information: [## CA2153: Do not catch corrupted state exceptions](#)

CA2229: Implement serialization constructors

The analyzer generates this warning when you create a type that implements the `ISerializable` interface but does not define the required serialization constructor. To fix a violation of this rule, implement the serialization constructor. For a sealed class, make the constructor private; otherwise, make it protected. The serialization

constructor has the following signature:

```
public class MyItemType
{
    // The special constructor is used to deserialize values.
    public MyItemType(SerializationInfo info, StreamingContext context)
    {
        // implementation removed.
    }
}
```

Category: Usage

Severity: Warning

Additional information: [CA2229: Implement serialization constructors](#)

CA2235: Mark all non-serializable fields

An instance field of a type that is not serializable is declared in a type that is serializable. You must explicitly mark that field with the [NonSerializedAttribute](#) to fix this warning.

Category: Usage

Severity: Warning

Additional information: [CA2235: Mark all non-serializable fields](#)

CA2237: Mark ISerializable types with serializable

To be recognized by the common language runtime as serializable, types must be marked by using the [SerializableAttribute](#) attribute even when the type uses a custom serialization routine by implementing the [ISerializable](#) interface.

Category: Usage

Severity: Warning

Additional information: [CA2237: Mark ISerializable types with serializable](#)

CA3075: Insecure DTD processing in XML

If you use insecure [DtdProcessing](#) instances or reference external entity sources, the parser may accept untrusted input and disclose sensitive information to attackers.

Category: Security

Severity: Warning

Additional information: [A3075: Insecure DTD processing in XML](#)

CA5350: Do not use weak cryptographic algorithms

Cryptographic algorithms degrade over time as attacks become more advanced. Depending on the type and application of this cryptographic algorithm, further degradation of its cryptographic strength may allow attackers to read enciphered messages, tamper with enciphered messages, forge digital signatures, tamper with hashed content, or otherwise compromise any cryptosystem based on this algorithm. For encryption, use an AES algorithm (AES-256, AES-192 and AES-128 are acceptable) with a key length greater than or equal to 128 bits. For hashing, use a hashing function in the SHA-2 family, such as SHA-2 512, SHA-2 384, or SHA-2 256.

Category: Security

Severity: Warning

Additional information: [CA5350: Do not use weak cryptographic algorithms](#)

CA5351: Do not use broken cryptographic algorithms

An attack making it computationally feasible to break this algorithm exists. This allows attackers to break the cryptographic guarantees it is designed to provide. Depending on the type and application of this cryptographic algorithm, this may allow attackers to read enciphered messages, tamper with enciphered messages, forge digital signatures, tamper with hashed content, or otherwise compromise any cryptosystem based on this algorithm. For encryption, use an AES algorithm (AES-256, AES-192 and AES-128 are acceptable) with a key length greater than or equal to 128 bits. For hashing, use a hashing function in the SHA-2 family, such as SHA512, SHA384, or SHA256. For digital signatures, use RSA with a key length greater than or equal to 2048-bits, or ECDSA with a key length greater than or equal to 256 bits.

Category: Security

Severity: Warning

Additional Information: [CA5351: Do not use broken cryptographic algorithms](#)

Handling and throwing exceptions in .NET

2/6/2019 • 2 minutes to read • [Edit Online](#)

Applications must be able to handle errors that occur during execution in a consistent manner. .NET provides a model for notifying applications of errors in a uniform way: .NET operations indicate failure by throwing exceptions.

Exceptions

An exception is any error condition or unexpected behavior that is encountered by an executing program. Exceptions can be thrown because of a fault in your code or in code that you call (such as a shared library), unavailable operating system resources, unexpected conditions that the runtime encounters (such as code that can't be verified), and so on. Your application can recover from some of these conditions, but not from others. Although you can recover from most application exceptions, you can't recover from most runtime exceptions.

In .NET, an exception is an object that inherits from the [System.Exception](#) class. An exception is thrown from an area of code where a problem has occurred. The exception is passed up the stack until the application handles it or the program terminates.

Exceptions vs. traditional error-handling methods

Traditionally, a language's error-handling model relied on either the language's unique way of detecting errors and locating handlers for them, or on the error-handling mechanism provided by the operating system. The way .NET implements exception handling provides the following advantages:

- Exception throwing and handling works the same for .NET programming languages.
- Doesn't require any particular language syntax for handling exceptions, but allows each language to define its own syntax.
- Exceptions can be thrown across process and even machine boundaries.
- Exception-handling code can be added to an application to increase program reliability.

Exceptions offer advantages over other methods of error notification, such as return codes. Failures don't go unnoticed because if an exception is thrown and you don't handle it, the runtime terminates your application. Invalid values don't continue to propagate through the system as a result of code that fails to check for a failure return code.

Common exceptions

The following table lists some common exceptions with examples of what can cause them.

EXCEPTION TYPE	DESCRIPTION	EXAMPLE
Exception	Base class for all exceptions.	None (use a derived class of this exception).
IndexOutOfRangeException	Thrown by the runtime only when an array is indexed improperly.	Indexing an array outside its valid range: <code>arr[arr.Length+1]</code>

EXCEPTION TYPE	DESCRIPTION	EXAMPLE
NullReferenceException	Thrown by the runtime only when a null object is referenced.	<code>object o = null; o.ToString();</code>
InvalidOperationException	Thrown by methods when in an invalid state.	Calling <code>Enumerator.MoveNext()</code> after removing an item from the underlying collection.
ArgumentException	Base class for all argument exceptions.	None (use a derived class of this exception).
ArgumentNullException	Thrown by methods that do not allow an argument to be null.	<code>String s = null; "Calculate".IndexOf(s);</code>
ArgumentOutOfRangeException	Thrown by methods that verify that arguments are in a given range.	<code>String s = "string"; s.Substring(s.Length+1);</code>

Assemblies in .NET

3/26/2019 • 4 minutes to read • [Edit Online](#)

Assemblies form the fundamental unit of deployment, version control, reuse, activation scoping, and security permissions for a .NET-based application. Assemblies take the form of an executable (.exe) file or dynamic link library (.dll) file, and are the building blocks of the .NET applications. They provide the common language runtime with the information it needs to be aware of type implementations. You can think of an assembly as a collection of types and resources that form a logical unit of functionality and are built to work together.

In .NET Core and .NET Framework, an assembly can be built from one or more source code files. In .NET Framework, assemblies can contain one or more modules. This allows larger projects to be planned in such a way that several individual developers work on separate source code files or modules, which are combined to create a single assembly. For more information about modules, see [How to: Build a Multifile Assembly](#).

Assemblies have the following properties:

- Assemblies are implemented as .exe or .dll files.
- For libraries that target the .NET Framework, you can share an assembly between applications by putting it in the [global assembly cache](#). Assemblies must be strong-named before they can be included in the global assembly cache. For more information, see [Strong-Named Assemblies](#).
- Assemblies are only loaded into memory if they are required. If they are not used, they are not loaded. This means that assemblies can be an efficient way to manage resources in larger projects.
- You can programmatically obtain information about an assembly by using reflection. For more information, see [Reflection \(C#\)](#) or [Reflection \(Visual Basic\)](#).
- You can load an assembly only to inspect it by calling a method [Assembly.ReflectionOnlyLoadFrom](#).

Assembly manifest

Within every assembly is an *assembly manifest*. Similar to a table of contents, the assembly manifest contains the following:

- The assembly's identity (its name and version).
- A file table describing all the other files that make up the assembly, such as other assemblies you created that your .exe or .dll file relies on, or even bitmap or Readme files.
- An *assembly reference list*, which is a list of all external dependencies — .dlls or other files your application needs that may have been created by someone else. Assembly references contain references to both global and private objects. Global objects are available to all other applications. In .NET Core, they are coupled with a particular .NET Core runtime. In .NET Framework, they reside in the global assembly cache. The [System.IO](#) namespace is an example of an assembly in the global assembly cache. Private objects must be in a directory at either the same level as or below the directory in which your application is installed.

Because assemblies contain information about content, versioning, and dependencies, the applications that use them need not rely on Windows registry values to function properly. Assemblies reduce .dll conflicts and make your applications more reliable and easier to deploy. In many cases, you can install a .NET-based application simply by copying its files to the target computer. For more information, see [Assembly Manifest](#).

Adding a reference to an assembly

To use an assembly, you must add a reference to it. Next, you can use the [using directive](#) for C# or [Imports statement](#) for Visual Basic to choose the namespace of the items you want to use. Once an assembly is referenced and imported, all the accessible types, properties, methods, and other members of its namespaces are available to your application as if their code were part of your source file.

NOTE

Most assemblies from the .NET Class Library are referenced automatically. In some cases, though, a system assembly may not automatically be referenced. In .NET Core, you can add a reference to the NuGet package that contains the assembly either by using NuGet Package Manager in Visual Studio or by adding a `<PackageReference>` element for the assembly to the `*.csproj` or `*.vbproj` project. In .NET Framework, you can add a reference to the assembly by using the [Add Reference](#) dialog in Visual Studio or by using the `-reference` command line option for the [C#](#) or [Visual Basic](#) compilers.

In C#, you can also use two versions of the same assembly in a single application. For more information, see [extern alias](#).

Creating an assembly

Compile your application by building it in Visual Studio, by building it from the command line by using .NET Core command-line interface (CLI) tools, or by building .NET Framework assemblies with a command-line compiler. For more information about building assemblies using .NET CLI tools, see [.NET Core command-line interface \(CLI\) tools](#). For building assemblies with the command-line compilers, see [Command-line build with csc.exe](#) for C# and [Building from the Command Line](#) for Visual Basic.

NOTE

To build an assembly in Visual Studio, on the **Build** menu choose **Build**.

.NET Assembly File Format

3/5/2019 • 2 minutes to read • [Edit Online](#)

.NET defines a binary file format - "assembly" - that is used to fully-describe and contain .NET programs. Assemblies are used for the programs themselves as well as any dependent libraries. A .NET program can be executed as one or more assemblies, with no other required artifacts, beyond the appropriate .NET implementation. Native dependencies, including operating system APIs, are a separate concern and are not contained within the .NET assembly format, although are sometimes described with this format (for example, WinRT).

Each CLI component carries the metadata for declarations, implementations, and references specific to that component. Therefore, the component-specific metadata is referred to as component metadata, and the resulting component is said to be self-describing – from ECMA 335 I.9.1, Components and assemblies.

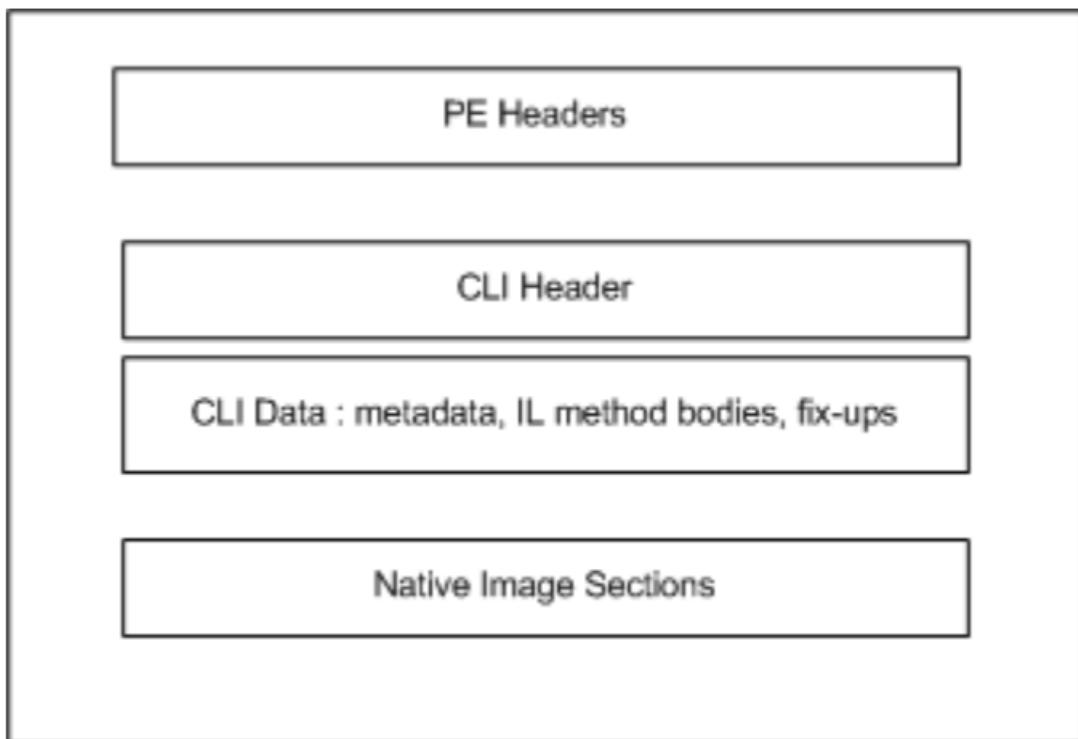

The format is fully specified and standardized as [ECMA 335](#). All .NET compilers and runtimes use this format. The presence of a documented and infrequently updated binary format has been a major benefit (arguably a requirement) for interoperability. The format was last updated in a substantive way in 2005 (.NET 2.0) to accommodate generics and processor architecture.

The format is CPU- and OS-agnostic. It has been used as part of .NET implementations that target many chips and CPUs. While the format itself has Windows heritage, it is implementable on any operating system. Its arguably most significant choice for OS interoperability is that most values are stored in little-endian format. It doesn't have a specific affinity to machine pointer size (for example, 32-bit, 64-bit).

The .NET assembly format is also very descriptive about the structure of a given program or library. It describes the internal components of an assembly, specifically: assembly references and types defined and their internal structure. Tools or APIs can read and process this information for display or to make programmatic decisions.

Format

The .NET binary format is based on the Windows [PE file](#) format. In fact, .NET class libraries are conformant Windows PEs, and appear on first glance to be Windows dynamic link libraries (DLLs) or application executables (EXEs). This is a very useful characteristic on Windows, where they can masquerade as native executable binaries and get some of the same treatment (for example, OS load, PE tools).

Assembly Headers from ECMA 335 II.25.1, Structure of the runtime file format.

Processing the Assemblies

It is possible to write tools or APIs to process assemblies. Assembly information enables making programmatic decisions at runtime, re-writing assemblies, providing API IntelliSense in an editor and generating documentation. [System.Reflection](#) and [Mono.Cecil](#) are good examples of tools that are frequently used for this purpose.

How to use and debug assembly unloadability in .NET Core

3/2/2019 • 12 minutes to read • [Edit Online](#)

Starting with .NET Core 3.0, the ability to load and later unload a set of assemblies is supported. In .NET Framework, custom app domains were used for this purpose, but .NET Core only supports a single default app domain.

.NET Core 3.0 and later versions support unloadability through `AssemblyLoadContext`. You can load a set of assemblies into a collectible `AssemblyLoadContext`, execute methods in them or just inspect them using reflection, and finally unload the `AssemblyLoadContext`. That unloads the assemblies loaded into that `AssemblyLoadContext`.

There's one noteworthy difference between the unloading using `AssemblyLoadContext` and using AppDomains. With AppDomains, the unloading is forced. At the unload time, all threads running in the target AppDomain are aborted, managed COM objects created in the target AppDomain are destroyed, etc. With `AssemblyLoadContext`, the unload is "cooperative". Calling the `AssemblyLoadContext.Unload` method just initiates the unloading. The unloading finishes after:

- No threads have methods from the assemblies loaded into the `AssemblyLoadContext` on their call stacks.
- None of the types from the assemblies loaded into the `AssemblyLoadContext`, instances of those types and the assemblies themselves outside of the `AssemblyLoadContext` are referenced by:
 - References outside of the `AssemblyLoadContext`, except of weak references (`WeakReference` or `WeakReference<T>`).
 - Strong GC handles (`GCHandleType.Normal` or `GCHandleType.Pinned`) from both inside and outside of the `AssemblyLoadContext`.

Using collectible AssemblyLoadContext

This section contains a detailed step-by-step tutorial that shows a simple way to load a .NET Core application into a collectible `AssemblyLoadContext`, execute its entry point, and then unload it. You can find a complete sample at <https://github.com/dotnet/samples/tree/master/core/tutorials/Unloading>.

Create a collectible AssemblyLoadContext

You need to derive your class from the `AssemblyLoadContext` and overload its `AssemblyLoadContext.Load` method. That method resolves references to all assemblies that are dependencies of assemblies loaded into that `AssemblyLoadContext`. The following code is an example of the simplest custom `AssemblyLoadContext`:

```
class TestAssemblyLoadContext : AssemblyLoadContext
{
    public TestAssemblyLoadContext() : base(isCollectible: true)
    {

    }

    protected override Assembly Load(AssemblyName name)
    {
        return null;
    }
}
```

As you can see, the `Load` method returns `null`. That means that all the dependency assemblies are loaded into the default context, and the new context contains only the assemblies explicitly loaded into it.

If you want to load some or all of the dependencies into the `AssemblyLoadContext` too, you can use the `AssemblyDependencyResolver` in the `Load` method. The `AssemblyDependencyResolver` resolves the assembly names to absolute assembly file paths using the `*.deps.json` file contained in the directory of the main assembly loaded into the context and using assembly files in that directory.

```
class TestAssemblyLoadContext : AssemblyLoadContext
{
    private AssemblyDependencyResolver _resolver;

    public TestAssemblyLoadContext(string mainAssemblyToLoadPath) : base(isCollectible: true)
    {
        _resolver = new AssemblyDependencyResolver(mainAssemblyToLoadPath);
    }

    protected override Assembly Load(AssemblyName name)
    {
        string assemblyPath = _resolver.ResolveAssemblyToPath(name);
        if (assemblyPath != null)
        {
            return LoadFromAssemblyPath(assemblyPath);
        }

        return null;
    }
}
```

Use a custom collectible `AssemblyLoadContext`

This section assumes the simpler version of the `TestAssemblyLoadContext` is being used.

You can create an instance of the custom `AssemblyLoadContext` and load an assembly into it as follows:

```
var alc = new TestAssemblyLoadContext();
Assembly a = alc.LoadFromAssemblyPath(assemblyPath);
```

For each of the assemblies referenced by the loaded assembly, the `TestAssemblyLoadContext.Load` method is called so that the `TestAssemblyLoadContext` can decide where to get the assembly from. In our case, it returns `null` to indicate that it should be loaded into the default context from locations that the runtime uses to load assemblies by default.

Now that an assembly was loaded, you can execute a method from it. Run the `Main` method:

```
var args = new object[1] { new string[] {"Hello"} };
int result = (int)a.EntryPoint.Invoke(null, args);
```

After the `Main` method returns, you can initiate unloading by either calling the `Unload` method on the custom `AssemblyLoadContext` or getting rid of the reference you have to the `AssemblyLoadContext`:

```
alc.Unload();
```

This is sufficient to unload the test assembly. Let's actually put all of this into a separate non-inlineable method to ensure that the `TestAssemblyLoadContext`, `Assembly`, and `MethodInfo` (the `Assembly.EntryPoint`) can't be kept alive by stack slot references (real- or JIT-introduced locals). That could keep the `TestAssemblyLoadContext` alive and prevent the unload.

Also, return a weak reference to the `AssemblyLoadContext` so that you can use it later to detect unload completion.

```
[MethodImpl(MethodImplOptions.NoInlining)]
static int ExecuteAndUnload(string assemblyPath, out WeakReference alcWeakRef)
{
    var alc = new TestAssemblyLoadContext();
    Assembly a = alc.LoadFromAssemblyPath(assemblyPath);

    alcWeakRef = new WeakReference(alc, trackResurrection: true);

    var args = new object[1] { new string[] {"Hello"} };
    int result = (int)a.EntryPoint.Invoke(null, args);

    alc.Unload();

    return result;
}
```

Now you can run this function to load, execute, and unload the assembly.

```
WeakReference testAlcWeakRef;
int result = ExecuteAndUnload("absolute/path/to/your/assembly", out testAlcWeakRef);
```

However, the unload doesn't complete immediately. As previously mentioned, it relies on the GC to collect all the objects from the test assembly. In many cases, it isn't necessary to wait for the unload completion. However, there are cases where it's useful to know that the unload has finished. For example, you may want to delete the assembly file that was loaded into the custom `AssemblyLoadContext` from disk. In such a case, the following code snippet can be used. It triggers a GC and waits for pending finalizers in a loop until the weak reference to the custom `AssemblyLoadContext` is set to `null`, indicating the target object was collected. Note that in most cases, just one pass through the loop is required. However, for more complex cases where objects created by the code running in the `AssemblyLoadContext` have finalizers, more passes may be needed.

```
for (int i = 0; testAlcWeakRef.IsAlive && (i < 10); i++)
{
    GC.Collect();
    GC.WaitForPendingFinalizers();
}
```

The Unloading event

In some cases, it may be necessary for the code loaded into a custom `AssemblyLoadContext` to perform some cleanup when the unloading is initiated. For example, it may need to stop threads, clean up some strong GC handles, etc. The `Unloading` event can be used in such cases. A handler that performs the necessary cleanup can be hooked to this event.

Troubleshoot unloadability issues

Due to the cooperative nature of the unloading, it's easy to forget about references keeping the stuff in a collectible `AssemblyLoadContext` alive and preventing unload. Here is a summary of things (some of them non-obvious) that can hold the references:

- Regular references held from outside of the collectible `AssemblyLoadContext`, stored in a stack slot or a processor register (method locals, either explicitly created by the user code or implicitly by the JIT), a static variable or a strong / pinning GC handle, and transitively pointing to:
 - An assembly loaded into the collectible `AssemblyLoadContext`.
 - A type from such an assembly.
 - An instance of a type from such an assembly.
- Threads running code from an assembly loaded into the collectible `AssemblyLoadContext`.

- Instances of custom non-collectible `AssemblyLoadContext` types created inside of the collectible `AssemblyLoadContext`
- Pending `RegisteredWaitHandle` instances with callbacks set to methods in the custom `AssemblyLoadContext`

Hints to find stack slot / processor register rooting an object:

- Passing function call results directly to another function may create a root even though there is no user-created local variable.
- If a reference to an object was available at any point in a method, the JIT might have decided to keep the reference in a stack slot / processor register for as long as it wants in the current function.

Debug unloading issues

Debugging issues with unloading can be tedious. You can get into situations where you don't know what can be holding an `AssemblyLoadContext` alive, but the unload fails. The best weapon to help with that is WinDbg (LLDB on Unix) with the SOS plugin. You need to find what's keeping a `LoaderAllocator` belonging to the specific `AssemblyLoadContext` alive. This plugin allows you to look at GC heap objects, their hierarchies, and roots. To load the plugin into the debugger, enter the following command in the debugger command line:

In WinDbg (it seems WinDbg does that automatically when breaking into .NET Core application):

```
.loadby sos coreclr
```

In LLDB:

```
plugin load /path/to/libssosplugin.so
```

Let's try to debug an example program that has problems with unloading. Source code is included below. When you run it under WinDbg, the program breaks into the debugger right after attempting to check for the unload success. You can then start looking for the culprits.

Note that if you debug using LLDB on Unix, the SOS commands in the following examples don't have the `!` in front of them.

```
!dumpheap -type LoaderAllocator
```

This command dumps all objects with a type name containing `LoaderAllocator` that are in the GC heap. Here is an example:

Address	MT	Size
000002b78000ce40	00007ffadc93a288	48
000002b78000ceb0	00007ffadc93a218	24

Statistics:

MT	Count	TotalSize	Class	Name
00007ffadc93a218	1	24	System.Reflection.	LoaderAllocatorScout
00007ffadc93a288	1	48	System.Reflection.	LoaderAllocator
Total	2	72		objects

In the "Statistics:" part below, check the `MT` (`MethodTable`) belonging to the `System.Reflection.LoaderAllocator`, which is the object we care about. Then in the list at the beginning, find the entry with `MT` matching that one and get the address of the object itself. In our case, it is "000002b78000ce40"

Now that we know the address of the `LoaderAllocator` object, we can use another command to find its GC roots

```
!gcroot -all 0x000002b78000ce40
```

This command dumps the chain of object references that lead to the `LoaderAllocator` instance. The list starts with the root, which is the entity that keeps our `LoaderAllocator` alive and thus is the core of the problem you're debugging. The root can be a stack slot, a processor register, a GC handle, or a static variable.

Here is an example of the output of the `gcroot` command:

```
Thread 4ac:
000000cf9499dd20 00007ffa7d0236bc example.Program.Main(System.String[])
[E:\unloadability\example\Program.cs @ 70]
    rbp-20: 000000cf9499dd90
        -> 000002b78000d328 System.Reflection.RuntimeMethodInfo
        -> 000002b78000d1f8 System.RuntimeType+RuntimeTypeCache
        -> 000002b78000d1d0 System.RuntimeType
        -> 000002b78000ce40 System.Reflection.LoaderAllocator

HandleTable:
000002b7f8a81198 (strong handle)
-> 000002b78000d948 test.Test
-> 000002b78000ce40 System.Reflection.LoaderAllocator

000002b7f8a815f8 (pinned handle)
-> 000002b790001038 System.Object[]
-> 000002b78000d390 example.TestInfo
-> 000002b78000d328 System.Reflection.RuntimeMethodInfo
-> 000002b78000d1f8 System.RuntimeType+RuntimeTypeCache
-> 000002b78000d1d0 System.RuntimeType
-> 000002b78000ce40 System.Reflection.LoaderAllocator

Found 3 roots.
```

Now you need to figure out where the root is located so you can fix it. The easiest case is when the root is a stack slot or a processor register. In that case, the `gcroot` shows you the name of the function whose frame contains the root and the thread executing that function. The difficult case is when the root is a static variable or a GC handle.

In the previous example, the first root is a local of type `System.Reflection.RuntimeMethodInfo` stored in the frame of the function `example.Program.Main(System.String[])` at address `rbp-20` (`rbp` is the processor register `rbp` and `-20` is a hexadecimal offset from that register).

The second root is a normal (strong) `GCHandle` that holds a reference to an instance of the `test.Test` class.

The third root is a pinned `GCHandle`. This one is actually a static variable. Unfortunately, there is no way to tell. Statics for reference types are stored in a managed object array in internal runtime structures.

Another case that can prevent unloading of an `AssemblyLoadContext` is when a thread has a frame of a method from an assembly loaded into the `AssemblyLoadContext` on its stack. You can check that by dumping managed call stacks of all threads:

```
~*e !clrstack
```

The command means "apply to all threads the `!clrstack` command". The following is the output of that command for the example. Unfortunately, LLDB on Unix doesn't have any way to apply a command to all threads, so you'll need to resort to manually switching threads and repeating the `clrstack` command. Ignore all threads where the debugger says "Unable to walk the managed stack."

```

0000001fc727f7f0 00007ffae5fdc1e3 [DebuggerU2MCatchHandlerFrame: 0000001fc727f7f0]

```

As you can see, the last thread has `test.Program.ThreadProc()`. This is a function from the assembly loaded into the `AssemblyLoadContext`, and so it keeps the `AssemblyLoadContext` alive.

Example source with unloadability issues

The following code is used in the previous debugging example.

Main testing program

```

using System;
using System.Reflection;
using System.Runtime.CompilerServices;
using System.Runtime.Loader;

namespace example

```

```

{
    class TestAssemblyLoadContext : AssemblyLoadContext
    {
        public TestAssemblyLoadContext() : base(true)
        {
        }
        protected override Assembly Load(AssemblyName name)
        {
            return null;
        }
    }

    class TestInfo
    {
        public TestInfo(MethodInfo mi)
        {
            entryPoint = mi;
        }
        MethodInfo entryPoint;
    }

    class Program
    {
        static TestInfo entryPoint;

        [MethodImpl(MethodImplOptions.NoInlining)]
        static int ExecuteAndUnload(string assemblyPath, out WeakReference testAlcWeakRef, out MethodInfo
testEntryPoint)
        {
            var alc = new TestAssemblyLoadContext();
            testAlcWeakRef = new WeakReference(alc);

            Assembly a = alc.LoadFromAssemblyPath(assemblyPath);
            if (a == null)
            {
                testEntryPoint = null;
                Console.WriteLine("Loading the test assembly failed");
                return -1;
            }

            var args = new object[1] {new string[] {"Hello"}};

            // Issue preventing unloading #1 - we keep MethodInfo of a method for an assembly loaded into the
            TestAssemblyLoadContext in a static variable
            entryPoint = new TestInfo(a.EntryPoint);
            testEntryPoint = a.EntryPoint;

            int result = (int)a.EntryPoint.Invoke(null, args);
            alc.Unload();

            return result;
        }

        static void Main(string[] args)
        {
            WeakReference testAlcWeakRef;
            // Issue preventing unloading #2 - we keep MethodInfo of a method for an assembly loaded into the
            TestAssemblyLoadContext in a local variable
            MethodInfo testEntryPoint;
            int result = ExecuteAndUnload(@"absolute/path/to/test.dll", out testAlcWeakRef, out
testEntryPoint);

            for (int i = 0; testAlcWeakRef.IsAlive && (i < 10); i++)
            {
                GC.Collect();
                GC.WaitForPendingFinalizers();
            }

            System.Diagnostics.Debugger.Break();
        }
    }
}

```

```
System.Diagnostics.Debugger.Break();  
  
        Console.WriteLine($"Test completed, result={result}, entryPoint: {testEntryPoint} unload success:  
{!testAlcWeakRef.IsAlive}");  
    }  
}  
}
```

Program loaded into the TestAssemblyLoadContext

The following code represents the `test.dll` passed to the `ExecuteAndUnload` method in the main testing program.

```
using System;  
using System.Runtime.InteropServices;  
  
namespace test  
{  
    class Test  
    {  
        string message = "Hello";  
    }  
  
    class Program  
    {  
        public static void ThreadProc()  
        {  
            // Issue preventing unloading #4 - a thread running method inside of the TestAssemblyLoadContext  
            // at the unload time  
            Thread.Sleep(Timeout.Infinite);  
        }  
  
        static GCHandle handle;  
        static int Main(string[] args)  
        {  
            // Issue preventing unloading #3 - normal GC handle  
            handle = GCHandle.Alloc(new Test());  
            Thread t = new Thread(new ThreadStart(ThreadProc));  
            t.IsBackground = true;  
            t.Start();  
            Console.WriteLine($"Hello from the test: args[0] = {args[0]}");  
  
            return 1;  
        }  
    }  
}
```

Memory Management and Garbage Collection in .NET

Generic types overview

3/26/2019 • 2 minutes to read • [Edit Online](#)

Developers use generics all the time in .NET, whether implicitly or explicitly. When you use LINQ in .NET, did you ever notice that you're working with `IEnumerable<T>`? Or if you ever saw an online sample of a "generic repository" for talking to databases using Entity Framework, did you see that most methods return `IQueryable<T>`? You may have wondered what the `T` is in these examples and why it's in there.

First introduced in the .NET Framework 2.0, **generics** are essentially a "code template" that allows developers to define **type-safe** data structures without committing to an actual data type. For example, `List<T>` is a **generic collection** that can be declared and used with any type, such as `List<int>`, `List<string>`, or `List<Person>`.

To understand why generics are useful, let's take a look at a specific class before and after adding generics: `ArrayList`. In .NET Framework 1.0, the `ArrayList` elements were of type `Object`. This meant that any element added was silently converted into an `Object`. The same would happen when reading the elements from the list. This process is known as **boxing and unboxing**, and it impacts performance. More than that, however, there's no way to determine the type of data in the list at compile time. This makes for some fragile code. Generics solve this problem by defining the type of data each instance of list will contain. For example, you can only add integers to `List<int>` and only add Persons to `List<Person>`.

Generics are also available at runtime. This means the runtime knows what type of data structure you're using and can store it in memory more efficiently.

The following example is a small program that illustrates the efficiency of knowing the data structure type at runtime:

```
using System;
using System.Collections;
using System.Collections.Generic;
using System.Diagnostics;

namespace GenericsExample {
    class Program {
        static void Main(string[] args) {
            //generic list
            List<int> ListGeneric = new List<int> { 5, 9, 1, 4 };
            //non-generic list
            ArrayList ListNonGeneric = new ArrayList { 5, 9, 1, 4 };
            // timer for generic list sort
            Stopwatch s = Stopwatch.StartNew();
            ListGeneric.Sort();
            s.Stop();
            Console.WriteLine($"Generic Sort: {ListGeneric} \n Time taken: {s.Elapsed.TotalMilliseconds}ms");

            //timer for non-generic list sort
            Stopwatch s2 = Stopwatch.StartNew();
            ListNonGeneric.Sort();
            s2.Stop();
            Console.WriteLine($"Non-Generic Sort: {ListNonGeneric} \n Time taken:
{s2.Elapsed.TotalMilliseconds}ms");
            Console.ReadLine();
        }
    }
}
```

This program produces output similar to the following:

```
Generic Sort: System.Collections.Generic.List`1[System.Int32]
Time taken: 0.0034ms
Non-Generic Sort: System.Collections.ArrayList
Time taken: 0.2592ms
```

The first thing you can notice here is that sorting the generic list is significantly faster than sorting the non-generic list. You might also notice that the type for the generic list is distinct ([System.Int32]), whereas the type for the non-generic list is generalized. Because the runtime knows the generic `List<int>` is of type `Int32`, it can store the list elements in an underlying integer array in memory while the non-generic `ArrayList` has to cast each list element to an object. As this example shows, the extra casts take up time and slow down the list sort.

An additional advantage of the runtime knowing the type of your generic is a better debugging experience. When you're debugging a generic in C#, you know what type each element is in your data structure. Without generics, you would have no idea what type each element was.

Delegates and lambdas

12/20/2018 • 4 minutes to read • [Edit Online](#)

Delegates define a type, which specify a particular method signature. A method (static or instance) that satisfies this signature can be assigned to a variable of that type, then called directly (with the appropriate arguments) or passed as an argument itself to another method and then called. The following example demonstrates delegate use.

```
using System;
using System.Linq;

public class Program
{
    public delegate string Reverse(string s);

    static string ReverseString(string s)
    {
        return new string(s.Reverse().ToArray());
    }

    static void Main(string[] args)
    {
        Reverse rev = ReverseString;

        Console.WriteLine(rev("a string"));
    }
}
```

- The `public delegate string Reverse(string s);` line creates a delegate type of a certain signature, in this case a method that takes a string parameter and then returns a string parameter.
- The `static string ReverseString(string s)` method, which has the exact same signature as the defined delegate type, implements the delegate.
- The `Reverse rev = ReverseString;` line shows that you can assign a method to a variable of the corresponding delegate type.
- The `Console.WriteLine(rev("a string"));` line demonstrates how to use a variable of a delegate type to invoke the delegate.

In order to streamline the development process, .NET includes a set of delegate types that programmers can reuse and not have to create new types. These are `Func<T>`, `Action<T>` and `Predicate<T>`, and they can be used in various places throughout the .NET APIs without the need to define new delegate types. Of course, there are some differences between the three as you will see in their signatures which mostly have to do with the way they were meant to be used:

- `Action<T>` is used when there is a need to perform an action using the arguments of the delegate.
- `Func<T>` is used usually when you have a transformation on hand, that is, you need to transform the arguments of the delegate into a different result. Projections are a prime example of this.
- `Predicate<T>` is used when you need to determine if the argument satisfies the condition of the delegate. It can also be written as a `Func<T, bool>`.

We can now take our example above and rewrite it using the `Func<T>` delegate instead of a custom type. The program will continue running exactly the same.

```

using System;
using System.Linq;

public class Program
{
    static string ReverseString(string s)
    {
        return new string(s.Reverse().ToArray());
    }

    static void Main(string[] args)
    {
        Func<string, string> rev = ReverseString;

        Console.WriteLine(rev("a string"));
    }
}

```

For this simple example, having a method defined outside of the `Main` method seems a bit superfluous. It is because of this that .NET Framework 2.0 introduced the concept of **anonymous delegates**. With their support you are able to create "inline" delegates without having to specify any additional type or method. You simply inline the definition of the delegate where you need it.

For an example, we are going to switch it up and use our anonymous delegate to filter out a list of only even numbers and then print them to the console.

```

using System;
using System.Collections.Generic;

public class Program
{
    public static void Main(string[] args)
    {
        List<int> list = new List<int>();

        for (int i = 1; i <= 100; i++)
        {
            list.Add(i);
        }

        List<int> result = list.FindAll(
            delegate (int no)
            {
                return (no % 2 == 0);
            });
    }

    foreach (var item in result)
    {
        Console.WriteLine(item);
    }
}

```

As you can see, the body of the delegate is just a set of expressions, as any other delegate. But instead of it being a separate definition, we've introduced it *ad hoc* in our call to the `List<T>.FindAll` method.

However, even with this approach, there is still much code that we can throw away. This is where **lambda expressions** come into play.

Lambda expressions, or just "lambdas" for short, were introduced first in C# 3.0, as one of the core building blocks of Language Integrated Query (LINQ). They are just a more convenient syntax for using delegates. They declare a

signature and a method body, but don't have an formal identity of their own, unless they are assigned to a delegate. Unlike delegates, they can be directly assigned as the left-hand side of event registration or in various LINQ clauses and methods.

Since a lambda expression is just another way of specifying a delegate, we should be able to rewrite the above sample to use a lambda expression instead of an anonymous delegate.

```
using System;
using System.Collections.Generic;

public class Program
{
    public static void Main(string[] args)
    {
        List<int> list = new List<int>();

        for (int i = 1; i <= 100; i++)
        {
            list.Add(i);
        }

        List<int> result = list.FindAll(i => i % 2 == 0);

        foreach (var item in result)
        {
            Console.WriteLine(item);
        }
    }
}
```

In the preceding example, the lambda expression used is `i => i % 2 == 0`. Again, it is just a **very** convenient syntax for using delegates, so what happens under the covers is similar to what happens with the anonymous delegate.

Again, lambdas are just delegates, which means that they can be used as an event handler without any problems, as the following code snippet illustrates.

```
public MainWindow()
{
    InitializeComponent();

    Loaded += (o, e) =>
    {
        this.Title = "Loaded";
    };
}
```

The `+=` operator in this context is used to subscribe to an [event](#). For more information, see [How to: Subscribe to and Unsubscribe from Events](#).

LINQ (Language Integrated Query)

2/28/2019 • 5 minutes to read • [Edit Online](#)

What is it?

LINQ provides language-level querying capabilities and a [higher-order function](#) API to C# and VB as a way to write expressive, declarative code.

Language-level query syntax:

```
var linqExperts = from p in programmers
                  where p.IsNewToLINQ
                  select new LINQExpert(p);
```

Same example using the `IEnumerable<T>` API:

```
var linqExperts = programmers.Where(p => p.IsNewToLINQ)
                               .Select(p => new LINQExpert(p));
```

LINQ is Expressive

Imagine you have a list of pets, but want to convert it into a dictionary where you can access a pet directly by its `RFID` value.

Traditional imperative code:

```
var petLookup = new Dictionary<int, Pet>();

foreach (var pet in pets)
{
    petLookup.Add(pet.RFID, pet);
}
```

The intention behind the code is not to create a new `Dictionary<int, Pet>` and add to it via a loop, it is to convert an existing list into a dictionary! LINQ preserves the intention whereas the imperative code does not.

Equivalent LINQ expression:

```
var petLookup = pets.ToDictionary(pet => pet.RFID);
```

The code using LINQ is valuable because it evens the playing field between intent and code when reasoning as a programmer. Another bonus is code brevity. Imagine reducing large portions of a codebase by 1/3 as done above. Pretty sweet deal, right?

LINQ Providers Simplify Data Access

For a significant chunk of software out in the wild, everything revolves around dealing with data from some source (Databases, JSON, XML, etc). Often this involves learning a new API for each data source, which can be annoying. LINQ simplifies this by abstracting common elements of data access into a query syntax which looks the same no matter which data source you pick.

Consider the following: finding all XML elements with a specific attribute value.

```
public static IEnumerable< XElement > FindAllElementsWithAttribute(XElement documentRoot, string elementName,
                                                               string attributeName, string value)
{
    return from el in documentRoot.Elements(elementName)
           where (string)el.Element(attributeName) == value
           select el;
}
```

Writing code to manually traverse the XML document to perform this task would be far more challenging.

Interacting with XML isn't the only thing you can do with LINQ Providers. [Linq to SQL](#) is a fairly bare-bones Object-Relational Mapper (ORM) for an MSSQL Server Database. The [JSON.NET](#) library provides efficient JSON Document traversal via LINQ. Furthermore, if there isn't a library which does what you need, you can also [write your own LINQ Provider!](#)

Why Use the Query Syntax?

This is a question which often comes up. After all, this,

```
var filteredItems = myItems.Where(item => item.Foo);
```

is a lot more concise than this:

```
var filteredItems = from item in myItems
                     where item.Foo
                     select item;
```

Isn't the API syntax just a more concise way to do the query syntax?

No. The query syntax allows for the use the **let** clause, which allows you to introduce and bind a variable within the scope of the expression, using it in subsequent pieces of the expression. Reproducing the same code with only the API syntax can be done, but will most likely lead to code which is hard to read.

So this begs the question, **should you just use the query syntax?**

The answer to this question is **yes** if...

- Your existing codebase already uses the query syntax
- You need to scope variables within your queries due to complexity
- You prefer the query syntax and it won't distract from your codebase

The answer to this question is **no** if...

- Your existing codebase already uses the API syntax
- You have no need to scope variables within your queries
- You prefer the API syntax and it won't distract from your codebase

Essential Samples

For a truly comprehensive list of LINQ samples, visit [101 LINQ Samples](#).

The following is a quick demonstration of some of the essential pieces of LINQ. This is in no way comprehensive, as LINQ provides significantly more functionality than what is showcased here.

- The bread and butter - `Where`, `Select`, and `Aggregate`:

```
// Filtering a list
var germanShepards = dogs.Where(dog => dog.Breed == DogBreed.GermanShepard);

// Using the query syntax
var queryGermanShepards = from dog in dogs
                           where dog.Breed == DogBreed.GermanShepard
                           select dog;

// Mapping a list from type A to type B
var cats = dogs.Select(dog => dog.TurnIntoACat());

// Using the query syntax
var queryCats = from dog in dogs
                  select dog.TurnIntoACat();

// Summing the lengths of a set of strings
int seed = 0;
int sumOfStrings = strings.Aggregate(seed, (s1, s2) => s1.Length + s2.Length);
```

- Flattening a list of lists:

```
// Transforms the list of kennels into a list of all their dogs.
var allDogsFromKennels = kennels.SelectMany(kennel => kennel.Dogs);
```

- Union between two sets (with custom comparator):

```
public class DogHairLengthComparer : IEqualityComparer<Dog>
{
    public bool Equals(Dog a, Dog b)
    {
        if (a == null && b == null)
        {
            return true;
        }
        else if ((a == null && b != null) ||
                  (a != null && b == null))
        {
            return false;
        }
        else
        {
            return a.HairLengthType == b.HairLengthType;
        }
    }

    public int GetHashCode(Dog d)
    {
        // default hashcode is enough here, as these are simple objects.
        return d.GetHashCode();
    }
}

...

// Gets all the short-haired dogs between two different kennels
var allShortHairedDogs = kennel1.Dogs.Union(kennel2.Dogs, new DogHairLengthComparer());
```

- Intersection between two sets:

```
// Gets the volunteers who spend share time with two humane societies.
var volunteers = humaneSociety1.Volunteers.Intersect(humaneSociety2.Volunteers,
    new VolunteerTimeComparer());
```

- Ordering:

```
// Get driving directions, ordering by if it's toll-free before estimated driving time.
var results = DirectionsProcessor.GetDirections(start, end)
    .OrderBy(direction => direction.HasNoTolls)
    .ThenBy(direction => direction.EstimatedTime);
```

- Finally, a more advanced sample: determining if the values of the properties of two instances of the same type are equal (Borrowed and modified from [this StackOverflow post](#)):

```
public static bool PublicInstancePropertiesEqual<T>(this T self, T to, params string[] ignore) where T : class
{
    if (self == null || to == null)
    {
        return self == to;
    }

    // Selects the properties which have unequal values into a sequence of those properties.
    var unequalProperties = from property in typeof(T).GetProperties(BindingFlags.Public |
BindingFlags.Instance)
                            where !ignore.Contains(property.Name)
                            let selfValue = property.GetValue(self, null)
                            let toValue = property.GetValue(to, null)
                            where !Equals(selfValue, toValue)
                            select property;
    return !unequalProperties.Any();
}
```

PLINQ

PLINQ, or Parallel LINQ, is a parallel execution engine for LINQ expressions. In other words, a regular LINQ expression can be trivially parallelized across any number of threads. This is accomplished via a call to `AsParallel()` preceding the expression.

Consider the following:

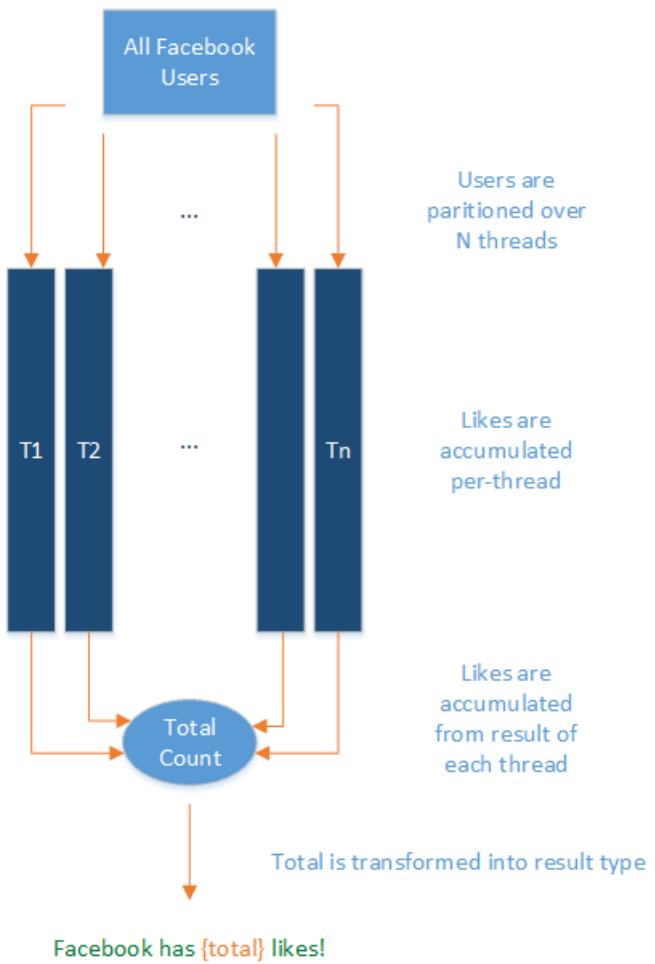

```
public static string GetAllFacebookUserLikesMessage(IEnumerable<FacebookUser> facebookUsers)
{
    var seed = default(UInt64);

    Func<UInt64, UInt64, UInt64> threadAccumulator = (t1, t2) => t1 + t2;
    Func<UInt64, UInt64, UInt64> threadResultAccumulator = (t1, t2) => t1 + t2;
    Func<UInt64, string> resultSelector = total => $"Facebook has {total} likes!";

    return facebookUsers.AsParallel()
        .Aggregate(seed, threadAccumulator, threadResultAccumulator, resultSelector);
}
```

This code will partition `facebookUsers` across system threads as necessary, sum up the total likes on each thread in parallel, sum the results computed by each thread, and project that result into a nice string.

In diagram form:

Parallelizable CPU-bound jobs which can be easily expressed via LINQ (in other words, are pure functions and have no side effects) are a great candidate for PLINQ. For jobs which *do* have a side effect, consider using the [Task Parallel Library](#).

Common Type System & Common Language Specification

3/8/2019 • 2 minutes to read • [Edit Online](#)

Again, two terms that are freely used in the .NET world, they actually are crucial to understand how a .NET implementation enables multi-language development and to understand how it works.

Common Type System

To start from the beginning, remember that a .NET implementation is *language agnostic*. This doesn't just mean that a programmer can write her code in any language that can be compiled to IL. It also means that she needs to be able to interact with code written in other languages that are able to be used on a .NET implementation.

In order to do this transparently, there has to be a common way to describe all supported types. This is what the Common Type System (CTS) is in charge of doing. It was made to do several things:

- Establish a framework for cross-language execution.
- Provide an object-oriented model to support implementing various languages on a .NET implementation.
- Define a set of rules that all languages must follow when it comes to working with types.
- Provide a library that contains the basic primitive types that are used in application development (such as, `Boolean` , `Byte` , `Char` etc.)

CTS defines two main kinds of types that should be supported: reference and value types. Their names point to their definitions.

Reference types' objects are represented by a reference to the object's actual value; a reference here is similar to a pointer in C/C++. It simply refers to a memory location where the objects' values are. This has a profound impact on how these types are used. If you assign a reference type to a variable and then pass that variable into a method, for instance, any changes to the object will be reflected on the main object; there is no copying.

Value types are the opposite, where the objects are represented by their values. If you assign a value type to a variable, you are essentially copying a value of the object.

CTS defines several categories of types, each with their specific semantics and usage:

- Classes
- Structures
- Enums
- Interfaces
- Delegates

CTS also defines all other properties of the types, such as access modifiers, what are valid type members, how inheritance and overloading works and so on. Unfortunately, going deep into any of those is beyond the scope of an introductory article such as this, but you can consult [More resources](#) section at the end for links to more in-depth content that covers these topics.

Common Language Specification

To enable full interoperability scenarios, all objects that are created in code must rely on some commonality in the languages that are consuming them (are their *callers*). Since there are numerous different languages, .NET has

specified those commonalities in something called the **Common Language Specification** (CLS). CLS defines a set of features that are needed by many common applications. It also provides a sort of recipe for any language that is implemented on top of .NET on what it needs to support.

CLS is a subset of the CTS. This means that all of the rules in the CTS also apply to the CLS, unless the CLS rules are more strict. If a component is built using only the rules in the CLS, that is, it exposes only the CLS features in its API, it is said to be **CLS-compliant**. For instance, the `<framework-librares>` are CLS-compliant precisely because they need to work across all of the languages that are supported on .NET.

You can consult the documents in the [More Resources](#) section below to get an overview of all the features in the CLS.

Parallel Processing, Concurrency, and Async Programming in .NET

5/2/2018 • 2 minutes to read • [Edit Online](#)

.NET provides several ways for you to write asynchronous code to make your application more responsive to a user and write parallel code that uses multiple threads of execution to maximize the performance of your user's computer.

In This Section

[Asynchronous Programming](#)

Describes mechanisms for asynchronous programming provided by .NET.

[Parallel Programming](#)

Describes a task-based programming model that simplifies parallel development, enabling you to write efficient, fine-grained, and scalable parallel code in a natural idiom without having to work directly with threads or the thread pool.

[Threading](#)

Describes the basic concurrency and synchronization mechanisms provided by .NET.

Async Overview

6/28/2018 • 2 minutes to read • [Edit Online](#)

Not so long ago, apps got faster simply by buying a newer PC or server and then that trend stopped. In fact, it reversed. Mobile phones appeared with 1ghz single core ARM chips and server workloads transitioned to VMs. Users still want responsive UI and business owners want servers that scale with their business. The transition to mobile and cloud and an internet-connected population of >3B users has resulted in a new set of software patterns.

- Client applications are expected to be always-on, always-connected and constantly responsive to user interaction (for example, touch) with high app store ratings!
- Services are expected to handle spikes in traffic by gracefully scaling up and down.

Async programming is a key technique that makes it straightforward to handle blocking I/O and concurrent operations on multiple cores. .NET provides the capability for apps and services to be responsive and elastic with easy-to-use, language-level asynchronous programming models in C#, VB, and F#.

Why Write Async Code?

Modern apps make extensive use of file and networking I/O. I/O APIs traditionally block by default, resulting in poor user experiences and hardware utilization unless you want to learn and use challenging patterns. Task-based async APIs and the language-level asynchronous programming model invert this model, making async execution the default with few new concepts to learn.

Async code has the following characteristics:

- Handles more server requests by yielding threads to handle more requests while waiting for I/O requests to return.
- Enables UIs to be more responsive by yielding threads to UI interaction while waiting for I/O requests and by transitioning long-running work to other CPU cores.
- Many of the newer .NET APIs are asynchronous.
- It's easy to write async code in .NET!

What's next?

For more information, see the [Async in depth](#) topic.

The [Asynchronous Programming Patterns](#) topic provides an overview of the three asynchronous programming patterns supported in .NET:

- [Asynchronous Programming Model \(APM\)](#) (legacy)
- [Event-based Asynchronous Pattern \(EAP\)](#) (legacy)
- [Task-based Asynchronous Pattern \(TAP\)](#) (recommended for new development)

For more information about recommended task-based programming model, see the [Task-based asynchronous programming](#) topic.

Async in depth

3/15/2019 • 9 minutes to read • [Edit Online](#)

Writing I/O- and CPU-bound asynchronous code is straightforward using the .NET Task-based async model. The model is exposed by the `Task` and `Task<T>` types and the `async` and `await` keywords in C# and Visual Basic. (Language-specific resources are found in the [See also](#) section.) This article explains how to use .NET async and provides insight into the async framework used under the covers.

Task and Task<T>

Tasks are constructs used to implement what is known as the [Promise Model of Concurrency](#). In short, they offer you a "promise" that work will be completed at a later point, letting you coordinate with the promise with a clean API.

- `Task` represents a single operation which does not return a value.
- `Task<T>` represents a single operation which returns a value of type `T`.

It's important to reason about tasks as abstractions of work happening asynchronously, and *not* an abstraction over threading. By default, tasks execute on the current thread and delegate work to the Operating System, as appropriate. Optionally, tasks can be explicitly requested to run on a separate thread via the `Task.Run` API.

Tasks expose an API protocol for monitoring, waiting upon and accessing the result value (in the case of `Task<T>`) of a task. Language integration, with the `await` keyword, provides a higher-level abstraction for using tasks.

Using `await` allows your application or service to perform useful work while a task is running by yielding control to its caller until the task is done. Your code does not need to rely on callbacks or events to continue execution after the task has been completed. The language and task API integration does that for you. If you're using `Task<T>`, the `await` keyword will additionally "unwrap" the value returned when the Task is complete. The details of how this works are explained further below.

You can learn more about tasks and the different ways to interact with them in the [Task-based Asynchronous Pattern \(TAP\)](#) topic.

Deeper Dive into Tasks for an I/O-Bound Operation

The following section describes a 10,000 foot view of what happens with a typical async I/O call. Let's start with a couple examples.

The first example calls an async method and returns an active task, likely yet to complete.

```
public Task<string> GetHtmlAsync()
{
    // Execution is synchronous here
    var client = new HttpClient();

    return client.GetStringAsync("https://www.dotnetfoundation.org");
}
```

The second example adds the use of the `async` and `await` keywords to operate on the task.

```

public async Task<string> GetFirstCharactersCountAsync(string url, int count)
{
    // Execution is synchronous here
    var client = new HttpClient();

    // Execution of GetFirstCharactersCountAsync() is yielded to the caller here
    // GetStringAsync returns a Task<string>, which is *awaited*
    var page = await client.GetStringAsync("https://www.dotnetfoundation.org");

    // Execution resumes when the client.GetStringAsync task completes,
    // becoming synchronous again.

    if (count > page.Length)
    {
        return page;
    }
    else
    {
        return page.Substring(0, count);
    }
}

```

The call to `GetStringAsync()` calls through lower-level .NET libraries (perhaps calling other `async` methods) until it reaches a P/Invoke interop call into a native networking library. The native library may subsequently call into a System API call (such as `write()` to a socket on Linux). A task object will be created at the native/managed boundary, possibly using `TaskCompletionSource`. The task object will be passed up through the layers, possibly operated on or directly returned, eventually returned to the initial caller.

In the second example above, a `Task<T>` object will be returned from `GetStringAsync`. The use of the `await` keyword causes the method to return a newly created task object. Control returns to the caller from this location in the `GetFirstCharactersCountAsync` method. The methods and properties of the `Task<T>` object enable callers to monitor the progress of the task, which will complete when the remaining code in `GetFirstCharactersCountAsync` has executed.

After the System API call, the request is now in kernel space, making its way to the networking subsystem of the OS (such as `/net` in the Linux Kernel). Here the OS will handle the networking request *asynchronously*. Details may be different depending on the OS used (the device driver call may be scheduled as a signal sent back to the runtime, or a device driver call may be made and *then* a signal sent back), but eventually the runtime will be informed that the networking request is in progress. At this time, the work for the device driver will either be scheduled, in-progress, or already finished (the request is already out "over the wire") - but because this is all happening asynchronously, the device driver is able to immediately handle something else!

For example, in Windows an OS thread makes a call to the network device driver and asks it to perform the networking operation via an Interrupt Request Packet (IRP) which represents the operation. The device driver receives the IRP, makes the call to the network, marks the IRP as "pending", and returns back to the OS. Because the OS thread now knows that the IRP is "pending", it doesn't have any more work to do for this job and "returns" back so that it can be used to perform other work.

When the request is fulfilled and data comes back through the device driver, it notifies the CPU of new data received via an interrupt. How this interrupt gets handled will vary depending on the OS, but eventually the data will be passed through the OS until it reaches a system interop call (for example, in Linux an interrupt handler will schedule the bottom half of the IRQ to pass the data up through the OS asynchronously). Note that this *also* happens asynchronously! The result is queued up until the next available thread is able to execute the `async` method and "unwrap" the result of the completed task.

Throughout this entire process, a key takeaway is that **no thread is dedicated to running the task**. Although work is executed in some context (that is, the OS does have to pass data to a device driver and respond to an interrupt), there is no thread dedicated to *waiting* for data from the request to come back. This allows the system

to handle a much larger volume of work rather than waiting for some I/O call to finish.

Although the above may seem like a lot of work to be done, when measured in terms of wall clock time, it's minuscule compared to the time it takes to do the actual I/O work. Although not at all precise, a potential timeline for such a call would look like this:

0-1

2-

3

- Time spent from points 0 to 1 is everything up until an async method yields control to its caller.
- Time spent from points 1 to 2 is the time spent on I/O, with no CPU cost.
- Finally, time spent from points 2 to 3 is passing control back (and potentially a value) to the async method, at which point it is executing again.

What does this mean for a server scenario?

This model works well with a typical server scenario workload. Because there are no threads dedicated to blocking on unfinished tasks, the server threadpool can service a much higher volume of web requests.

Consider two servers: one that runs async code, and one that does not. For the purpose of this example, each server only has 5 threads available to service requests. Note that these numbers are imaginarily small and serve only in a demonstrative context.

Assume both servers receive 6 concurrent requests. Each request performs an I/O operation. The server *without* async code has to queue up the 6th request until one of the 5 threads have finished the I/O-bound work and written a response. At the point that the 20th request comes in, the server might start to slow down, because the queue is getting too long.

The server *with* async code running on it still queues up the 6th request, but because it uses `async` and `await`, each of its threads are freed up when the I/O-bound work starts, rather than when it finishes. By the time the 20th request comes in, the queue for incoming requests will be far smaller (if it has anything in it at all), and the server won't slow down.

Although this is a contrived example, it works in a very similar fashion in the real world. In fact, you can expect a server to be able to handle an order of magnitude more requests using `async` and `await` than if it were dedicating a thread for each request it receives.

What does this mean for client scenario?

The biggest gain for using `async` and `await` for a client app is an increase in responsiveness. Although you can make an app responsive by spawning threads manually, the act of spawning a thread is an expensive operation relative to just using `async` and `await`. Especially for something like a mobile game, impacting the UI thread as little as possible where I/O is concerned is crucial.

More importantly, because I/O-bound work spends virtually no time on the CPU, dedicating an entire CPU thread to perform barely any useful work would be a poor use of resources.

Additionally, dispatching work to the UI thread (such as updating a UI) is very simple with `async` methods, and does not require extra work (such as calling a thread-safe delegate).

Deeper Dive into Task and Task<T> for a CPU-Bound Operation

CPU-bound `async` code is a bit different than I/O-bound `async` code. Because the work is done on the CPU, there's no way to get around dedicating a thread to the computation. The use of `async` and `await` provides you with a clean way to interact with a background thread and keep the caller of the async method responsive. Note that this does not provide any protection for shared data. If you are using shared data, you will still need to apply an appropriate synchronization strategy.

Here's a 10,000 foot view of a CPU-bound async call:

```
public async Task<int> CalculateResult(InputData data)
{
    // This queues up the work on the threadpool.
    var expensiveResultTask = Task.Run(() => DoExpensiveCalculation(data));

    // Note that at this point, you can do some other work concurrently,
    // as CalculateResult() is still executing!

    // Execution of CalculateResult is yielded here!
    var result = await expensiveResultTask;

    return result;
}
```

`CalculateResult()` executes on the thread it was called on. When it calls `Task.Run`, it queues the expensive CPU-bound operation, `DoExpensiveCalculation()`, on the thread pool and receives a `Task<int>` handle.

`DoExpensiveCalculation()` is eventually run concurrently on the next available thread, likely on another CPU core. It's possible to do concurrent work while `DoExpensiveCalculation()` is busy on another thread, because the thread which called `CalculateResult()` is still executing.

Once `await` is encountered, the execution of `CalculateResult()` is yielded to its caller, allowing other work to be done with the current thread while `DoExpensiveCalculation()` is churning out a result. Once it has finished, the result is queued up to run on the main thread. Eventually, the main thread will return to executing `CalculateResult()`, at which point it will have the result of `DoExpensiveCalculation()`.

Why does `async` help here?

`async` and `await` are the best practice for managing CPU-bound work when you need responsiveness. There are multiple patterns for using `async` with CPU-bound work. It's important to note that there is a small cost to using `async` and it's not recommended for tight loops. It's up to you to determine how you write your code around this new capability.

Asynchronous programming patterns

10/17/2018 • 2 minutes to read • [Edit Online](#)

.NET provides three patterns for performing asynchronous operations:

- **Task-based Asynchronous Pattern (TAP)**, which uses a single method to represent the initiation and completion of an asynchronous operation. TAP was introduced in the .NET Framework 4. **It's the recommended approach to asynchronous programming in .NET.** The `async` and `await` keywords in C# and the `Async` and `Await` operators in Visual Basic add language support for TAP. For more information, see [Task-based Asynchronous Pattern \(TAP\)](#).
- **Event-based Asynchronous Pattern (EAP)**, which is the event-based legacy model for providing asynchronous behavior. It requires a method that has the `Async` suffix and one or more events, event handler delegate types, and `EventArgs`-derived types. EAP was introduced in the .NET Framework 2.0. It's no longer recommended for new development. For more information, see [Event-based Asynchronous Pattern \(EAP\)](#).
- **Asynchronous Programming Model (APM)** pattern (also called the `IAsyncResult` pattern), which is the legacy model that uses the `IAsyncResult` interface to provide asynchronous behavior. In this pattern, synchronous operations require `Begin` and `End` methods (for example, `BeginWrite` and `EndWrite` to implement an asynchronous write operation). This pattern is no longer recommended for new development. For more information, see [Asynchronous Programming Model \(APM\)](#).

Comparison of patterns

For a quick comparison of how the three patterns model asynchronous operations, consider a `Read` method that reads a specified amount of data into a provided buffer starting at a specified offset:

```
public class MyClass
{
    public int Read(byte [] buffer, int offset, int count);
}
```

The TAP counterpart of this method would expose the following single `ReadAsync` method:

```
public class MyClass
{
    public Task<int> ReadAsync(byte [] buffer, int offset, int count);
}
```

The EAP counterpart would expose the following set of types and members:

```
public class MyClass
{
    public void ReadAsync(byte [] buffer, int offset, int count);
    public event ReadCompletedEventHandler ReadCompleted;
}
```

The APM counterpart would expose the `BeginRead` and `EndRead` methods:

```
public class MyClass
{
    public IAsyncResult BeginRead(
        byte [] buffer, int offset, int count,
        AsyncCallback callback, object state);
    public int EndRead(IAsyncResult asyncResult);
}
```

Parallel Programming in .NET

2/28/2019 • 2 minutes to read • [Edit Online](#)

Many personal computers and workstations have multiple CPU cores that enable multiple threads to be executed simultaneously. To take advantage of the hardware, you can parallelize your code to distribute work across multiple processors.

In the past, parallelization required low-level manipulation of threads and locks. Visual Studio and the .NET Framework enhance support for parallel programming by providing a runtime, class library types, and diagnostic tools. These features, which were introduced with the .NET Framework 4, simplify parallel development. You can write efficient, fine-grained, and scalable parallel code in a natural idiom without having to work directly with threads or the thread pool.

The following illustration provides a high-level overview of the parallel programming architecture in the .NET Framework:

Managed Threading

11/9/2018 • 2 minutes to read • [Edit Online](#)

Whether you are developing for computers with one processor or several, you want your application to provide the most responsive interaction with the user, even if the application is currently doing other work. Using multiple threads of execution is one of the most powerful ways to keep your application responsive to the user and at the same time make use of the processor in between or even during user events. While this section introduces the basic concepts of threading, it focuses on managed threading concepts and using managed threading.

NOTE

Starting with the .NET Framework 4, multithreaded programming is greatly simplified with the [System.Threading.Tasks.Parallel](#) and [System.Threading.Tasks.Task](#) classes, [Parallel LINQ \(PLINQ\)](#), new concurrent collection classes in the [System.Collections.Concurrent](#) namespace, and a new programming model that is based on the concept of tasks rather than threads. For more information, see [Parallel Programming](#).

In This Section

[Managed Threading Basics](#)

Provides an overview of managed threading and discusses when to use multiple threads.

[Using Threads and Threading](#)

Explains how to create, start, pause, resume, and abort threads.

[Managed Threading Best Practices](#)

Discusses levels of synchronization, how to avoid deadlocks and race conditions, and other threading issues.

[Threading Objects and Features](#)

Describes the managed classes you can use to synchronize the activities of threads and the data of objects accessed on different threads, and provides an overview of thread pool threads.

Memory- and span-related types

3/8/2019 • 2 minutes to read • [Edit Online](#)

Starting with .NET Core 2.1, .NET includes a number of interrelated types that represent a contiguous, strongly-typed region of arbitrary memory. These include:

- [System.Span<T>](#), a type that is used to access a contiguous region of memory. A [Span<T>](#) instance can be backed by an array of type `T`, a [String](#), a buffer allocated with [stackalloc](#), or a pointer to unmanaged memory. Because it has to be allocated on the stack, it has a number of restrictions. For example, a field in a class cannot be of type [Span<T>](#), nor can span be used in asynchronous operations.
- [System.ReadOnlySpan<T>](#), an immutable version of the [Span<T>](#) structure.
- [System.Memory<T>](#), a contiguous region of memory that is allocated on the managed heap rather than the stack. A [Memory<T>](#) instance can be backed by an array of type `T` or a [String](#). Because it can be stored on the managed heap, [Memory<T>](#) has none of the limitations of [Span<T>](#).
- [System.ReadOnlyMemory<T>](#), an immutable version of the [Memory<T>](#) structure.
- [System.Buffers.MemoryPool<T>](#), which allocates strongly-typed blocks of memory from a memory pool to an owner. [IMemoryOwner<T>](#) instances can be rented from the pool by calling [MemoryPool<T>.Rent](#) and released back to the pool by calling [MemoryPool<T>.Dispose\(\)](#).
- [System.Buffers.IMemoryOwner<T>](#), which represents the owner of a block of memory and controls its lifetime management.
- [MemoryManager<T>](#), an abstract base class that can be used to replace the implementation of [Memory<T>](#) so that [Memory<T>](#) can be backed by additional types, such as safe handles. [MemoryManager<T>](#) is intended for advanced scenarios.
- [ArraySegment<T>](#), a wrapper for a particular number of array elements starting at a particular index.
- [System.MemoryExtensions](#), a collection of extension methods for converting strings, arrays, and array segments to [Memory<T>](#) blocks.

NOTE

For earlier frameworks, [Span<T>](#) and [Memory<T>](#) are available in the [System.Memory NuGet package](#).

For more information, see the [System.Buffers](#) namespace.

Working with memory and span

Because the memory- and span-related types are typically used to store data in a processing pipeline, it is important that developers follow a set of best practices when using [Span<T>](#), [Memory<T>](#), and related types. These best practices are documented in [Memory<T> and Span<T> usage guidelines](#).

Memory<T> and Span<T> usage guidelines

3/27/2019 • 14 minutes to read • [Edit Online](#)

.NET Core includes a number of types that represent an arbitrary contiguous region of memory. .NET Core 2.0 introduced [Span<T>](#) and [ReadOnlySpan<T>](#), which are lightweight memory buffers that can be backed by managed or unmanaged memory. Because these types can be stored on the stack, they are unsuitable for a number of scenarios, including asynchronous method calls. .NET Core 2.1 adds a number of additional types, including [Memory<T>](#), [ReadOnlyMemory<T>](#), [IMemoryOwner<T>](#), and [MemoryPool<T>](#). Like [Span<T>](#), [Memory<T>](#) and its related types can be backed by both managed and unmanaged memory. Unlike [Span<T>](#), [Memory<T>](#) can only be stored on the managed heap.

Both [Span<T>](#) and [Memory<T>](#) are buffers of structured data that can be used in pipelines. That is, they are designed so that some or all of the data can be efficiently passed to components in the pipeline, which can process them and optionally modify the buffer. Because [Memory<T>](#) and its related types can be accessed by multiple components or by multiple threads, it's important that developers follow some standard usage guidelines to produce robust code.

Owners, consumers, and lifetime management

Since buffers can be passed around between APIs, and since buffers can sometimes be accessed from multiple threads, it's important to consider lifetime management. There are three core concepts:

- **Ownership.** The owner of a buffer instance is responsible for lifetime management, including destroying the buffer when it's no longer in use. All buffers have a single owner. Generally the owner is the component that created the buffer or that received the buffer from a factory. Ownership can also be transferred; **Component-A** can relinquish control of the buffer to **Component-B**, at which point **Component-A** may no longer use the buffer, and **Component-B** becomes responsible for destroying the buffer when it's no longer in use.
- **Consumption.** The consumer of a buffer instance is allowed to use the buffer instance by reading from it and possibly writing to it. Buffers can have one consumer at a time unless some external synchronization mechanism is provided. Note that the active consumer of a buffer isn't necessarily the buffer's owner.
- **Lease.** The lease is the length of time that a particular component is allowed to be the consumer of the buffer.

The following pseudo-code example illustrates these three concepts. It includes a `Main` method that instantiates a [Memory<T>](#) buffer of type [Char](#), calls the `WriteInt32ToBuffer` method to write the string representation of an integer to the buffer, and then calls the `DisplayBufferToConsole` method to display the value of the buffer.

```

using System;

class Program
{
    // Write 'value' as a human-readable string to the output buffer.
    void WriteInt32ToBuffer(int value, Buffer buffer);

    // Display the contents of the buffer to the console.
    void DisplayBufferToConsole(Buffer buffer);

    // Application code
    static void Main()
    {
        var buffer = CreateBuffer();
        try
        {
            int value = Int32.Parse(Console.ReadLine());
            WriteInt32ToBuffer(value, buffer);
            DisplayBufferToConsole(buffer);
        }
        finally
        {
            buffer.Destroy();
        }
    }
}

```

The `Main` method creates the buffer (in this case an `Span<T>` instance) and so is its owner. Therefore, `Main` is responsible for destroying the buffer when it's no longer in use. It does this by calling the buffer's `Span<T>.Clear()` method. (The `Clear()` method here actually clears the buffer's memory; the `Span<T>` structure doesn't actually have a method that destroys the buffer.)

The buffer has two consumers, `WriteInt32ToBuffer` and `DisplayBufferToConsole`. There is only one consumer at a time (first `WriteInt32ToBuffer`, then `DisplayBufferToConsole`), and neither of the consumers owns the buffer. Note also that "consumer" in this context doesn't imply a read-only view of the buffer; consumers can modify the buffer's contents, as `WriteInt32ToBuffer` does, if given a read/write view of the buffer.

The `WriteInt32ToBuffer` method has a lease on (can consume) the buffer between the start of the method call and the time the method returns. Similarly, `DisplayBufferToConsole` has a lease on the buffer while it's executing, and the lease is released when the method unwinds. (There is no API for lease management; a "lease" is a conceptual matter.)

Memory<T> and the owner/consumer model

As the [Owners, consumers, and lifetime management](#) section notes, a buffer always has an owner. .NET Core supports two ownership models:

- A model that supports single ownership. A buffer has a single owner for its entire lifetime.
- A model that supports ownership transfer. Ownership of a buffer can be transferred from its original owner (its creator) to another component, which then becomes responsible for the buffer's lifetime management. That owner can in turn transfer ownership to another component, and so on.

You use the `System.Buffers.IMemoryOwner<T>` interface to explicitly manage the ownership of a buffer.

`IMemoryOwner<T>` supports both ownership models. The component that has an `IMemoryOwner<T>` reference owns the buffer. The following example uses an `IMemoryOwner<T>` instance to reflect the ownership of an `Memory<T>` buffer.

```

using System;
using System.Buffers;

class Example
{
    static void Main()
    {
        IMemoryOwner<char> owner = MemoryPool<char>.Shared.Rent();

        Console.Write("Enter a number: ");
        try {
            var value = Int32.Parse(Console.ReadLine());

            var memory = owner.Memory;

            WriteInt32ToBuffer(value, memory);

            DisplayBufferToConsole(owner.Memory.Slice(0, value.ToString().Length));
        }
        catch (FormatException) {
            Console.WriteLine("You did not enter a valid number.");
        }
        catch (OverflowException) {
            Console.WriteLine($"You entered a number less than {Int32.MinValue:N0} or greater than
{Int32.MaxValue:N0}.");
        }
        finally {
            owner?.Dispose();
        }
    }

    static void WriteInt32ToBuffer(int value, Memory<char> buffer)
    {
        var strValue = value.ToString();

        var span = buffer.Span;
        for (int ctr = 0; ctr < strValue.Length; ctr++)
            span[ctr] = strValue[ctr];
    }

    static void DisplayBufferToConsole(Memory<char> buffer) =>
        Console.WriteLine($"Contents of the buffer: '{buffer}'");
    }
}

```

We can also write this example with the `using` :

```

using System;
using System.Buffers;

class Example
{
    static void Main()
    {
        using (IMemoryOwner<char> owner = MemoryPool<char>.Shared.Rent())
        {
            Console.Write("Enter a number: ");
            try {
                var value = Int32.Parse(Console.ReadLine());

                var memory = owner.Memory;
                WriteInt32ToBuffer(value, memory);
                DisplayBufferToConsole(memory.Slice(0, value.ToString().Length));
            }
            catch (FormatException) {
                Console.WriteLine("You did not enter a valid number.");
            }
            catch (OverflowException) {
                Console.WriteLine($"You entered a number less than {Int32.MinValue:N0} or greater than
{Int32.MaxValue:N0}.");
            }
        }
    }

    static void WriteInt32ToBuffer(int value, Memory<char> buffer)
    {
        var strValue = value.ToString();

        var span = buffer.Slice(0, strValue.Length).Span;
        strValue.AsSpan().CopyTo(span);
    }

    static void DisplayBufferToConsole(Memory<char> buffer) =>
        Console.WriteLine($"Contents of the buffer: '{buffer}'");
    }
}

```

In this code:

- The `Main` method holds the reference to the `IMemoryOwner<T>` instance, so the `Main` method is the owner of the buffer.
- The `WriteInt32ToBuffer` and `DisplayBufferToConsole` methods accept `xref:System.Memory%601>` as a public API. Therefore, they are consumers of the buffer. And they only consume it one at a time.

Although the `WriteInt32ToBuffer` method is intended to write a value to the buffer, the `DisplayBufferToConsole` method isn't. To reflect this, it could have accepted an argument of type `ReadOnlyMemory<T>`. For additional information on `ReadOnlyMemory<T>`, see [Rule #2: Use `ReadOnlySpan<T>` or `ReadOnlyMemory<T>` if the buffer should be read-only](#).

"Ownerless" `Memory<T>` instances

You can create a `Memory<T>` instance without using `IMemoryOwner<T>`. In this case, ownership of the buffer is implicit rather than explicit, and only the single-owner model is supported. You can do this by:

- Calling one of the `Memory<T>` constructors directly, passing in a `T[]`, as the following example does.
- Calling the `String.AsMemory` extension method to produce a `ReadOnlyMemory<char>` instance.

```

using System;

class Example
{
    static void Main()
    {
        Memory<char> memory = new char[64];

        Console.Write("Enter a number: ");
        var value = Int32.Parse(Console.ReadLine());

        WriteInt32ToBuffer(value, memory);
        DisplayBufferToConsole(memory);
    }

    static void WriteInt32ToBuffer(int value, Memory<char> buffer)
    {
        var strValue = value.ToString();
        strValue.AsSpan().CopyTo(buffer.Slice(0, strValue.Length).Span);
    }

    static void DisplayBufferToConsole(Memory<char> buffer) =>
        Console.WriteLine($"Contents of the buffer: '{buffer}'");
}

```

The method that initially creates the `Memory<T>` instance is the implicit owner of the buffer. Ownership cannot be transferred to any other component because there is no `IMemoryOwner<T>` instance to facilitate the transfer. (As an alternative, you can also imagine that the runtime's garbage collector owns the buffer, and all methods just consume the buffer.)

Usage guidelines

Because a memory block is owned but is intended to be passed to multiple components, some of which may operate upon a particular memory block simultaneously, it is important to establish guidelines for using both `Memory<T>` and `Span<T>`. Guidelines are necessary because:

- It is possible for a component to retain a reference to a memory block after its owner has released it.
- It is possible for a component to operate on a buffer at the same time that another component is operating on it, in the process corrupting the data in the buffer.
- While the stack-allocated nature of `Span<T>` optimizes performance and makes `Span<T>` the preferred type for operating on a memory block, it also subjects `Span<T>` to some major restrictions. It is important to know when to use a `Span<T>` and when to use `Memory<T>`.

The following are our recommendations for successfully using `Memory<T>` and its related types. Note that guidance that applies to `Memory<T>` and `Span<T>` also applies to `ReadOnlyMemory<T>` and `ReadOnlySpan<T>` unless we explicitly note otherwise.

Rule #1: For a synchronous API, use `Span<T>` instead of `Memory<T>` as a parameter if possible.

`Span<T>` is more versatile than `Memory<T>` and can represent a wider variety of contiguous memory buffers. `Span<T>` also offers better performance than `Memory<T>`. Finally, you can use the `Memory<T>.Span` property to convert a `Memory<T>` instance to a `Span<T>`, although `Span<T>`-to-`Memory<T>` conversion isn't possible. So if your callers happen to have a `Memory<T>` instance, they'll be able to call your methods with `Span<T>` parameters anyway.

Using a parameter of type `Span<T>` instead of type `Memory<T>` also helps you write a correct consuming method implementation. You'll automatically get compile-time checks to ensure that you're not attempting to access the buffer beyond your method's lease (more on this later).

Sometimes, you'll have to use a `Memory<T>` parameter instead of a `Span<T>` parameter, even if you're fully synchronous. Perhaps an API that you depend on accepts only `Memory<T>` arguments. This is fine, but be aware of the tradeoffs involved when using `Memory<T>` synchronously.

Rule #2: Use `ReadOnlySpan<T>` or `ReadOnlyMemory<T>` if the buffer should be read-only.

In the earlier examples, the `DisplayBufferToConsole` method only reads from the buffer; it doesn't modify the contents of the buffer. The method signature should be changed to the following.

```
void DisplayBufferToConsole(ReadOnlyMemory<char> buffer);
```

In fact, if we combine this rule and Rule #1, we can do even better and rewrite the method signature as follows:

```
void DisplayBufferToConsole(ReadOnlySpan<char> buffer);
```

The `DisplayBufferToConsole` method now works with virtually every buffer type imaginable: `T[]`, storage allocated with `stackalloc`, and so on. You can even pass a `String` directly into it!

Rule #3: If your method accepts `Memory<T>` and returns `void`, you must not use the `Memory<T>` instance after your method returns.

This relates to the "lease" concept mentioned earlier. A void-returning method's lease on the `Memory<T>` instance begins when the method is entered, and it ends when the method exits. Consider the following example, which calls `Log` in a loop based on input from the console.

```
using System;
using System.Buffers;

public class Example
{
    // implementation provided by third party
    static extern void Log(ReadOnlyMemory<char> message);

    // user code
    public static void Main()
    {
        using (var owner = MemoryPool<char>.Shared.Rent())
        {
            var memory = owner.Memory;
            var span = memory.Span;
            while (true)
            {
                int value = Int32.Parse(Console.ReadLine());
                if (value < 0)
                    return;

                int numCharsWritten = ToBuffer(value, span);
                Log(memory.Slice(0, numCharsWritten));
            }
        }
    }

    private static int ToBuffer(int value, Span<char> span)
    {
        string strValue = value.ToString();
        int length = strValue.Length;
        strValue.AsSpan().CopyTo(span.Slice(0, length));
        return length;
    }
}
```

If `Log` is a fully synchronous method, this code will behave as expected because there is only one active consumer of the memory instance at any given time. But imagine instead that `Log` has this implementation.

```
// !!! INCORRECT IMPLEMENTATION !!!
static void Log(ReadOnlyMemory<char> message)
{
    // Run in background so that we don't block the main thread while performing IO.
    Task.Run(() =>
    {
        StreamWriter sw = File.AppendText(@".\input-numbers.dat");
        sw.WriteLine(message);
    });
}
```

In this implementation, `Log` violates its lease because it still attempts to use the `Memory<T>` instance in the background after the original method has returned. The `Main` method could mutate the buffer while `Log` attempts to read from it, which could result in data corruption.

There are several ways to resolve this:

- The `Log` method can return a `Task` instead of `void`, as the following implementation of the `Log` method does.

```
// An acceptable implementation.
static Task Log(ReadOnlyMemory<char> message)
{
    // Run in the background so that we don't block the main thread while performing IO.
    return Task.Run(() => {
        StreamWriter sw = File.AppendText(@".\input-numbers.dat");
        sw.WriteLine(message);
        sw.Flush();
    });
}
```

- `Log` can instead be implemented as follows:

```
// An acceptable implementation.
static void Log(ReadOnlyMemory<char> message)
{
    // Run in the background so that we don't block the main thread while performing IO.
    Task.Run(() => {
        string defensiveCopy = message.ToString();
        StreamWriter sw = File.AppendText(@".\input-numbers.dat");
        sw.WriteLine(defensiveCopy);
        sw.Flush();
    });
}
```

Rule #4: If your method accepts a `Memory<T>` and returns a `Task`, you must not use the `Memory<T>` instance after the `Task` transitions to a terminal state.

This is just the async variant of Rule #3. The `Log` method from the earlier example can be written as follows to comply with this rule:

```
// An acceptable implementation.
static void Log(ReadOnlyMemory<char> message)
{
    // Run in the background so that we don't block the main thread while performing IO.
    Task.Run(() => {
        string defensiveCopy = message.ToString();
        StreamWriter sw = File.AppendText(@"..\input-numbers.dat");
        sw.WriteLine(defensiveCopy);
        sw.Flush();
    });
}
```

Here, "terminal state" means that the task transitions to a completed, faulted, or canceled state. In other words, "terminal state" means "anything that would cause await to throw or to continue execution."

This guidance applies to methods that return `Task`, `Task<TResult>`, `ValueTask<TResult>`, or any similar type.

Rule #5: If your constructor accepts `Memory<T>` as a parameter, instance methods on the constructed object are assumed to be consumers of the `Memory<T>` instance.

Consider the following example:

```
class OddValueExtractor
{
    public OddValueExtractor(ReadOnlyMemory<int> input);
    public bool TryReadNextOddValue(out int value);
}

void PrintAllOddValues(ReadOnlyMemory<int> input)
{
    var extractor = new OddValueExtractor(input);
    while (extractor.TryReadNextOddValue(out int value))
    {
        Console.WriteLine(value);
    }
}
```

Here, the `OddValueExtractor` constructor accepts a `ReadOnlyMemory<int>` as a constructor parameter, so the constructor itself is a consumer of the `ReadOnlyMemory<int>` instance, and all instance methods on the returned value are also consumers of the original `ReadOnlyMemory<int>` instance. This means that `TryReadNextOddValue` consumes the `ReadOnlyMemory<int>` instance, even though the instance isn't passed directly to the `TryReadNextOddValue` method.

Rule #6: If you have a settable `Memory<T>`-typed property (or an equivalent instance method) on your type, instance methods on that object are assumed to be consumers of the `Memory<T>` instance.

This is really just a variant of Rule #5. This rule exists because property setters or equivalent methods are assumed to capture and persist their inputs, so instance methods on the same object may utilize the captured state.

The following example triggers this rule:

```
class Person
{
    // Settable property.
    public Memory<char> FirstName { get; set; }

    // alternatively, equivalent "setter" method
    public SetFirstName(Memory<char> value);

    // alternatively, a public settable field
    public Memory<char> FirstName;
}
```

Rule #7: If you have an `IMemoryOwner<T>` reference, you must at some point dispose of it or transfer its ownership (but not both).

Since a `Memory<T>` instance may be backed by either managed or unmanaged memory, the owner must call `MemoryPool<T>.Dispose` when work performed on the `Memory<T>` instance is complete. Alternatively, the owner may transfer ownership of the `IMemoryOwner<T>` instance to a different component, at which point the acquiring component becomes responsible for calling `MemoryPool<T>.Dispose` at the appropriate time (more on this later).

Failure to call the `Dispose` method may lead to unmanaged memory leaks or other performance degradation.

This rule also applies to code that calls factory methods like `MemoryPool<T>.Rent`. The caller becomes the owner of the returned `IMemoryOwner<T>` and is responsible for disposing of the instance when finished.

Rule #8: If you have an `IMemoryOwner<T>` parameter in your API surface, you are accepting ownership of that instance.

Accepting an instance of this type signals that your component intends to take ownership of this instance. Your component becomes responsible for proper disposal according to Rule #7.

Any component that transfers ownership of the `IMemoryOwner<T>` instance to a different component should no longer use that instance after the method call completes.

IMPORTANT

If your constructor accepts `IMemoryOwner<T>` as a parameter, its type should implement `IDisposable`, and your `Dispose` method should call `MemoryPool<T>.Dispose`.

Rule #9: If you're wrapping a synchronous p/invoke method, your API should accept `Span<T>` as a parameter.

According to Rule #1, `Span<T>` is generally the correct type to use for synchronous APIs. You can pin `Span<T><T>` instances via the `fixed` keyword, as in the following example.

```

using System.Runtime.InteropServices;

[DllImport(...)]
private static extern unsafe int ExportedMethod(byte* pbData, int cbData);

public unsafe int ManagedWrapper(Span<byte> data)
{
    fixed (byte* pbData = &MemoryMarshal.GetReference(data))
    {
        int retVal = ExportedMethod(pbData, data.Length);

        /* error checking retVal goes here */

        return retVal;
    }
}

```

In the previous example, `pbData` can be null if, for example, the input span is empty. If the exported method absolutely requires that `pbData` be non-null, even if `cbData` is 0, the method can be implemented as follows:

```

public unsafe int ManagedWrapper(Span<byte> data)
{
    fixed (byte* pbData = &MemoryMarshal.GetReference(data))
    {
        byte dummy = 0;
        int retVal = ExportedMethod((pbData != null) ? pbData : &dummy, data.Length);

        /* error checking retVal goes here */

        return retVal;
    }
}

```

Rule #10: If you're wrapping an asynchronous p/invoke method, your API should accept `Memory<T>` as a parameter.

Since you cannot use the `fixed` keyword across asynchronous operations, you use the `Memory<T>.Pin` method to pin `Memory<T>` instances, regardless of the kind of contiguous memory the instance represents. The following example shows how to use this API to perform an asynchronous p/invoke call.

```

using System.Runtime.InteropServices;

[UnmanagedFunctionPointer(...)]
private delegate void OnCompletedCallback(IntPtr state, int result);

[DllImport(...)]
private static extern unsafe int ExportedAsyncMethod(byte* pbData, int cbData, IntPtr pState, IntPtr lpfnOnCompletedCallback);

private static readonly IntPtr _callbackPtr = GetCompletionCallbackPointer();

public unsafe Task<int> ManagedWrapperAsync(Memory<byte> data)
{
    // setup
    var tcs = new TaskCompletionSource<int>();
    var state = new MyCompletedCallbackState
    {
        Tcs = tcs
    };
    var pState = (IntPtr)GCHandle.Alloc(state);

    var memoryHandle = data.Pin();
    state.MemoryHandle = memoryHandle;
}
```

```

// make the call
int result;
try
{
    result = ExportedAsyncMethod((byte*)memoryHandle.Pointer, data.Length, pState, _callbackPtr);
}
catch
{
    ((GCHandle)pState).Free(); // cleanup since callback won't be invoked
    memoryHandle.Dispose();
    throw;
}

if (result != PENDING)
{
    // Operation completed synchronously; invoke callback manually
    // for result processing and cleanup.
    MyCompletedCallbackImplementation(pState, result);
}

return tcs.Task;
}

private static void MyCompletedCallbackImplementation(IntPtr state, int result)
{
    GCHandle handle = (GCHandle)state;
    var actualState = (MyCompletedCallbackState)state;
    handle.Free();
    actualState.MemoryHandle.Dispose();

    /* error checking result goes here */

    if (error)
    {
        actualState.Tcs.SetException(...);
    }
    else
    {
        actualState.Tcs.SetResult(result);
    }
}

private static IntPtr GetCompletionCallbackPointer()
{
    OnCompletedCallback callback = MyCompletedCallbackImplementation;
    GCHandle.Alloc(callback); // keep alive for lifetime of application
    return Marshal.GetFunctionPointerForDelegate(callback);
}

private class MyCompletedCallbackState
{
    public TaskCompletionSource<int> Tcs;
    public MemoryHandle MemoryHandle;
}

```

Native interoperability

1/24/2019 • 2 minutes to read • [Edit Online](#)

The following articles show the various ways of doing "native interoperability" in .NET.

There are a few reasons why you'd want to call into native code:

- Operating systems come with a large volume of APIs that aren't present in the managed class libraries. A prime example for this scenario would be access to hardware or operating system management functions.
- Communicating with other components that have or can produce C-style ABIs (native ABIs), such as Java code that is exposed via [Java Native Interface \(JNI\)](#) or any other managed language that could produce a native component.
- On Windows, most of the software that gets installed, such as the Microsoft Office suite, registers COM components that represent their programs and allow developers to automate them or use them. This also requires native interoperability.

The previous list doesn't cover all of the potential situations and scenarios in which the developer would want/like/need to interface with native components. .NET class library, for instance, uses the native interoperability support to implement a fair number of its APIs, like console support and manipulation, file system access and others. However, it's important to note that there's an option if needed.

NOTE

Most of the examples in this section will be presented for all three supported platforms for .NET Core (Windows, Linux and macOS). However, for some short and illustrative examples, just one sample is shown that uses Windows filenames and extensions (that is, "dll" for libraries). This doesn't mean that those features aren't available on Linux or macOS, it was done merely for convenience sake.

Platform Invoke (P/Invoke)

3/25/2019 • 6 minutes to read • [Edit Online](#)

P/Invoke is a technology that allows you to access structs, callbacks, and functions in unmanaged libraries from your managed code. Most of the P/Invoke API is contained in two namespaces: `System` and `System.Runtime.InteropServices`. Using these two namespaces give you the tools to describe how you want to communicate with the native component.

Let's start from the most common example, and that is calling unmanaged functions in your managed code. Let's show a message box from a command-line application:

```
using System.Runtime.InteropServices;

public class Program {

    // Import user32.dll (containing the function we need) and define
    // the method corresponding to the native function.
    [DllImport("user32.dll")]
    public static extern int MessageBox(IntPtr hWnd, String text, String caption, int options);

    public static void Main(string[] args) {
        // Invoke the function as a regular managed method.
        MessageBox(IntPtr.Zero, "Command-line message box", "Attention!", 0);
    }
}
```

The previous example is simple, but it does show off what's needed to invoke unmanaged functions from managed code. Let's step through the example:

- Line #1 shows the `using` statement for the `System.Runtime.InteropServices` namespace that holds all the items needed.
- Line #7 introduces the `[DllImport]` attribute. This attribute is crucial, as it tells the runtime that it should load the unmanaged DLL. The string passed in is the DLL our target function is in.
- Line #8 is the crux of the P/Invoke work. It defines a managed method that has the **exact same signature** as the unmanaged one. The declaration has a new keyword that you can notice, `extern`, which tells the runtime this is an external method, and that when you invoke it, the runtime should find it in the DLL specified in `DllImport` attribute.

The rest of the example is just invoking the method as you would any other managed method.

The sample is similar for macOS. The name of the library in the `DllImport` attribute needs to change since macOS has a different scheme of naming dynamic libraries. The following sample uses the `getpid(2)` function to get the process ID of the application and print it out to the console:

```

using System;
using System.Runtime.InteropServices;

namespace PInvokeSamples {
    public static class Program {

        // Import the libSystem shared library and define the method corresponding to the native function.
        [DllImport("libSystem.dylib")]
        private static extern int getpid();

        public static void Main(string[] args){
            // Invoke the function and get the process ID.
            int pid = getpid();
            Console.WriteLine(pid);
        }
    }
}

```

It is also similar on Linux. The function name is the same, since `getpid(2)` is a standard [POSIX](#) system call.

```

using System;
using System.Runtime.InteropServices;

namespace PInvokeSamples {
    public static class Program {

        // Import the libc shared library and define the method corresponding to the native function.
        [DllImport("libc.so.6")]
        private static extern int getpid();

        public static void Main(string[] args){
            // Invoke the function and get the process ID.
            int pid = getpid();
            Console.WriteLine(pid);
        }
    }
}

```

Invoking managed code from unmanaged code

The runtime allows communication to flow in both directions, enabling you to call back into managed code from native functions by using function pointers. The closest thing to a function pointer in managed code is a **delegate**, so this is what is used to allow callbacks from native code into managed code.

The way to use this feature is similar to the managed to native process previously described. For a given callback, you define a delegate that matches the signature and pass that into the external method. The runtime will take care of everything else.

```

using System;
using System.Runtime.InteropServices;

namespace ConsoleApplication1 {

    class Program {

        // Define a delegate that corresponds to the unmanaged function.
        delegate bool EnumWC(IntPtr hwnd, IntPtr lParam);

        // Import user32.dll (containing the function we need) and define
        // the method corresponding to the native function.
        [DllImport("user32.dll")]
        static extern int EnumWindows(EnumWC lpEnumFunc, IntPtr lParam);

        // Define the implementation of the delegate; here, we simply output the window handle.
        static bool OutputWindow(IntPtr hwnd, IntPtr lParam) {
            Console.WriteLine(hwnd.ToInt64());
            return true;
        }

        static void Main(string[] args) {
            // Invoke the method; note the delegate as a first parameter.
            EnumWindows(OutputWindow, IntPtr.Zero);
        }
    }
}

```

Before walking through the example, it's good to review the signatures of the unmanaged functions you need to work with. The function to be called to enumerate all of the windows has the following signature:

```
BOOL EnumWindows (WNDENUMPROC lpEnumFunc, LPARAM lParam);
```

The first parameter is a callback. The said callback has the following signature:

```
BOOL CALLBACK EnumWindowsProc (HWND hwnd, LPARAM lParam);
```

Now, let's walk through the example:

- Line #9 in the example defines a delegate that matches the signature of the callback from unmanaged code. Notice how the LPARAM and HWND types are represented using `IntPtr` in the managed code.
- Lines #13 and #14 introduce the `EnumWindows` function from the user32.dll library.
- Lines #17 - 20 implement the delegate. For this simple example, we just want to output the handle to the console.
- Finally, in line #24, the external method is called and passed in the delegate.

The Linux and macOS examples are shown below. For them, we use the `ftw` function that can be found in `libc`, the C library. This function is used to traverse directory hierarchies and it takes a pointer to a function as one of its parameters. The said function has the following signature:

```
int (*fn) (const char *fpath, const struct stat *sb, int typeflag).
```

```

using System;
using System.Runtime.InteropServices;

namespace PInvokeSamples {
    public static class Program {

        // Define a delegate that has the same signature as the native function.
        delegate int DirClbk(string fName, StatClass stat, int typeFlag);

        // Import the libc and define the method to represent the native function.
        [DllImport("libc.so.6")]
        static extern int ftw(string dirpath, DirClbk cl, int descriptors);

        // Implement the above DirClbk delegate;
        // this one just prints out the filename that is passed to it.
        static int DisplayEntry(string fName, StatClass stat, int typeFlag) {
            Console.WriteLine(fName);
            return 0;
        }

        public static void Main(string[] args){
            // Call the native function.
            // Note the second parameter which represents the delegate (callback).
            ftw(".", DisplayEntry, 10);
        }
    }

    // The native callback takes a pointer to a struct. The below class
    // represents that struct in managed code. You can find more information
    // about this in the section on marshalling below.
    [StructLayout(LayoutKind.Sequential)]
    public class StatClass {
        public uint DeviceID;
        public uint InodeNumber;
        public uint Mode;
        public uint HardLinks;
        public uint UserID;
        public uint GroupID;
        public uint SpecialDeviceID;
        public ulong Size;
        public ulong BlockSize;
        public uint Blocks;
        public long TimeLastAccess;
        public long TimeLastModification;
        public long TimeLastStatusChange;
    }
}

```

macOS example uses the same function, and the only difference is the argument to the `DllImport` attribute, as macOS keeps `libc` in a different place.

```

using System;
using System.Runtime.InteropServices;

namespace PInvokeSamples {
    public static class Program {

        // Define a delegate that has the same signature as the native function.
        delegate int DirClbk(string fName, StatClass stat, int typeFlag);

        // Import the libc and define the method to represent the native function.
        [DllImport("libc")]
        static extern int ftw(string dirpath, DirClbk cl, int descriptors);

        // Implement the above DirClbk delegate;
        // this one just prints out the filename that is passed to it.
        static int DisplayEntry(string fName, StatClass stat, int typeFlag) {
            Console.WriteLine(fName);
            return 0;
        }

        public static void Main(string[] args){
            // Call the native function.
            // Note the second parameter which represents the delegate (callback).
            ftw(".", DisplayEntry, 10);
        }
    }

    // The native callback takes a pointer to a struct. The below class
    // represents that struct in managed code.
    [StructLayout(LayoutKind.Sequential)]
    public class StatClass {
        public uint DeviceID;
        public uint InodeNumber;
        public uint Mode;
        public uint HardLinks;
        public uint UserID;
        public uint GroupID;
        public uint SpecialDeviceID;
        public ulong Size;
        public ulong BlockSize;
        public uint Blocks;
        public long TimeLastAccess;
        public long TimeLastModification;
        public long TimeLastStatusChange;
    }
}

```

Both of the previous examples depend on parameters, and in both cases, the parameters are given as managed types. Runtime does the "right thing" and processes these into its equivalents on the other side. Learn about how types are marshalled to native code in our page on [Type marshalling](#).

Type marshalling

3/19/2019 • 4 minutes to read • [Edit Online](#)

Marshalling is the process of transforming types when they need to cross between managed and native code.

Marshalling is needed because the types in the managed and unmanaged code are different. In managed code, for instance, you have a `String`, while in the unmanaged world strings can be Unicode ("wide"), non-Unicode, null-terminated, ASCII, etc. By default, the P/Invoke subsystem tries to do the right thing based on the default behavior, described on this article. However, for those situations where you need extra control, you can employ the `MarshalAs` attribute to specify what is the expected type on the unmanaged side. For instance, if you want the string to be sent as a null-terminated ANSI string, you could do it like this:

```
[DllImport("somenativelibrary.dll")]
static extern int MethodA([MarshalAs(UnmanagedType.LPStr)] string parameter);
```

Default rules for marshalling common types

Generally, the runtime tries to do the "right thing" when marshalling to require the least amount of work from you. The following tables describe how each type is marshalled by default when used in a parameter or field. The C99/C++11 fixed-width integer and character types are used to ensure that the following table is correct for all platforms. You can use any native type that has the same alignment and size requirements as these types.

This first table describes the mappings for various types for whom the marshalling is the same for both P/Invoke and field marshalling.

.NET TYPE	NATIVE TYPE
<code>byte</code>	<code>uint8_t</code>
<code>sbyte</code>	<code>int8_t</code>
<code>short</code>	<code>int16_t</code>
<code>ushort</code>	<code>uint16_t</code>
<code>int</code>	<code>int32_t</code>
<code>uint</code>	<code>uint32_t</code>
<code>long</code>	<code>int64_t</code>
<code>ulong</code>	<code>uint64_t</code>
<code>char</code>	Either <code>char</code> or <code>char16_t</code> depending on the <code>Charset</code> of the P/Invoke or structure. See the charset documentation .
<code>string</code>	Either <code>char*</code> or <code>char16_t*</code> depending on the <code>Charset</code> of the P/Invoke or structure. See the charset documentation .

.NET TYPE	NATIVE TYPE
System.IntPtr	intptr_t
System.UIntPtr	uintptr_t
.NET Pointer types (ex. void*)	void*
Type derived from System.Runtime.InteropServices.SafeHandle	void*
Type derived from System.Runtime.InteropServices.CriticalHandle	void*
bool	Win32 BOOL type
decimal	COM DECIMAL struct
.NET Delegate	Native function pointer
System.DateTime	Win32 DATE type
System.Guid	Win32 GUID type

A few categories of marshalling have different defaults if you're marshalling as a parameter or structure.

.NET TYPE	NATIVE TYPE (PARAMETER)	NATIVE TYPE (FIELD)
.NET array	A pointer to the start of an array of native representations of the array elements.	Not allowed without a [MarshalAs] attribute
A class with a LayoutKind of Sequential or Explicit	A pointer to the native representation of the class	The native representation of the class

The following table includes the default marshalling rules that are Windows-only. On non-Windows platforms, you cannot marshal these types.

.NET TYPE	NATIVE TYPE (PARAMETER)	NATIVE TYPE (FIELD)
object	VARIANT	IUnknown*
System.Array	COM interface	Not allowed without a [MarshalAs] attribute
System.ArgIterator	va_list	Not allowed
System.Collections.IEnumerable	IEnumVARIANT*	Not allowed
System.Collections.IEnumerable	IDispatch*	Not allowed

.NET TYPE	NATIVE TYPE (PARAMETER)	NATIVE TYPE (FIELD)	
<code>System.DateTimeOffset</code>	<code>int64_t</code> representing the number of ticks since midnight on January 1, 1601		<code>int64_t</code> representing the number of ticks since midnight on January 1, 1601

Some types can only be marshalled as parameters and not as fields. These types are listed in the following table:

.NET TYPE	NATIVE TYPE (PARAMETER ONLY)
<code>System.Text.StringBuilder</code>	Either <code>char*</code> or <code>char16_t*</code> depending on the <code>CharSet</code> of the P/Invoke. See the charset documentation .
<code>System.ArgIterator</code>	<code>va_list</code> (on Windows x86/x64/arm64 only)
<code>System.Runtime.InteropServices.ArrayWithOffset</code>	<code>void*</code>
<code>System.Runtime.InteropServices.HandleRef</code>	<code>void*</code>

If these defaults don't do exactly what you want, you can customize how parameters are marshalled. The [parameter marshalling](#) article walks you through how to customize how different parameter types are marshalled.

Marshalling classes and structs

Another aspect of type marshalling is how to pass in a struct to an unmanaged method. For instance, some of the unmanaged methods require a struct as a parameter. In these cases, you need to create a corresponding struct or a class in managed part of the world to use it as a parameter. However, just defining the class isn't enough, you also need to instruct the marshaler how to map fields in the class to the unmanaged struct. Here the `StructLayout` attribute becomes useful.

```
[DllImport("kernel32.dll")]
static extern void GetSystemTime(SystemTime systemTime);

[StructLayout(LayoutKind.Sequential)]
class SystemTime {
    public ushort Year;
    public ushort Month;
    public ushort DayOfWeek;
    public ushort Day;
    public ushort Hour;
    public ushort Minute;
    public ushort Second;
    public ushort Milisecond;
}

public static void Main(string[] args) {
    SystemTime st = new SystemTime();
    GetSystemTime(st);
    Console.WriteLine(st.Year);
}
```

The previous code shows a simple example of calling into `GetSystemTime()` function. The interesting bit is on line 4. The attribute specifies that the fields of the class should be mapped sequentially to the struct on the other (unmanaged) side. This means that the naming of the fields isn't important, only their order is important, as it needs to correspond to the unmanaged struct, shown in the following example:

```
typedef struct _SYSTEMTIME {
    WORD wYear;
    WORD wMonth;
    WORD wDayOfWeek;
    WORD wDay;
    WORD wHour;
    WORD wMinute;
    WORD wSecond;
    WORD wMilliseconds;
} SYSTEMTIME, *PSYSTEMTIME*;
```

Sometimes the default marshalling for your structure doesn't do what you need. The [Customizing structure marshalling](#) article teaches you how to customize how your structure is marshaled.

Customizing structure marshalling

3/8/2019 • 6 minutes to read • [Edit Online](#)

Sometimes the default marshalling rules for structures aren't exactly what you need. The .NET runtimes provide a few extension points for you to customize your structure's layout and how fields are marshaled.

Customizing structure layout

.NET provides the [StructLayoutAttribute](#) attribute and the [System.Runtime.InteropServices.LayoutKind](#) enumeration to allow you to customize how fields are placed in memory. The following guidance will help you avoid common issues.

- ✓ **CONSIDER** using `LayoutKind.Sequential` whenever possible.
- ✓ **DO** only use `LayoutKind.Explicit` in marshalling when your native struct is also has an explicit layout, such as a union.
- ✗ **AVOID** using `LayoutKind.Explicit` when marshalling structures on non-Windows platforms. The .NET Core runtime doesn't support passing explicit structures by value to native functions on Intel or AMD 64-bit non-Windows systems. However, the runtime supports passing explicit structures by reference on all platforms.

Customizing boolean field marshalling

Native code has many different boolean representations. On Windows alone, there are three ways to represent boolean values. The runtime doesn't know the native definition of your structure, so the best it can do is make a guess on how to marshal your boolean values. The .NET runtime provides a way to indicate how to marshal your boolean field. The following examples show how to marshal .NET `bool` to different native boolean types.

Boolean values default to marshalling as a native 4-byte Win32 `BOOL` value as shown in the following example:

```
public struct WinBool
{
    public bool b;
}
```

```
struct WinBool
{
    public BOOL b;
};
```

If you want to be explicit, you can use the [UnmanagedType.Bool](#) value to get the same behavior as above:

```
public struct WinBool
{
    [MarshalAs(UnmanagedType.Bool)]
    public bool b;
}
```

```
struct WinBool
{
    public BOOL b;
};
```

Using the `UnmanagedType.U1` or `UnmanagedType.I1` values below, you can tell the runtime to marshal the `b` field as a 1-byte native `bool` type.

```
public struct CBool
{
    [MarshalAs(UnmanagedType.U1)]
    public bool b;
}
```

```
struct CBool
{
    public bool b;
};
```

On Windows, you can use the `UnmanagedType.VariantBool` value to tell the runtime to marshal your boolean value to a 2-byte `VARIANT_BOOL` value:

```
public struct VariantBool
{
    [MarshalAs(UnmanagedType.VariantBool)]
    public bool b;
}
```

```
struct VariantBool
{
    public VARIANT_BOOL b;
};
```

NOTE

`VARIANT_BOOL` is different than most bool types in that `VARIANT_TRUE = -1` and `VARIANT_FALSE = 0`. Additionally, all values that aren't equal to `VARIANT_TRUE` are considered false.

Customizing array field marshalling

.NET also includes a few ways to customize array marshalling.

By default, .NET marshals arrays as a pointer to a contiguous list of the elements:

```
public struct DefaultArray
{
    public int[] values;
}
```

```
struct DefaultArray
{
    int* values;
};
```

If you're interfacing with COM APIs, you may have to marshal arrays as `SAFEARRAY*` objects. You can use the [System.Runtime.InteropServices.MarshalAsAttribute](#) and the [UnmanagedType.SafeArray](#) value to tell the runtime to marshal an array as a `SAFEARRAY*`:

```
public struct SafeArrayExample
{
    [MarshalAs(UnmanagedType.SafeArray)]
    public int[] values;
}
```

```
struct SafeArrayExample
{
    SAFEARRAY* values;
};
```

If you need to customize what type of element is in the `SAFEARRAY`, then you can use the [MarshalAsAttribute.SafeArraySubType](#) and [MarshalAsAttribute.SafeArrayUserDefinedSubType](#) fields to customize the exact element type of the `SAFEARRAY`.

If you need to marshal the array in-place, you can use the [UnmanagedType.ByValArray](#) value to tell the marshaler to marshal the array in-place. When you're using this marshalling, you also must supply a value to the [MarshalAsAttribute.SizeConst](#) field for the number of elements in the array so the runtime can correctly allocate space for the structure.

```
public struct InPlaceArray
{
    [MarshalAs(UnmanagedType.ByValArray, SizeConst = 4)]
    public int[] values;
}
```

```
struct InPlaceArray
{
    int values[4];
};
```

NOTE

.NET doesn't support marshalling a variable length array field as a C99 Flexible Array Member.

Customizing string field marshalling

.NET also provides a wide variety of customizations for marshalling string fields.

By default, .NET marshals a string as a pointer to a null-terminated string. The encoding depends on the value of the [StructLayoutAttribute.CharSet](#) field in the [StructLayoutAttribute](#). If no attribute is specified, the encoding defaults to an ANSI encoding.

```
[StructLayout(LayoutKind.Sequential, CharSet = CharSet.Ansi)]
public struct DefaultString
{
    public string str;
}
```

```
struct DefaultString
{
    char* str;
};
```

```
[StructLayout(LayoutKind.Sequential, CharSet = CharSet.Unicode)]
public struct DefaultString
{
    public string str;
}
```

```
struct DefaultString
{
    char16_t* str; // Could also be wchar_t* on Windows.
};
```

If you need to use different encodings for different fields or just prefer to be more explicit in your struct definition, you can use the [UnmanagedType.LPStr](#) or [UnmanagedType.LPWStr](#) values on a [System.Runtime.InteropServices.MarshalAsAttribute](#) attribute.

```
public struct AnsiString
{
    [MarshalAs(UnmanagedType.LPStr)]
    public string str;
}
```

```
struct AnsiString
{
    char* str;
};
```

```
public struct UnicodeString
{
    [MarshalAs(UnmanagedType.LPWStr)]
    public string str;
}
```

```
struct UnicodeString
{
    char16_t* str; // Could also be wchar_t* on Windows.
};
```

If you want to marshal your strings using the UTF-8 encoding, you can use the [UnmanagedType.LPUTF8Str](#) value in your [MarshalAsAttribute](#).

```
public struct UTF8String
{
    [MarshalAs(UnmanagedType.LPUTF8Str)]
    public string str;
}
```

```
struct UTF8String
{
    char* str;
};
```

NOTE

Using [UnmanagedType.LPUTF8Str](#) requires either .NET Framework 4.7 (or later versions) or .NET Core 1.1 (or later versions). It isn't available in .NET Standard 2.0.

If you're working with COM APIs, you may need to marshal a string as a [BSTR](#). Using the [UnmanagedType.BStr](#) value, you can marshal a string as a [BSTR](#).

```
public struct BString
{
    [MarshalAs(UnmanagedType.BStr)]
    public string str;
}
```

```
struct BString
{
    BSTR str;
};
```

When using a WinRT-based API, you may need to marshal a string as an [HSTRING](#). Using the [UnmanagedType.HString](#) value, you can marshal a string as a [HSTRING](#).

```
public struct HString
{
    [MarshalAs(UnmanagedType.HString)]
    public string str;
}
```

```
struct BString
{
    HSTRING str;
};
```

If your API requires you to pass the string in-place in the structure, you can use the [UnmanagedType.ByValTStr](#) value. Do note that the encoding for a string marshalled by [ByValTStr](#) is determined from the [Charset](#) attribute. Additionally, it requires that a string length is passed by the [MarshalAsAttribute.SizeConst](#) field.

```
[StructLayout(LayoutKind.Sequential, CharSet = CharSet.Ansi)]
public struct DefaultString
{
    [MarshalAs(UnmanagedType.ByValTStr, SizeConst = 4)]
    public string str;
}
```

```
struct DefaultString
{
    char str[4];
};
```

```
[StructLayout(LayoutKind.Sequential, CharSet = CharSet.Unicode)]
public struct DefaultString
{
    [MarshalAs(UnmanagedType.ByValTStr, SizeConst = 4)]
    public string str;
}
```

```
struct DefaultString
{
    char16_t str[4]; // Could also be wchar_t[4] on Windows.
};
```

Customizing decimal field marshalling

If you're working on Windows, you might encounter some APIs that use the native `CY` or `CURRENCY` structure. By default, the .NET `decimal` type marshals to the native `DECIMAL` structure. However, you can use a `MarshalAsAttribute` with the `UnmanagedType.Currency` value to instruct the marshaler to convert a `decimal` value to a native `CY` value.

```
public struct Currency
{
    [MarshalAs(UnmanagedType.Currency)]
    public decimal dec;
}
```

```
struct Currency
{
    CY dec;
};
```

Marshalling `System.Object`s

On Windows, you can marshal `object`-typed fields to native code. You can marshal these fields to one of three types:

- `VARIANT`
- `IUnknown*`
- `IDispatch*`

By default, an `object`-typed field will be marshalled to an `IUnknown*` that wraps the object.

```
public struct ObjectDefault
{
    public object obj;
}
```

```
struct ObjectDefault
{
    IUnknown* obj;
};
```

If you want to marshal an object field to an `IDispatch*`, add a [MarshalAsAttribute](#) with the `UnmanagedType.IDispatch` value.

```
public struct ObjectDispatch
{
    [MarshalAs(UnmanagedType.IDispatch)]
    public object obj;
}
```

```
struct ObjectDispatch
{
    IDispatch* obj;
};
```

If you want to marshal it as a `VARIANT`, add a [MarshalAsAttribute](#) with the `UnmanagedType.Struct` value.

```
public struct ObjectVariant
{
    [MarshalAs(UnmanagedType.Struct)]
    public object obj;
}
```

```
struct ObjectVariant
{
    VARIANT obj;
};
```

The following table describes how different runtime types of the `obj` field map to the various types stored in a `VARIANT`:

.NET TYPE	VARIANT TYPE	.NET TYPE	VARIANT TYPE
<code>byte</code>	<code>VT_UI1</code>		<code>System.Runtime.InteropServices.VT_BSTR</code> <code>StringWrapper</code>
<code>sbyte</code>	<code>VT_I1</code>	<code>object</code>	<code>VT_DISPATCH</code>
<code>short</code>	<code>VT_I2</code>		<code>System.Runtime.InteropServices.VT_UNKNOWN</code> <code>UnknownWrapper</code>
<code>ushort</code>	<code>VT_UI2</code>		<code>System.Runtime.InteropServices.VT_DISPATCH</code> <code>ObjectWrapper</code>
<code>int</code>	<code>VT_I4</code>		<code>System.Reflection.Missing</code> <code>VT_ERROR</code>

.NET TYPE	VARIANT TYPE	.NET TYPE	VARIANT TYPE
uint	VT_UI4	(object)null	VT_EMPTY
long	VT_I8	bool	VT_BOOL
ulong	VT_UI8	System.DateTime	VT_DATE
float	VT_R4	decimal	VT_DECIMAL
double	VT_R8	System.Runtime.InteropServices.VT_CURRENCY	VT_CURRENCYWrapper
char	VT_UI2	System.DBNull	VT_NULL
string	VT_BSTR		

Customizing parameter marshalling

1/19/2019 • 2 minutes to read • [Edit Online](#)

When the .NET runtime's default parameter marshalling behavior doesn't do what you want, use can use the [System.Runtime.InteropServices.MarshalAsAttribute](#) attribute to customize how your parameters are marshaled.

Customizing string parameters

.NET has a variety of formats for marshalling strings. These methods are split into distinct sections on C-style strings and Windows-centric string formats.

C-Style strings

Each of these formats passes a null-terminated string to native code. They differ by the encoding of the native string.

SYSTEM.RUNTIME.INTEROPSERVICES.UNMANAGEDTYPE	VALUE	ENCODING
LPStr		ANSI
LPUTF8Str		UTF-8
LPWStr		UTF-16

The [UnmanagedType.VBByRefStr](#) format is slightly different. Like `LPWStr`, it marshals the string to a native C-style string encoded in UTF-16. However, the managed signature has you pass in the string by reference and the matching native signature takes the string by value. This distinction allows you to use a native API that takes a string by value and modifies it in-place without having to use a `StringBuilder`. We recommend against manually using this format since it's prone to cause confusion with the mismatching native and managed signatures.

Windows-centric string formats

When interacting with COM or OLE interfaces, you'll likely find that the native functions take strings as `BSTR` arguments. You can use the [UnmanagedType.BStr](#) unmanaged type to marshal a string as a `BSTR`.

If you're interacting with WinRT APIs, you can use the [UnmanagedType.HString](#) format to marshal a string as an `HSTRING`.

Customizing array parameters

.NET also provides you multiple ways to marshal array parameters. If you're calling an API that takes a C-style array, use the [UnmanagedType.LPArray](#) unmanaged type. If the values in the array need customized marshalling, you can use the [ArraySubType](#) field on the `[MarshalAs]` attribute for that.

If you're using COM APIs, you'll likely have to marshal your array parameters as `SAFEARRAY*`s. To do so, you can use the [UnmanagedType.SafeArray](#) unmanaged type. The default type of the elements of the `SAFEARRAY` can be seen in the table on [customizing object fields](#). You can use the [MarshalAsAttribute.SafeArraySubType](#) and [MarshalAsAttribute.SafeArrayUserDefinedSubType](#) fields to customize the exact element type of the `SAFEARRAY`.

Customizing boolean or decimal parameters

For information on marshalling boolean or decimal parameters, see [Customizing structure marshalling](#).

Customizing object parameters (Windows-only)

On Windows, the .NET runtime provides a number of different ways to marshal object parameters to native code.

Marshalling as specific COM interfaces

If your API takes a pointer to a COM object, you can use any of the following `UnmanagedType` formats on an `object`-typed parameter to tell .NET to marshal as these specific interfaces:

- `IUnknown`
- `IDispatch`
- `IIInspectable`

Additionally, if your type is marked `[ComVisible(true)]` or you're marshalling the `object` type, you can use the `UnmanagedType.Interface` format to marshal your object as a COM callable wrapper for the COM view of your type.

Marshalling to a `VARIANT`

If your native API takes a Win32 `VARIANT`, you can use the `UnmanagedType.Struct` format on your `object` parameter to marshal your objects as `VARIANT`s. See the documentation on [customizing `object` fields](#) for a mapping between .NET types and `VARIANT` types.

Custom marshalers

If you want to project a native COM interface into a different managed type, you can use the `UnmanagedType.CustomMarshaler` format and an implementation of `ICustomMarshaler` to provide your own custom marshalling code.

Native interoperability best practices

3/25/2019 • 9 minutes to read [Edit Online](#)

.NET gives you a variety of ways to customize your native interoperability code. This article includes the guidance that Microsoft's .NET teams follow for native interoperability.

General guidance

The guidance in this section applies to all interop scenarios.

- ✓ **DO** use the same naming and capitalization for your methods and parameters as the native method you want to call.
- ✓ **DO** **CONSIDER** using the same naming and capitalization for constant values.
- ✓ **DO** use .NET types that map closest to the native type. For example, in C#, use `uint` when the native type is `unsigned int`.
- ✓ **DO** only use `[In]` and `[Out]` attributes when the behavior you want differs from the default behavior.
- ✓ **DO** **CONSIDER** using `System.Buffers.ArrayPool<T>` to pool your native array buffers.
- ✓ **DO** **CONSIDER** wrapping your P/Invoke declarations in a class with the same name and capitalization as your native library.
 - This allows your `[DllImport]` attributes to use the C# `nameof` language feature to pass in the name of the native library and ensure that you didn't misspell the name of the native library.

DllImport attribute settings

SETTING	DEFAULT	RECOMMENDATION	DETAILS
PreserveSig	<code>true</code>	keep default	When this is explicitly set to <code>false</code> , failed HRESULT return values will be turned into exceptions (and the return value in the definition becomes <code>null</code> as a result).
SetLastError	<code>false</code>	depends on the API	Set this to <code>true</code> if the API uses <code>GetLastError</code> and use <code>Marshal.GetLastWin32Error</code> to get the value. If the API sets a condition that says it has an error, get the error before making other calls to avoid inadvertently having it overwritten.
CharSet	<code>CharSet.None</code> , which falls back to <code>CharSet.Ansi</code> behavior	Explicitly use <code>CharSet.Unicode</code> or <code>CharSet.Ansi</code> when strings or characters are present in the definition	This specifies marshalling behavior of strings and what <code>ExactSpelling</code> does when <code>false</code> . Note that <code>CharSet.Ansi</code> is actually UTF8 on Unix. Most of the time Windows uses Unicode while Unix uses UTF8. See more information on the documentation on charsets .

SETTING	DEFAULT	RECOMMENDATION	DETAILS
ExactSpelling	false	true	Set this to true and gain a slight perf benefit as the runtime will not look for alternate function names with either an "A" or "W" suffix depending on the value of the <code>CharSet</code> setting ("A" for <code>CharSet.Ansi</code> and "W" for <code>CharSet.Unicode</code>).

String parameters

When the `CharSet` is Unicode or the argument is explicitly marked as `[MarshalAs(UnmanagedType.LPWSTR)]` and the string is passed by value (not `ref` or `out`), the string will be pinned and used directly by native code (rather than copied).

Remember to mark the `[DllImport]` as `Charset.Unicode` unless you explicitly want ANSI treatment of your strings.

□ **DO NOT** use `[Out] string` parameters. String parameters passed by value with the `[out]` attribute can destabilize the runtime if the string is an interned string. See more information about string interning in the documentation for [String.Intern](#).

□ **AVOID** `StringBuilder` parameters. `StringBuilder` marshalling *always* creates a native buffer copy. As such, it can be extremely inefficient. Take the typical scenario of calling a Windows API that takes a string:

1. Create a SB of the desired capacity (allocates managed capacity) **{1}**
2. Invoke
 - a. Allocates a native buffer **{2}**
 - b. Copies the contents if `[In]` (*the default for a `StringBuilder` parameter*)
 - c. Copies the native buffer into a newly allocated managed array if `[out]` **{3}** (*also the default for `StringBuilder`*)
3. `ToString()` allocates yet another managed array **{4}**

That is **{4}** allocations to get a string out of native code. The best you can do to limit this is to reuse the `StringBuilder` in another call but this still only saves 1 allocation. It's much better to use and cache a character buffer from `ArrayPool` - you can then get down to just the allocation for the `ToString()` on subsequent calls.

The other issue with `StringBuilder` is that it always copies the return buffer back up to the first null. If the passed back string isn't terminated or is a double-null-terminated string, your P/Invoke is incorrect at best.

If you *do* use `StringBuilder`, one last gotcha is that the capacity does **not** include a hidden null, which is always accounted for in interop. It's common for people to get this wrong as most APIs want the size of the buffer *including* the null. This can result in wasted/unnecessary allocations. Additionally, this gotcha prevents the runtime from optimizing `StringBuilder` marshalling to minimize copies.

✓ □ **CONSIDER** using `char[]`'s from an `ArrayPool`.

For more information on string marshalling, see [Default Marshalling for Strings](#) and [Customizing string marshalling](#).

Windows Specific

For `[Out]` strings the CLR will use `CoTaskMemFree` by default to free strings or `SysStringFree` for strings that are marked as `UnmanagedType.BSTR`.

For most APIs with an output string buffer:

The passed in character count must include the null. If the returned value is less than the passed in character count the call has succeeded and the value is the number of characters *without* the trailing null. Otherwise the count is

the required size of the buffer *including* the null character.

- Pass in 5, get 4: The string is 4 characters long with a trailing null.
- Pass in 5, get 6: The string is 5 characters long, need a 6 character buffer to hold the null.

[Windows Data Types for Strings](#)

Boolean parameters and fields

Booleans are easy to mess up. By default, a .NET `bool` is marshalled to a Windows `BOOL`, where it's a 4-byte value. However, the `_Bool`, and `bool` types in C and C++ are a *single* byte. This can lead to hard to track down bugs as half the return value will be discarded, which will only *potentially* change the result. For more information on marshalling .NET `bool` values to C or C++ `bool` types, see the documentation on [customizing boolean field marshalling](#).

GUIDs

GUIDs are usable directly in signatures. Many Windows APIs take `GUID&` type aliases like `REFIID`. When passed by `ref`, they can either be passed by `ref` or with the `[MarshalAs(UnmanagedType.LPStruct)]` attribute.

GUID	BY-REF GUID
<code>KNOWNFOLDERID</code>	<code>REFKNOWNFOLDERID</code>

□ **DO NOT** Use `[MarshalAs(UnmanagedType.LPStruct)]` for anything other than `ref` GUID parameters.

Blittable types

Blittable types are types that have the same bit-level representation in managed and native code. As such they do not need to be converted to another format to be marshalled to and from native code, and as this improves performance they should be preferred.

Blittable types:

- `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `single`, `double`
- non-nested one-dimensional arrays of blittable types (for example, `int[]`)
- structs and classes with fixed layout that only have blittable value types for instance fields
 - fixed layout requires `[StructLayout(LayoutKind.Sequential)]` or `[StructLayout(LayoutKind.Explicit)]`
 - structs are `LayoutKind.Sequential` by default, classes are `LayoutKind.Auto`

NOT blittable:

- `bool`

SOMETIMES blittable:

- `char`, `string`

When blittable types are passed by reference, they're simply pinned by the marshaller instead of being copied to an intermediate buffer. (Classes are inherently passed by reference, structs are passed by reference when used with `ref` or `out`.)

`char` is blittable in a one-dimensional array **or** if it's part of a type that contains it's explicitly marked with `[StructLayout]` with `CharSet = CharSet.Unicode`.

```
[StructLayout(LayoutKind.Sequential, CharSet = CharSet.Unicode)]
public struct UnicodeCharStruct
{
    public char c;
}
```

`string` is blittable if it isn't contained in another type and it's being passed as an argument that is marked with `[MarshalAs(UnmanagedType.LPWStr)]` or the `[DllImport]` has `CharSet = CharSet.Unicode` set.

You can see if a type is blittable by attempting to create a pinned `GCHandle`. If the type isn't a string or considered blittable, `GCHandle.Alloc` will throw an `ArgumentException`.

✓ DO make your structures blittable when possible.

For more information, see:

- [Blittable and Non-Blittable Types](#)
- [Type Marshalling](#)

Keeping managed objects alive

`GC.KeepAlive()` will ensure an object stays in scope until the `KeepAlive` method is hit.

`HandleRef` allows the marshaller to keep an object alive for the duration of a P/Invoke. It can be used instead of `IntPtr` in method signatures. `SafeHandle` effectively replaces this class and should be used instead.

`GCHandle` allows pinning a managed object and getting the native pointer to it. The basic pattern is:

```
GCHandle handle = GCHandle.Alloc(obj, GCHandleType.Pinned);
IntPtr ptr = handle.AddrOfPinnedObject();
handle.Free();
```

Pinning isn't the default for `GCHandle`. The other major pattern is for passing a reference to a managed object through native code and back to managed code, usually with a callback. Here is the pattern:

```
GCHandle handle = GCHandle.Alloc(obj);
SomeNativeEnumerator(callbackDelegate, GCHandle.ToIntPtr(handle));

// In the callback
GCHandle handle = GCHandle.FromIntPtr(param);
object managedObject = handle.Target;

// After the last callback
handle.Free();
```

Don't forget that `GCHandle` needs to be explicitly freed to avoid memory leaks.

Common Windows data types

Here is a list of data types commonly used in Windows APIs and which C# types to use when calling into the Windows code.

The following types are the same size on 32-bit and 64-bit Windows, despite their names.

WIDTH	WINDOWS	C (WINDOWS)	C#	ALTERNATIVE
32	<code>BOOL</code>	<code>int</code>	<code>int</code>	<code>bool</code>

WIDTH	WINDOWS	C (WINDOWS)	C#	ALTERNATIVE
8	BOOLEAN	unsigned char	byte	[MarshalAs(UnmanagedType.U1)] bool
8	BYTE	unsigned char	byte	
8	CHAR	char	sbyte	
8	UCHAR	unsigned char	byte	
16	SHORT	short	short	
16	CSHORT	short	short	
16	USHORT	unsigned short	ushort	
16	WORD	unsigned short	ushort	
16	ATOM	unsigned short	ushort	
32	INT	int	int	
32	LONG	long	int	
32	ULONG	unsigned long	uint	
32	DWORD	unsigned long	uint	
64	QWORD	long long	long	
64	LARGE_INTEGER	long long	long	
64	LONGLONG	long long	long	
64	ULONGLONG	unsigned long long	ulong	
64	ULARGE_INTEGER	unsigned long long	ulong	
32	HRESULT	long	int	
32	NTSTATUS	long	int	

The following types, being pointers, do follow the width of the platform. Use `IntPtr` / `UIntPtr` for these.

SIGNED POINTER TYPES (USE <code>IntPtr</code>)	UNSIGNED POINTER TYPES (USE <code>UIntPtr</code>)
HANDLE	WPARAM
HWND	UINT_PTR
HINSTANCE	ULONG_PTR

SIGNED POINTER TYPES (USE `INTPTR`)

`LPARAM`

`LRESULT`

`LONG_PTR`

`INT_PTR`

UNSIGNED POINTER TYPES (USE `UINTPTR`)

`SIZE_T`

A Windows `PVOID` which is a C `void*` can be marshaled as either `IntPtr` or `UIntPtr`, but prefer `void*` when possible.

Windows Data Types

Data Type Ranges

Structs

Managed structs are created on the stack and aren't removed until the method returns. By definition then, they are "pinned" (it won't get moved by the GC). You can also simply take the address in unsafe code blocks if native code won't use the pointer past the end of the current method.

Blittable structs are much more performant as they can simply be used directly by the marshalling layer. Try to make structs blittable (for example, avoid `bool`). For more information, see the [Blittable Types](#) section.

If the struct is blittable, use `sizeof()` instead of `Marshal.SizeOf<MyStruct>()` for better performance. As mentioned above, you can validate that the type is blittable by attempting to create a pinned `GCHandle`. If the type is not a string or considered blittable, `GCHandle.Alloc` will throw an `ArgumentException`.

Pointers to structs in definitions must either be passed by `ref` or use `unsafe` and `*`.

✓ DO match the managed struct as closely as possible to the shape and names that are used in the official platform documentation or header.

✓ DO use the C# `sizeof()` instead of `Marshal.SizeOf<MyStruct>()` for blittable structures to improve performance.

An array like `INT_PTR Reserved1[2]` has to be marshaled to two `IntPtr` fields, `Reserved1a` and `Reserved1b`. When the native array is a primitive type, we can use the `fixed` keyword to write it a little more cleanly. For example,

`SYSTEM_PROCESS_INFORMATION` looks like this in the native header:

```
typedef struct _SYSTEM_PROCESS_INFORMATION {
    ULONG NextEntryOffset;
    ULONG NumberOfThreads;
    BYTE Reserved1[48];
    UNICODE_STRING ImageName;
    ...
} SYSTEM_PROCESS_INFORMATION
```

In C#, we can write it like this:

```
internal unsafe struct SYSTEM_PROCESS_INFORMATION
{
    internal uint NextEntryOffset;
    internal uint NumberOfThreads;
    private fixed byte Reserved1[48];
    internal Interop.UNICODE_STRING ImageName;
    ...
}
```

However, there are some gotchas with fixed buffers. Fixed buffers of non-blittable types won't be correctly marshalled, so the in-place array needs to be expanded out to multiple individual fields. Additionally, in .NET Framework and .NET Core before 3.0, if a struct containing a fixed buffer field is nested within a non-blittable struct, the fixed buffer field won't be correctly marshalled to native code.

Charsets and marshalling

1/19/2019 • 2 minutes to read • [Edit Online](#)

The way `char` values, `string` objects, and `System.Text.StringBuilder` objects are marshalled depends on the value of the `Charset` field on either the P/Invoke or structure. You can set the `CharSet` of a P/Invoke by setting the `DllImportAttribute.CharSet` field when declaring your P/Invoke. To set the `CharSet` for a structure, set the `StructLayoutAttribute.CharSet` field on your struct declaration. When these attribute fields are not set, it is up to the language compiler to determine which `Charset` to use. C# uses the `Ansi` charset by default.

The following table shows a mapping between each charset and how a character or string is represented when marshalled with that charset:

CHARSET	WINDOWS	UNIX	MONO ON UNIX
Ansi	<code>char</code> (ANSI)	<code>char</code> (ANSI on macOS, UTF-8 on Linux)	<code>char</code> (UTF-8)
Unicode	<code>wchar_t</code> (UTF-16)	<code>char16_t</code> (UTF-16)	<code>char16_t</code> (UTF-16)
Auto	<code>wchar_t</code> (UTF-16)	<code>char16_t</code> (UTF-16)	<code>char</code> (UTF-8)

Make sure you know what representation your native representation expects when picking your charset.

Collections and Data Structures

2/26/2019 • 4 minutes to read • [Edit Online](#)

Similar data can often be handled more efficiently when stored and manipulated as a collection. You can use the [System.Array](#) class or the classes in the [System.Collections](#), [System.Collections.Generic](#), [System.Collections.Concurrent](#), [System.Collections.Immutable](#) namespaces to add, remove, and modify either individual elements or a range of elements in a collection.

There are two main types of collections; generic collections and non-generic collections. Generic collections were added in the .NET Framework 2.0 and provide collections that are type-safe at compile time. Because of this, generic collections typically offer better performance. Generic collections accept a type parameter when they are constructed and do not require that you cast to and from the [Object](#) type when you add or remove items from the collection. In addition, most generic collections are supported in Windows Store apps. Non-generic collections store items as [Object](#), require casting, and most are not supported for Windows Store app development. However, you may see non-generic collections in older code.

Starting with the .NET Framework 4, the collections in the [System.Collections.Concurrent](#) namespace provide efficient thread-safe operations for accessing collection items from multiple threads. The immutable collection classes in the [System.Collections.Immutable](#) namespace ([NuGet package](#)) are inherently thread-safe because operations are performed on a copy of the original collection and the original collection cannot be modified.

Common collection features

All collections provide methods for adding, removing or finding items in the collection. In addition, all collections that directly or indirectly implement the [ICollection](#) interface or the [ICollection<T>](#) interface share these features:

- **The ability to enumerate the collection**

.NET Framework collections either implement [System.Collections.IEnumerable](#) or [System.Collections.Generic.IEnumerable<T>](#) to enable the collection to be iterated through. An enumerator can be thought of as a movable pointer to any element in the collection. The [foreach](#), [in](#) statement and the [For Each...Next Statement](#) use the enumerator exposed by the [GetEnumerator](#) method and hide the complexity of manipulating the enumerator. In addition, any collection that implements [System.Collections.Generic.IEnumerable<T>](#) is considered a *queryable type* and can be queried with LINQ. LINQ queries provide a common pattern for accessing data. They are typically more concise and readable than standard [foreach](#) loops, and provide filtering, ordering and grouping capabilities. LINQ queries can also improve performance. For more information, see [LINQ to Objects \(C#\)](#), [LINQ to Objects \(Visual Basic\)](#), [Parallel LINQ \(PLINQ\)](#), [Introduction to LINQ Queries \(C#\)](#), and [Basic Query Operations \(Visual Basic\)](#).

- **The ability to copy the collection contents to an array**

All collections can be copied to an array using the [CopyTo](#) method; however, the order of the elements in the new array is based on the sequence in which the enumerator returns them. The resulting array is always one-dimensional with a lower bound of zero.

In addition, many collection classes contain the following features:

- **Capacity and Count properties**

The capacity of a collection is the number of elements it can contain. The count of a collection is the number of elements it actually contains. Some collections hide the capacity or the count or both.

Most collections automatically expand in capacity when the current capacity is reached. The memory is reallocated, and the elements are copied from the old collection to the new one. This reduces the code required to use the collection; however, the performance of the collection might be negatively affected. For example, for `List<T>`, If `Count` is less than `Capacity`, adding an item is an $O(1)$ operation. If the capacity needs to be increased to accommodate the new element, adding an item becomes an $O(n)$ operation, where n is `Count`. The best way to avoid poor performance caused by multiple reallocations is to set the initial capacity to be the estimated size of the collection.

A `BitArray` is a special case; its capacity is the same as its length, which is the same as its count.

- **A consistent lower bound**

The lower bound of a collection is the index of its first element. All indexed collections in the `System.Collections` namespaces have a lower bound of zero, meaning they are 0-indexed. `Array` has a lower bound of zero by default, but a different lower bound can be defined when creating an instance of the `Array` class using `Array.CreateInstance`.

- **Synchronization for access from multiple threads** (`System.Collections` classes only).

Non-generic collection types in the `System.Collections` namespace provide some thread safety with synchronization; typically exposed through the `SyncRoot` and `IsSynchronized` members. These collections are not thread-safe by default. If you require scalable and efficient multi-threaded access to a collection, use one of the classes in the `System.Collections.Concurrent` namespace or consider using an immutable collection. For more information, see [Thread-Safe Collections](#).

Choosing a collection

In general, you should use generic collections. The following table describes some common collection scenarios and the collection classes you can use for those scenarios. If you are new to generic collections, this table will help you choose the generic collection that works the best for your task.

I WANT TO...	GENERIC COLLECTION OPTIONS	NON-GENERIC COLLECTION OPTIONS	THREAD-SAFE OR IMMUTABLE COLLECTION OPTIONS
Store items as key/value pairs for quick look-up by key	<code>Dictionary< TKey, TValue ></code>	<code>Hashtable</code> (A collection of key/value pairs that are organized based on the hash code of the key.)	<code>ConcurrentDictionary< TKey, TValue ></code> <code>ReadOnlyDictionary< TKey, TValue ></code> <code>ImmutableDictionary< TKey, TValue ></code>
Access items by index	<code>List< T ></code>	<code>Array</code> <code>ArrayList</code>	<code>ImmutableList< T ></code> <code>ImmutableArray</code>
Use items first-in-first-out (FIFO)	<code>Queue< T ></code>	<code>Queue</code>	<code>ConcurrentQueue< T ></code> <code>ImmutableQueue< T ></code>
Use data Last-In-First-Out (LIFO)	<code>Stack< T ></code>	<code>Stack</code>	<code>ConcurrentStack< T ></code> <code>ImmutableStack< T ></code>
Access items sequentially	<code>LinkedList< T ></code>	No recommendation	No recommendation

I WANT TO...	GENERIC COLLECTION OPTIONS	NON-GENERIC COLLECTION OPTIONS	THREAD-SAFE OR IMMUTABLE COLLECTION OPTIONS
Receive notifications when items are removed or added to the collection. (implements INotifyPropertyChanged and INotifyCollectionChanged)	ObservableCollection<T>	No recommendation	No recommendation
A sorted collection	SortedList< TKey, TValue >	SortedList	ImmutableSortedDictionary< TKey, TValue > ImmutableSortedSet< T >
A set for mathematical functions	HashSet<T> SortedSet<T>	No recommendation	ImmutableHashSet<T> ImmutableSortedSet< T >

Numerics in .NET

10/24/2018 • 3 minutes to read • [Edit Online](#)

.NET provides a range of numeric integer and floating-point primitives, as well as [System.Numerics.BigInteger](#), which is an integral type with no theoretical upper or lower bound, [System.Numerics.Complex](#), which represents complex numbers, and a set of SIMD-enabled types in the [System.Numerics](#) namespace.

Integer types

.NET supports both signed and unsigned 8-, 16-, 32-, and 64-bit integer types, which are listed in the following table:

TYPE	SIGNED/UNSIGNED	SIZE (IN BYTES)	MINIMUM VALUE	MAXIMUM VALUE
System.Byte	Unsigned	1	0	255
System.Int16	Signed	2	-32,768	32,767
System.Int32	Signed	4	-2,147,483,648	2,147,483,647
System.Int64	Signed	8	-9,223,372,036,854,775,808	9,223,372,036,854,775,807
System.SByte	Signed	1	-128	127
System.UInt16	Unsigned	2	0	65,535
System.UInt32	Unsigned	4	0	4,294,967,295
System.UInt64	Unsigned	8	0	18,446,744,073,709,551,615

Each integer type supports a set of standard arithmetic operators. The [System.Math](#) class provides methods for a broader set of mathematical functions.

You can also work with the individual bits in an integer value by using the [System.BitConverter](#) class.

NOTE

The unsigned integer types are not CLS-compliant. For more information, see [Language Independence and Language-Independent Components](#).

BigInteger

The [System.Numerics.BigInteger](#) structure is an immutable type that represents an arbitrarily large integer whose value in theory has no upper or lower bounds. The methods of the [BigInteger](#) type closely parallel those of the other integral types.

Floating-point types

.NET includes three primitive floating-point types, which are listed in the following table:

TYPE	SIZE (IN BYTES)	APPROXIMATE RANGE	PRECISION
System.Single	4	$\pm 1.5 \times 10^{-45}$ to $\pm 3.4 \times 10^{38}$	~6-9 digits
System.Double	8	$\pm 5.0 \times 10^{-324}$ to $\pm 1.7 \times 10^{308}$	~15-17 digits
System.Decimal	16	$\pm 1.0 \times 10^{-28}$ to $\pm 7.9228 \times 10^{28}$	28-29 digits

Both [Single](#) and [Double](#) types support special values that represent not-a-number and infinity. For example, the [Double](#) type provides the following values: [Double.NaN](#), [Double.NegativeInfinity](#), and [Double.PositiveInfinity](#). You use the [Double.IsNaN](#), [Double.IsInfinity](#), [Double.IsPositiveInfinity](#), and [Double.IsNegativeInfinity](#) methods to test for these special values.

Each floating-point type supports a set of standard arithmetic operators. The [System.Math](#) class provides methods for a broader set of mathematical functions. .NET Core 2.0 and later includes the [System.MathF](#) class that provides methods which accept arguments of the [Single](#) type.

You can also work with the individual bits in [Double](#) and [Single](#) values by using the [System.BitConverter](#) class. The [System.Decimal](#) structure has its own methods, [Decimal.GetBits](#) and [Decimal.Decimal\(Int32\[\]\)](#), for working with a decimal value's individual bits, as well as its own set of methods for performing some additional mathematical operations.

The [Double](#) and [Single](#) types are intended to be used for values that by their nature are imprecise (for example, the distance between two stars) and for applications in which a high degree of precision and small rounding error is not required. You should use the [System.Decimal](#) type for cases in which greater precision is required and rounding errors should be minimized.

NOTE

The [Decimal](#) type doesn't eliminate the need for rounding. Rather, it minimizes errors due to rounding.

Complex

The [System.Numerics.Complex](#) structure represents a complex number, that is, a number with a real number part and an imaginary number part. It supports a standard set of arithmetic, comparison, equality, explicit and implicit conversion operators, as well as mathematical, algebraic, and trigonometric methods.

SIMD-enabled types

The [System.Numerics](#) namespace includes a set of .NET SIMD-enabled types. SIMD (Single Instruction Multiple Data) operations can be parallelized at the hardware level. That increases the throughput of the vectorized computations, which are common in mathematical, scientific, and graphics apps.

The .NET SIMD-enabled types include the following:

- The [Vector2](#), [Vector3](#), and [Vector4](#) types, which represent vectors with 2, 3, and 4 [Single](#) values.
- Two matrix types, [Matrix3x2](#), which represents a 3x2 matrix, and [Matrix4x4](#), which represents a 4x4 matrix.
- The [Plane](#) type, which represents a plane in three-dimensional space.

- The [Quaternion](#) type, which represents a vector that is used to encode three-dimensional physical rotations.
- The [Vector<T>](#) type, which represents a vector of a specified numeric type and provides a broad set of operators that benefit from SIMD support. The count of a [Vector<T>](#) instance is fixed, but its value [Vector<T>.Count](#) depends on the CPU of the machine, on which code is executed.

NOTE

The [Vector<T>](#) type is not included into the .NET Framework. You must install the [System.Numerics.Vectors](#) NuGet package to get access to this type.

The SIMD-enabled types are implemented in such a way that they can be used with non-SIMD-enabled hardware or JIT compilers. To take advantage of SIMD instructions, your 64-bit apps must be run by the runtime that uses the RyuJIT compiler, which is included in .NET Core and in the .NET Framework 4.6 and later versions. It adds SIMD support when targeting 64-bit processors.

Dates, times, and time zones

5/2/2018 • 2 minutes to read • [Edit Online](#)

In addition to the basic [DateTime](#) structure, .NET provides the following classes that support working with time zones:

- [TimeZone](#)

Use this class to work with the system's local time zone and the Coordinated Universal Time (UTC) zone. The functionality of the [TimeZone](#) class is largely superseded by the [TimeZoneInfo](#) class.

- [TimeZoneInfo](#)

Use this class to work with any time zone that is predefined on a system, to create new time zones, and to easily convert dates and times from one time zone to another. For new development, use the [TimeZoneInfo](#) class instead of the [TimeZone](#) class.

- [DateTimeOffset](#)

Use this structure to work with dates and times whose offset (or difference) from UTC is known. The [DateTimeOffset](#) structure combines a date and time value with that time's offset from UTC. Because of its relationship to UTC, an individual date and time value unambiguously identifies a single point in time. This makes a [DateTimeOffset](#) value more portable from one computer to another than a [DateTime](#) value.

This section of the documentation provides the information that you need to work with time zones and to create time zone-aware applications that can convert dates and times from one time zone to another.

In this section

[Time zone overview](#) Discusses the terminology, concepts, and issues involved in creating time zone-aware applications.

[Choosing between DateTime, DateTimeOffset, TimeSpan, and TimeZoneInfo](#) Discusses when to use the [DateTime](#), [DateTimeOffset](#), and [TimeZoneInfo](#) types when working with date and time data.

[Finding the time zones defined on a local system](#) Describes how to enumerate the time zones found on a local system.

[How to: Enumerate time zones present on a computer](#) Provides examples that enumerate the time zones defined in a computer's registry and that let users select a predefined time zone from a list.

[How to: Access the predefined UTC and local time zone objects](#) Describes how to access Coordinated Universal Time and the local time zone.

[How to: Instantiate a TimeZoneInfo object](#) Describes how to instantiate a [TimeZoneInfo](#) object from the local system registry.

[Instantiating a DateTimeOffset object](#) Discusses the ways in which a [DateTimeOffset](#) object can be instantiated, and the ways in which a [DateTime](#) value can be converted to a [DateTimeOffset](#) value.

[How to: Create time zones without adjustment rules](#) Describes how to create a custom time zone that does not support the transition to and from daylight saving time.

[How to: Create time zones with adjustment rules](#) Describes how to create a custom time zone that supports one or more transitions to and from daylight saving time.

[Saving and restoring time zones](#) Describes `TimeZoneInfo` support for serialization and deserialization of time zone data and illustrates some of the scenarios in which these features can be used.

[How to: Save time zones to an embedded resource](#) Describes how to create a custom time zone and save its information in a resource file.

[How to: Restore time zones from an embedded resource](#) Describes how to instantiate custom time zones that have been saved to an embedded resource file.

[Performing arithmetic operations with dates and times](#) Discusses the issues involved in adding, subtracting, and comparing `DateTime` and `DateTimeOffset` values.

[How to: Use time zones in date and time arithmetic](#) Discusses how to perform date and time arithmetic that reflects a time zone's adjustment rules.

[Converting between DateTime and DateTimeOffset](#) Describes how to convert between `DateTime` and `DateTimeOffset` values.

[Converting times between time zones](#) Describes how to convert times from one time zone to another.

[How to: Resolve ambiguous times](#) Describes how to resolve an ambiguous time by mapping it to the time zone's standard time.

[How to: Let users resolve ambiguous times](#) Describes how to let a user determine the mapping between an ambiguous local time and Coordinated Universal Time.

Handling and raising events

3/22/2019 • 7 minutes to read • [Edit Online](#)

Events in .NET are based on the delegate model. The delegate model follows the [observer design pattern](#), which enables a subscriber to register with and receive notifications from a provider. An event sender pushes a notification that an event has happened, and an event receiver receives that notification and defines a response to it. This article describes the major components of the delegate model, how to consume events in applications, and how to implement events in your code.

For information about handling events in Windows 8.x Store apps, see [Events and routed events overview](#).

Events

An event is a message sent by an object to signal the occurrence of an action. The action can be caused by user interaction, such as a button click, or it can result from some other program logic, such as changing a property's value. The object that raises the event is called the *event sender*. The event sender doesn't know which object or method will receive (handle) the events it raises. The event is typically a member of the event sender; for example, the [Click](#) event is a member of the [Button](#) class, and the [PropertyChanged](#) event is a member of the class that implements the [INotifyPropertyChanged](#) interface.

To define an event, you use the C# `event` or the Visual Basic `Event` keyword in the signature of your event class, and specify the type of delegate for the event. Delegates are described in the next section.

Typically, to raise an event, you add a method that is marked as `protected` and `virtual` (in C#) or `Protected` and `Overridable` (in Visual Basic). Name this method `on EventName`; for example, `OnDataReceived`. The method should take one parameter that specifies an event data object, which is an object of type [EventArgs](#) or a derived type. You provide this method to enable derived classes to override the logic for raising the event. A derived class should always call the `on EventName` method of the base class to ensure that registered delegates receive the event.

The following example shows how to declare an event named `ThresholdReached`. The event is associated with the [EventHandler](#) delegate and raised in a method named `OnThresholdReached`.

```
class Counter
{
    public event EventHandler ThresholdReached;

    protected virtual void OnThresholdReached(EventArgs e)
    {
        EventHandler handler = ThresholdReached;
        handler?.Invoke(this, e);
    }

    // provide remaining implementation for the class
}
```

```

Public Class Counter
    Public Event ThresholdReached As EventHandler

    Protected Overridable Sub OnThresholdReached(e As EventArgs)
        RaiseEvent ThresholdReached(Me, e)
    End Sub

    ' provide remaining implementation for the class
End Class

```

Delegates

A delegate is a type that holds a reference to a method. A delegate is declared with a signature that shows the return type and parameters for the methods it references, and it can hold references only to methods that match its signature. A delegate is thus equivalent to a type-safe function pointer or a callback. A delegate declaration is sufficient to define a delegate class.

Delegates have many uses in .NET. In the context of events, a delegate is an intermediary (or pointer-like mechanism) between the event source and the code that handles the event. You associate a delegate with an event by including the delegate type in the event declaration, as shown in the example in the previous section. For more information about delegates, see the [Delegate](#) class.

.NET provides the [EventHandler](#) and [EventHandler<TEventArgs>](#) delegates to support most event scenarios. Use the [EventHandler](#) delegate for all events that do not include event data. Use the [EventHandler<TEventArgs>](#) delegate for events that include data about the event. These delegates have no return type value and take two parameters (an object for the source of the event, and an object for event data).

Delegates are [multicast](#), which means that they can hold references to more than one event-handling method. For details, see the [Delegate](#) reference page. Delegates provide flexibility and fine-grained control in event handling. A delegate acts as an event dispatcher for the class that raises the event by maintaining a list of registered event handlers for the event.

For scenarios where the [EventHandler](#) and [EventHandler<TEventArgs>](#) delegates do not work, you can define a delegate. Scenarios that require you to define a delegate are very rare, such as when you must work with code that does not recognize generics. You mark a delegate with the C# [delegate](#) and Visual Basic [Delegate](#) keyword in the declaration. The following example shows how to declare a delegate named `ThresholdReachedEventHandler`.

```
public delegate void ThresholdReachedEventHandler(object sender, ThresholdReachedEventArgs e);
```

```
Public Delegate Sub ThresholdReachedEventHandler(sender As Object, e As ThresholdReachedEventArgs)
```

Event data

Data that is associated with an event can be provided through an event data class. .NET provides many event data classes that you can use in your applications. For example, the [SerialDataReceivedEventArgs](#) class is the event data class for the [SerialPort.DataReceived](#) event. .NET follows a naming pattern of ending all event data classes with `EventArgs`. You determine which event data class is associated with an event by looking at the delegate for the event. For example, the [SerialDataReceivedEventHandler](#) delegate includes the [SerialDataReceivedEventArgs](#) class as one of its parameters.

The [EventArgs](#) class is the base type for all event data classes. [EventArgs](#) is also the class you use when an event does not have any data associated with it. When you create an event that is only meant to notify other classes that something happened and does not need to pass any data, include the [EventArgs](#) class as the second parameter in

the delegate. You can pass the `EventArgs.Empty` value when no data is provided. The `EventHandler` delegate includes the `EventArgs` class as a parameter.

When you want to create a customized event data class, create a class that derives from `EventArgs`, and then provide any members needed to pass data that is related to the event. Typically, you should use the same naming pattern as .NET and end your event data class name with `EventArgs`.

The following example shows an event data class named `ThresholdReachedEventArgs`. It contains properties that are specific to the event being raised.

```
public class ThresholdReachedEventArgs : EventArgs
{
    public int Threshold { get; set; }
    public DateTime TimeReached { get; set; }
}
```

```
Public Class ThresholdReachedEventArgs
    Inherits EventArgs

    Public Property Threshold As Integer
    Public Property TimeReached As DateTime
End Class
```

Event handlers

To respond to an event, you define an event handler method in the event receiver. This method must match the signature of the delegate for the event you are handling. In the event handler, you perform the actions that are required when the event is raised, such as collecting user input after the user clicks a button. To receive notifications when the event occurs, your event handler method must subscribe to the event.

The following example shows an event handler method named `c_ThresholdReached` that matches the signature for the `EventHandler` delegate. The method subscribes to the `ThresholdReached` event.

```
class Program
{
    static void Main()
    {
        var c = new Counter();
        c.ThresholdReached += c_ThresholdReached;

        // provide remaining implementation for the class
    }

    static void c_ThresholdReached(object sender, EventArgs e)
    {
        Console.WriteLine("The threshold was reached.");
    }
}
```

```

Module Module1

Sub Main()
    Dim c As New Counter()
    AddHandler c.ThresholdReached, AddressOf c_ThresholdReached

    ' provide remaining implementation for the class
End Sub

Sub c_ThresholdReached(sender As Object, e As EventArgs)
    Console.WriteLine("The threshold was reached.")
End Sub
End Module

```

Static and dynamic event handlers

.NET allows subscribers to register for event notifications either statically or dynamically. Static event handlers are in effect for the entire life of the class whose events they handle. Dynamic event handlers are explicitly activated and deactivated during program execution, usually in response to some conditional program logic. For example, they can be used if event notifications are needed only under certain conditions or if an application provides multiple event handlers and run-time conditions define the appropriate one to use. The example in the previous section shows how to dynamically add an event handler. For more information, see [Events](#) (in Visual Basic) and [Events](#) (in C#).

Raising multiple events

If your class raises multiple events, the compiler generates one field per event delegate instance. If the number of events is large, the storage cost of one field per delegate may not be acceptable. For those situations, .NET provides event properties that you can use with another data structure of your choice to store event delegates.

Event properties consist of event declarations accompanied by event accessors. Event accessors are methods that you define to add or remove event delegate instances from the storage data structure. Note that event properties are slower than event fields, because each event delegate must be retrieved before it can be invoked. The trade-off is between memory and speed. If your class defines many events that are infrequently raised, you will want to implement event properties. For more information, see [How to: Handle Multiple Events Using Event Properties](#).

Managed Execution Process

1/23/2019 • 7 minutes to read • [Edit Online](#)

The managed execution process includes the following steps, which are discussed in detail later in this topic:

1. Choosing a compiler.

To obtain the benefits provided by the common language runtime, you must use one or more language compilers that target the runtime.

2. Compiling your code to MSIL.

Compiling translates your source code into Microsoft intermediate language (MSIL) and generates the required metadata.

3. Compiling MSIL to native code.

At execution time, a just-in-time (JIT) compiler translates the MSIL into native code. During this compilation, code must pass a verification process that examines the MSIL and metadata to find out whether the code can be determined to be type safe.

4. Running code.

The common language runtime provides the infrastructure that enables execution to take place and services that can be used during execution.

Choosing a Compiler

To obtain the benefits provided by the common language runtime (CLR), you must use one or more language compilers that target the runtime, such as Visual Basic, C#, Visual C++, F#, or one of many third-party compilers such as an Eiffel, Perl, or COBOL compiler.

Because it is a multilanguage execution environment, the runtime supports a wide variety of data types and language features. The language compiler you use determines which runtime features are available, and you design your code using those features. Your compiler, not the runtime, establishes the syntax your code must use. If your component must be completely usable by components written in other languages, your component's exported types must expose only language features that are included in the [Language Independence and Language-Independent Components](#) (CLS). You can use the [CLSCompliantAttribute](#) attribute to ensure that your code is CLS-compliant. For more information, see [Language Independence and Language-Independent Components](#).

[Back to top](#)

Compiling to MSIL

When compiling to managed code, the compiler translates your source code into Microsoft intermediate language (MSIL), which is a CPU-independent set of instructions that can be efficiently converted to native code. MSIL includes instructions for loading, storing, initializing, and calling methods on objects, as well as instructions for arithmetic and logical operations, control flow, direct memory access, exception handling, and other operations. Before code can be run, MSIL must be converted to CPU-specific code, usually by a [just-in-time \(JIT\) compiler](#). Because the common language runtime supplies one or more JIT compilers for each computer architecture it supports, the same set of MSIL can be JIT-compiled and run on any supported architecture.

When a compiler produces MSIL, it also produces metadata. Metadata describes the types in your code, including

the definition of each type, the signatures of each type's members, the members that your code references, and other data that the runtime uses at execution time. The MSIL and metadata are contained in a portable executable (PE) file that is based on and that extends the published Microsoft PE and common object file format (COFF) used historically for executable content. This file format, which accommodates MSIL or native code as well as metadata, enables the operating system to recognize common language runtime images. The presence of metadata in the file together with MSIL enables your code to describe itself, which means that there is no need for type libraries or Interface Definition Language (IDL). The runtime locates and extracts the metadata from the file as needed during execution.

[Back to top](#)

Compiling MSIL to Native Code

Before you can run Microsoft intermediate language (MSIL), it must be compiled against the common language runtime to native code for the target machine architecture. The .NET Framework provides two ways to perform this conversion:

- A .NET Framework just-in-time (JIT) compiler.
- The .NET Framework [Ngen.exe \(Native Image Generator\)](#).

Compilation by the JIT Compiler

JIT compilation converts MSIL to native code on demand at application run time, when the contents of an assembly are loaded and executed. Because the common language runtime supplies a JIT compiler for each supported CPU architecture, developers can build a set of MSIL assemblies that can be JIT-compiled and run on different computers with different machine architectures. However, if your managed code calls platform-specific native APIs or a platform-specific class library, it will run only on that operating system.

JIT compilation takes into account the possibility that some code might never be called during execution. Instead of using time and memory to convert all the MSIL in a PE file to native code, it converts the MSIL as needed during execution and stores the resulting native code in memory so that it is accessible for subsequent calls in the context of that process. The loader creates and attaches a stub to each method in a type when the type is loaded and initialized. When a method is called for the first time, the stub passes control to the JIT compiler, which converts the MSIL for that method into native code and modifies the stub to point directly to the generated native code. Therefore, subsequent calls to the JIT-compiled method go directly to the native code.

Install-Time Code Generation Using NGen.exe

Because the JIT compiler converts an assembly's MSIL to native code when individual methods defined in that assembly are called, it affects performance adversely at run time. In most cases, that diminished performance is acceptable. More importantly, the code generated by the JIT compiler is bound to the process that triggered the compilation. It cannot be shared across multiple processes. To allow the generated code to be shared across multiple invocations of an application or across multiple processes that share a set of assemblies, the common language runtime supports an ahead-of-time compilation mode. This ahead-of-time compilation mode uses the [Ngen.exe \(Native Image Generator\)](#) to convert MSIL assemblies to native code much like the JIT compiler does. However, the operation of Ngen.exe differs from that of the JIT compiler in three ways:

- It performs the conversion from MSIL to native code before running the application instead of while the application is running.
- It compiles an entire assembly at a time, instead of one method at a time.
- It persists the generated code in the Native Image Cache as a file on disk.

Code Verification

As part of its compilation to native code, the MSIL code must pass a verification process unless an administrator has established a security policy that allows the code to bypass verification. Verification examines MSIL and

metadata to find out whether the code is type safe, which means that it accesses only the memory locations it is authorized to access. Type safety helps isolate objects from each other and helps protect them from inadvertent or malicious corruption. It also provides assurance that security restrictions on code can be reliably enforced.

The runtime relies on the fact that the following statements are true for code that is verifiably type safe:

- A reference to a type is strictly compatible with the type being referenced.
- Only appropriately defined operations are invoked on an object.
- Identities are what they claim to be.

During the verification process, MSIL code is examined in an attempt to confirm that the code can access memory locations and call methods only through properly defined types. For example, code cannot allow an object's fields to be accessed in a manner that allows memory locations to be overrun. Additionally, verification inspects code to determine whether the MSIL has been correctly generated, because incorrect MSIL can lead to a violation of the type safety rules. The verification process passes a well-defined set of type-safe code, and it passes only code that is type safe. However, some type-safe code might not pass verification because of some limitations of the verification process, and some languages, by design, do not produce verifiably type-safe code. If type-safe code is required by the security policy but the code does not pass verification, an exception is thrown when the code is run.

[Back to top](#)

Running Code

The common language runtime provides the infrastructure that enables managed execution to take place and services that can be used during execution. Before a method can be run, it must be compiled to processor-specific code. Each method for which MSIL has been generated is JIT-compiled when it is called for the first time, and then run. The next time the method is run, the existing JIT-compiled native code is run. The process of JIT-compiling and then running the code is repeated until execution is complete.

During execution, managed code receives services such as garbage collection, security, interoperability with unmanaged code, cross-language debugging support, and enhanced deployment and versioning support.

In Microsoft Windows XP and Windows Vista, the operating system loader checks for managed modules by examining a bit in the COFF header. The bit being set denotes a managed module. If the loader detects managed modules, it loads mscoree.dll, and `_CorValidateImage` and `_CorImageUnloading` notify the loader when the managed module images are loaded and unloaded. `_CorValidateImage` performs the following actions:

1. Ensures that the code is valid managed code.
2. Changes the entry point in the image to an entry point in the runtime.

On 64-bit Windows, `_CorValidateImage` modifies the image that is in memory by transforming it from PE32 to PE32+ format.

Metadata and Self-Describing Components

5/2/2018 • 8 minutes to read • [Edit Online](#)

In the past, a software component (.exe or .dll) that was written in one language could not easily use a software component that was written in another language. COM provided a step towards solving this problem. The .NET Framework makes component interoperation even easier by allowing compilers to emit additional declarative information into all modules and assemblies. This information, called metadata, helps components to interact seamlessly.

Metadata is binary information describing your program that is stored either in a common language runtime portable executable (PE) file or in memory. When you compile your code into a PE file, metadata is inserted into one portion of the file, and your code is converted to Microsoft intermediate language (MSIL) and inserted into another portion of the file. Every type and member that is defined and referenced in a module or assembly is described within metadata. When code is executed, the runtime loads metadata into memory and references it to discover information about your code's classes, members, inheritance, and so on.

Metadata describes every type and member defined in your code in a language-neutral manner. Metadata stores the following information:

- Description of the assembly.
 - Identity (name, version, culture, public key).
 - The types that are exported.
 - Other assemblies that this assembly depends on.
 - Security permissions needed to run.
- Description of types.
 - Name, visibility, base class, and interfaces implemented.
 - Members (methods, fields, properties, events, nested types).
- Attributes.
 - Additional descriptive elements that modify types and members.

Benefits of Metadata

Metadata is the key to a simpler programming model, and eliminates the need for Interface Definition Language (IDL) files, header files, or any external method of component reference. Metadata enables .NET Framework languages to describe themselves automatically in a language-neutral manner, unseen by both the developer and the user. Additionally, metadata is extensible through the use of attributes. Metadata provides the following major benefits:

- Self-describing files.

Common language runtime modules and assemblies are self-describing. A module's metadata contains everything needed to interact with another module. Metadata automatically provides the functionality of IDL in COM, so you can use one file for both definition and implementation. Runtime modules and assemblies do not even require registration with the operating system. As a result, the descriptions used by the runtime always reflect the actual code in your compiled file, which increases application reliability.

- Language interoperability and easier component-based design.

Metadata provides all the information required about compiled code for you to inherit a class from a PE file written in a different language. You can create an instance of any class written in any managed language (any language that targets the common language runtime) without worrying about explicit marshaling or using custom interoperability code.

- Attributes.

The .NET Framework lets you declare specific kinds of metadata, called attributes, in your compiled file. Attributes can be found throughout the .NET Framework and are used to control in more detail how your program behaves at run time. Additionally, you can emit your own custom metadata into .NET Framework files through user-defined custom attributes. For more information, see [Attributes](#).

Metadata and the PE File Structure

Metadata is stored in one section of a .NET Framework portable executable (PE) file, while Microsoft intermediate language (MSIL) is stored in another section of the PE file. The metadata portion of the file contains a series of table and heap data structures. The MSIL portion contains MSIL and metadata tokens that reference the metadata portion of the PE file. You might encounter metadata tokens when you use tools such as the [MSIL Disassembler \(Ildasm.exe\)](#) to view your code's MSIL, for example.

Metadata Tables and Heaps

Each metadata table holds information about the elements of your program. For example, one metadata table describes the classes in your code, another table describes the fields, and so on. If you have ten classes in your code, the class table will have tens rows, one for each class. Metadata tables reference other tables and heaps. For example, the metadata table for classes references the table for methods.

Metadata also stores information in four heap structures: string, blob, user string, and GUID. All the strings used to name types and members are stored in the string heap. For example, a method table does not directly store the name of a particular method, but points to the method's name stored in the string heap.

Metadata Tokens

Each row of each metadata table is uniquely identified in the MSIL portion of the PE file by a metadata token. Metadata tokens are conceptually similar to pointers, persisted in MSIL, that reference a particular metadata table.

A metadata token is a four-byte number. The top byte denotes the metadata table to which a particular token refers (method, type, and so on). The remaining three bytes specify the row in the metadata table that corresponds to the programming element being described. If you define a method in C# and compile it into a PE file, the following metadata token might exist in the MSIL portion of the PE file:

```
0x06000004
```

The top byte (`0x06`) indicates that this is a **MethodDef** token. The lower three bytes (`000004`) tells the common language runtime to look in the fourth row of the **MethodDef** table for the information that describes this method definition.

Metadata within a PE File

When a program is compiled for the common language runtime, it is converted to a PE file that consists of three parts. The following table describes the contents of each part.

PE SECTION	CONTENTS OF PE SECTION
------------	------------------------

PE SECTION	CONTENTS OF PE SECTION
PE header	The index of the PE file's main sections and the address of the entry point. The runtime uses this information to identify the file as a PE file and to determine where execution starts when loading the program into memory.
MSIL instructions	The Microsoft intermediate language instructions (MSIL) that make up your code. Many MSIL instructions are accompanied by metadata tokens.
Metadata	Metadata tables and heaps. The runtime uses this section to record information about every type and member in your code. This section also includes custom attributes and security information.

Run-Time Use of Metadata

To better understand metadata and its role in the common language runtime, it might be helpful to construct a simple program and illustrate how metadata affects its run-time life. The following code example shows two methods inside a class called `MyApp`. The `Main` method is the program entry point, while the `Add` method simply returns the sum of two integer arguments.

```
Public Class MyApp
    Public Shared Sub Main()
        Dim ValueOne As Integer = 10
        Dim ValueTwo As Integer = 20
        Console.WriteLine("The Value is: {0}", Add(ValueOne, ValueTwo))
    End Sub

    Public Shared Function Add(One As Integer, Two As Integer) As Integer
        Return (One + Two)
    End Function
End Class
```

```
using System;
public class MyApp
{
    public static int Main()
    {
        int ValueOne = 10;
        int ValueTwo = 20;
        Console.WriteLine("The Value is: {0}", Add(ValueOne, ValueTwo));
        return 0;
    }
    public static int Add(int One, int Two)
    {
        return (One + Two);
    }
}
```

When the code runs, the runtime loads the module into memory and consults the metadata for this class. Once loaded, the runtime performs extensive analysis of the method's Microsoft intermediate language (MSIL) stream to convert it to fast native machine instructions. The runtime uses a just-in-time (JIT) compiler to convert the MSIL instructions to native machine code one method at a time as needed.

The following example shows part of the MSIL produced from the previous code's `Main` function. You can view the MSIL and metadata from any .NET Framework application using the [MSIL Disassembler \(Ildasm.exe\)](#).

```
.entrypoint
.maxstack 3
.locals ([0] int32 ValueOne,
[1] int32 ValueTwo,
[2] int32 V_2,
[3] int32 V_3)
IL_0000: ldc.i4.s 10
IL_0002: stloc.0
IL_0003: ldc.i4.s 20
IL_0005: stloc.1
IL_0006: ldstr     "The Value is: {0}"
IL_000b: ldloc.0
IL_000c: ldloc.1
IL_000d: call int32 ConsoleApplication.MyApp::Add(int32,int32) /* 06000003 */
```

The JIT compiler reads the MSIL for the whole method, analyzes it thoroughly, and generates efficient native instructions for the method. At `IL_000d`, a metadata token for the `Add` method (`/* 06000003 */`) is encountered and the runtime uses the token to consult the third row of the **MethodDef** table.

The following table shows part of the **MethodDef** table referenced by the metadata token that describes the `Add` method. While other metadata tables exist in this assembly and have their own unique values, only this table is discussed.

ROW	RELATIVE VIRTUAL ADDRESS (RVA)	IMPLFLAGS	FLAGS	NAME (POINTS TO STRING HEAP.)	SIGNATURE (POINTS TO BLOB HEAP.)
1	0x00002050	IL Managed	Public ReuseSlot SpecialName RTSpecialName .ctor	.ctor (constructor)	
2	0x00002058	IL Managed	Public Static ReuseSlot	Main	String
3	0x0000208c	IL Managed	Public Static ReuseSlot	Add	int, int, int

Each column of the table contains important information about your code. The **RVA** column allows the runtime to calculate the starting memory address of the MSIL that defines this method. The **ImplFlags** and **Flags** columns contain bitmasks that describe the method (for example, whether the method is public or private). The **Name** column indexes the name of the method from the string heap. The **Signature** column indexes the definition of the method's signature in the blob heap.

The runtime calculates the desired offset address from the **RVA** column in the third row and returns this address

to the JIT compiler, which then proceeds to the new address. The JIT compiler continues to process MSIL at the new address until it encounters another metadata token and the process is repeated.

Using metadata, the runtime has access to all the information it needs to load your code and process it into native machine instructions. In this manner, metadata enables self-describing files and, together with the common type system, cross-language inheritance.

Building Console Applications in the .NET Framework

1/23/2019 • 2 minutes to read • [Edit Online](#)

Applications in the .NET Framework can use the [System.Console](#) class to read characters from and write characters to the console. Data from the console is read from the standard input stream, data to the console is written to the standard output stream, and error data to the console is written to the standard error output stream. These streams are automatically associated with the console when the application starts and are presented as the [In](#), [Out](#), and [Error](#) properties, respectively.

The value of the [Console.In](#) property is a [System.IO.TextReader](#) object, whereas the values of the [Console.Out](#) and [Console.Error](#) properties are [System.IO.TextWriter](#) objects. You can associate these properties with streams that do not represent the console, making it possible for you to point the stream to a different location for input or output. For example, you can redirect the output to a file by setting the [Console.Out](#) property to a [System.IO.StreamWriter](#), which encapsulates a [System.IO.FileStream](#) by means of the [Console.SetOut](#) method. The [Console.In](#) and [Console.Out](#) properties do not need to refer to the same stream.

NOTE

For more information about building console applications, including examples in C#, Visual Basic, and C++, see the documentation for the [Console](#) class.

If the console does not exist, as in a Windows-based application, output written to the standard output stream will not be visible, because there is no console to write the information to. Writing information to an inaccessible console does not cause an exception to be raised.

Alternately, to enable the console for reading and writing within a Windows-based application that is developed using Visual Studio, open the project's **Properties** dialog box, click the **Application** tab, and set the **Application type** to **Console Application**.

Console applications lack a message pump that starts by default. Therefore, console calls to Microsoft Win32 timers might fail.

The **System.Console** class has methods that can read individual characters or entire lines from the console. Other methods convert data and format strings, and then write the formatted strings to the console. For more information on formatting strings, see [Formatting Types](#).

.NET Framework Application Essentials

5/2/2018 • 2 minutes to read • [Edit Online](#)

This section of the .NET Framework documentation provides information about basic application development tasks in the .NET Framework.

In This Section

[Base Types](#)

Discusses formatting and parsing base data types and using regular expressions to process text.

[Collections and Data Structures](#)

Discusses the various collection types available in the .NET Framework, including stacks, queues, lists, arrays, and structs.

[Generics](#)

Describes the Generics feature, including the generic collections, delegates, and interfaces provided by the .NET Framework. Provides links to feature documentation for C#, Visual Basic and Visual C++, and to supporting technologies such as Reflection.

[Numerics](#)

Describes the numeric types in the .NET Framework.

[Events](#)

Provides an overview of the event model in the .NET Framework.

[Exceptions](#)

Describes error handling provided by the .NET Framework and the fundamentals of handling exceptions.

[File and Stream I/O](#)

Explains how you can perform synchronous and asynchronous file and data stream access and how to use to isolated storage.

[Dates, Times, and Time Zones](#)

Describes how to work with time zones and time zone conversions in time zone-aware applications.

[Application Domains and Assemblies](#)

Describes how to create and work with assemblies and application domains.

[Serialization](#)

Discusses the process of converting the state of an object into a form that can be persisted or transported.

[Resources in Desktop Apps](#)

Describes the .NET Framework support for creating and storing resources. This section also describes support for localized resources and the satellite assembly resource model for packaging and deploying those localized resources.

[Globalization and Localization](#)

Provides information to help you design and develop world-ready applications.

[Accessibility](#)

Provides information about Microsoft UI Automation, which is an accessibility framework that addresses the needs of assistive technology products and automated test frameworks by providing programmatic access to information about the user interface (UI).

Attributes

Describes how you can use attributes to customize metadata.

64-bit Applications

Discusses issues relevant to developing applications that will run on a Windows 64-bit operating system.

Related Sections

Development Guide

Provides a guide to all key technology areas and tasks for application development, including creating, configuring, debugging, securing, and deploying your application, and information about dynamic programming, interoperability, extensibility, memory management, and threading.

Security

Provides information about the classes and services in the common language runtime and the .NET Framework that facilitate secure application development.

File and Stream I/O

2/26/2019 • 7 minutes to read • [Edit Online](#)

File and stream I/O (input/output) refers to the transfer of data either to or from a storage medium. In the .NET Framework, the `System.IO` namespaces contain types that enable reading and writing, both synchronously and asynchronously, on data streams and files. These namespaces also contain types that perform compression and decompression on files, and types that enable communication through pipes and serial ports.

A file is an ordered and named collection of bytes that has persistent storage. When you work with files, you work with directory paths, disk storage, and file and directory names. In contrast, a stream is a sequence of bytes that you can use to read from and write to a backing store, which can be one of several storage mediums (for example, disks or memory). Just as there are several backing stores other than disks, there are several kinds of streams other than file streams, such as network, memory, and pipe streams.

Files and directories

You can use the types in the `System.IO` namespace to interact with files and directories. For example, you can get and set properties for files and directories, and retrieve collections of files and directories based on search criteria.

For path naming conventions and the ways to express a file path for Windows systems, including with the DOS device syntax supported in .NET Core 1.1 and later and the .NET Framework 4.6.2 and later, see [File path formats on Windows systems](#).

Here are some commonly used file and directory classes:

- `File` - provides static methods for creating, copying, deleting, moving, and opening files, and helps create a `FileStream` object.
- `FileInfo` - provides instance methods for creating, copying, deleting, moving, and opening files, and helps create a `FileStream` object.
- `Directory` - provides static methods for creating, moving, and enumerating through directories and subdirectories.
- `DirectoryInfo` - provides instance methods for creating, moving, and enumerating through directories and subdirectories.
- `Path` - provides methods and properties for processing directory strings in a cross-platform manner.

You should always provide robust exception handling when calling filesystem methods. For more information, see [Handling I/O errors](#).

In addition to using these classes, Visual Basic users can use the methods and properties provided by the `Microsoft.VisualBasic.FileIO.FileSystem` class for file I/O.

See [How to: Copy Directories](#), [How to: Create a Directory Listing](#), and [How to: Enumerate Directories and Files](#).

Streams

The abstract base class `Stream` supports reading and writing bytes. All classes that represent streams inherit from the `Stream` class. The `Stream` class and its derived classes provide a common view of data sources and repositories, and isolate the programmer from the specific details of the operating system and underlying devices.

Streams involve three fundamental operations:

- Reading - transferring data from a stream into a data structure, such as an array of bytes.
- Writing - transferring data to a stream from a data source.
- Seeking - querying and modifying the current position within a stream.

Depending on the underlying data source or repository, a stream might support only some of these capabilities. For example, the [PipeStream](#) class does not support seeking. The [CanRead](#), [CanWrite](#), and [CanSeek](#) properties of a stream specify the operations that the stream supports.

Here are some commonly used stream classes:

- [FileStream](#) – for reading and writing to a file.
- [IsolatedStorageFileStream](#) – for reading and writing to a file in isolated storage.
- [MemoryStream](#) – for reading and writing to memory as the backing store.
- [BufferedStream](#) – for improving performance of read and write operations.
- [NetworkStream](#) – for reading and writing over network sockets.
- [PipeStream](#) – for reading and writing over anonymous and named pipes.
- [CryptoStream](#) – for linking data streams to cryptographic transformations.

For an example of working with streams asynchronously, see [Asynchronous File I/O](#).

Readers and writers

The [System.IO](#) namespace also provides types for reading encoded characters from streams and writing them to streams. Typically, streams are designed for byte input and output. The reader and writer types handle the conversion of the encoded characters to and from bytes so the stream can complete the operation. Each reader and writer class is associated with a stream, which can be retrieved through the class's `BaseStream` property.

Here are some commonly used reader and writer classes:

- [BinaryReader](#) and [BinaryWriter](#) – for reading and writing primitive data types as binary values.
- [StreamReader](#) and [StreamWriter](#) – for reading and writing characters by using an encoding value to convert the characters to and from bytes.
- [StringReader](#) and [StringWriter](#) – for reading and writing characters to and from strings.
- [TextReader](#) and [TextWriter](#) – serve as the abstract base classes for other readers and writers that read and write characters and strings, but not binary data.

See [How to: Read Text from a File](#), [How to: Write Text to a File](#), [How to: Read Characters from a String](#), and [How to: Write Characters to a String](#).

Asynchronous I/O operations

Reading or writing a large amount of data can be resource-intensive. You should perform these tasks asynchronously if your application needs to remain responsive to the user. With synchronous I/O operations, the UI thread is blocked until the resource-intensive operation has completed. Use asynchronous I/O operations when developing Windows 8.x Store apps to prevent creating the impression that your app has stopped working.

The asynchronous members contain `Async` in their names, such as the [CopyToAsync](#), [FlushAsync](#), [ReadAsync](#), and [WriteAsync](#) methods. You use these methods with the `async` and `await` keywords.

For more information, see [Asynchronous File I/O](#).

Compression

Compression refers to the process of reducing the size of a file for storage. Decompression is the process of extracting the contents of a compressed file so they are in a usable format. The [System.IO.Compression](#) namespace contains types for compressing and decompressing files and streams.

The following classes are frequently used when compressing and decompressing files and streams:

- [ZipArchive](#) – for creating and retrieving entries in the zip archive.
- [ZipArchiveEntry](#) – for representing a compressed file.
- [ZipFile](#) – for creating, extracting, and opening a compressed package.
- [ZipFileExtensions](#) – for creating and extracting entries in a compressed package.
- [DeflateStream](#) – for compressing and decompressing streams using the Deflate algorithm.
- [GZipStream](#) – for compressing and decompressing streams in gzip data format.

See [How to: Compress and Extract Files](#).

Isolated storage

Isolated storage is a data storage mechanism that provides isolation and safety by defining standardized ways of associating code with saved data. The storage provides a virtual file system that is isolated by user, assembly, and (optionally) domain. Isolated storage is particularly useful when your application does not have permission to access user files. You can save settings or files for your application in a manner that is controlled by the computer's security policy.

Isolated storage is not available for Windows 8.x Store apps; instead, use application data classes in the [Windows.Storage](#) namespace. For more information, see [Application data](#).

The following classes are frequently used when implementing isolated storage:

- [IsolatedStorage](#) – provides the base class for isolated storage implementations.
- [IsolatedStorageFile](#) – provides an isolated storage area that contains files and directories.
- [IsolatedStorageFileStream](#) - exposes a file within isolated storage.

See [Isolated Storage](#).

I/O operations in Windows Store apps

The .NET for Windows 8.x Store apps contains many of the types for reading from and writing to streams; however, this set does not include all the .NET Framework I/O types.

Some important differences to note when using I/O operations in Windows 8.x Store apps:

- Types specifically related to file operations, such as [File](#), [FileInfo](#), [Directory](#) and [DirectoryInfo](#), are not included in the .NET for Windows 8.x Store apps. Instead, use the types in the [Windows.Storage](#) namespace of the Windows Runtime, such as [StorageFile](#) and [StorageFolder](#).
- Isolated storage is not available; instead, use [application data](#).
- Use asynchronous methods, such as [ReadAsync](#) and [WriteAsync](#), to prevent blocking the UI thread.
- The path-based compression types [ZipFile](#) and [ZipFileExtensions](#) are not available. Instead, use the types in the [Windows.Storage.Compression](#) namespace.

You can convert between .NET Framework streams and Windows Runtime streams, if necessary. For more information, see [How to: Convert Between .NET Framework Streams and Windows Runtime Streams](#) or [WindowsRuntimeStreamExtensions](#).

For more information about I/O operations in a Windows 8.x Store app, see [Quickstart: Reading and writing files](#).

I/O and security

When you use the classes in the [System.IO](#) namespace, you must follow operating system security requirements such as access control lists (ACLs) to control access to files and directories. This requirement is in addition to any [FileIOPermission](#) requirements. You can manage ACLs programmatically. For more information, see [How to: Add or Remove Access Control List Entries](#).

Default security policies prevent Internet or intranet applications from accessing files on the user's computer. Therefore, do not use the I/O classes that require a path to a physical file when writing code that will be downloaded over the Internet or intranet. Instead, use [isolated storage](#) for traditional .NET Framework applications, or use [application data](#) for Windows 8.x Store apps.

A security check is performed only when the stream is constructed. Therefore, do not open a stream and then pass it to less-trusted code or application domains.

Globalizing and localizing .NET applications

2/26/2019 • 2 minutes to read • [Edit Online](#)

Developing a world-ready application, including an application that can be localized into one or more languages, involves three steps: globalization, localizability review, and localization.

Globalization

This step involves designing and coding an application that is culture-neutral and language-neutral, and that supports localized user interfaces and regional data for all users. It involves making design and programming decisions that are not based on culture-specific assumptions. While a globalized application is not localized, it nevertheless is designed and written so that it can be subsequently localized into one or more languages with relative ease.

Localizability review

This step involves reviewing an application's code and design to ensure that it can be localized easily and to identify potential roadblocks for localization, and verifying that the application's executable code is separated from its resources. If the globalization stage was effective, the localizability review will confirm the design and coding choices made during globalization. The localizability stage may also identify any remaining issues so that an application's source code doesn't have to be modified during the localization stage.

Localization

This step involves customizing an application for specific cultures or regions. If the globalization and localizability steps have been performed correctly, localization consists primarily of translating the user interface.

Following these three steps provides two advantages:

- It frees you from having to retrofit an application that is designed to support a single culture, such as U.S. English, to support additional cultures.
- It results in localized applications that are more stable and have fewer bugs.

.NET provides extensive support for the development of world-ready and localized applications. In particular, many type members in the .NET class library aid globalization by returning values that reflect the conventions of either the current user's culture or a specified culture. Also, .NET supports satellite assemblies, which facilitate the process of localizing an application.

For additional information, see the [Globalization documentation](#).

In this section

Globalization

Discusses the first stage of creating a world-ready application, which involves designing and coding an application that is culture-neutral and language-neutral.

Localizability review

Discusses the second stage of creating a localized application, which involves identifying potential roadblocks to localization.

Localization

Discusses the final stage of creating a localized application, which involves customizing an application's user

interface for specific regions or cultures.

Culture-insensitive string operations

Describes how to use .NET methods and classes that are culture-sensitive by default to obtain culture-insensitive results.

Best practices for developing world-ready applications

Describes the best practices to follow for globalization, localization, and developing world-ready ASP.NET applications.

Reference

- [System.Globalization](#) namespace

Contains classes that define culture-related information, including the language, the country/region, the calendars in use, the format patterns for dates, currency, and numbers, and the sort order for strings.

- [System.Resources](#) namespace

Provides classes for creating, manipulating, and using resources.

- [System.Text](#) namespace

Contains classes representing ASCII, ANSI, Unicode, and other character encodings.

- [Resgen.exe \(Resource File Generator\)](#)

Describes how to use Resgen.exe to convert .txt files and XML-based resource format (.resx) files to common language runtime binary .resources files.

- [Winres.exe \(Windows Forms Resource Editor\)](#)

Describes how to use Winres.exe to localize Windows Forms forms.

Extending Metadata Using Attributes

5/2/2018 • 2 minutes to read • [Edit Online](#)

The common language runtime allows you to add keyword-like descriptive declarations, called attributes, to annotate programming elements such as types, fields, methods, and properties. When you compile your code for the runtime, it is converted into Microsoft intermediate language (MSIL) and placed inside a portable executable (PE) file along with metadata generated by the compiler. Attributes allow you to place extra descriptive information into metadata that can be extracted using runtime reflection services. The compiler creates attributes when you declare instances of special classes that derive from [System.Attribute](#).

The .NET Framework uses attributes for a variety of reasons and to address a number of issues. Attributes describe how to serialize data, specify characteristics that are used to enforce security, and limit optimizations by the just-in-time (JIT) compiler so the code remains easy to debug. Attributes can also record the name of a file or the author of code, or control the visibility of controls and members during forms development.

Framework Design Guidelines

2/26/2019 • 2 minutes to read

This section provides guidelines for designing libraries that extend and interact with the .NET Framework. The goal is to help library designers ensure API consistency and ease of use by providing a unified programming model that is independent of the programming language used for development. We recommend that you follow these design guidelines when developing classes and components that extend the .NET Framework. Inconsistent library design adversely affects developer productivity and discourages adoption.

The guidelines are organized as simple recommendations prefixed with the terms **Do**, **Consider**, **Avoid**, and **Do not**. These guidelines are intended to help class library designers understand the trade-offs between different solutions. There might be situations where good library design requires that you violate these design guidelines. Such cases should be rare, and it is important that you have a clear and compelling reason for your decision.

These guidelines are excerpted from the book *Framework Design Guidelines: Conventions, Idioms, and Patterns for Reusable .NET Libraries, 2nd Edition*, by Krzysztof Cwalina and Brad Abrams.

In This Section

[Naming Guidelines](#)

Provides guidelines for naming assemblies, namespaces, types, and members in class libraries.

[Type Design Guidelines](#)

XML Documents and Data

2/26/2019 • 3 minutes to read • [Edit Online](#)

The .NET Framework provides a comprehensive and integrated set of classes that enable you to build XML-aware apps easily. The classes in the following namespaces support parsing and writing XML, editing XML data in memory, data validation, and XSLT transformation.

- [System.Xml](#)
- [System.Xml.XPath](#)
- [System.Xml.Xsl](#)
- [System.Xml.Schema](#)
- [System.Xml.Linq](#)

For a full list, search for "System.Xml" on the [.NET API browser](#).

The classes in these namespaces support World Wide Web Consortium (W3C) recommendations. For example:

- The [System.Xml.XmlDocument](#) class implements the [W3C Document Object Model \(DOM\) Level 1 Core](#) and [DOM Level 2 Core](#) recommendations.
- The [System.Xml.XmlReader](#) and [System.Xml.XmlWriter](#) classes support the [W3C XML 1.0](#) and the [Namespaces in XML](#) recommendations.
- Schemas in the [System.Xml.Schema.XmlSchemaSet](#) class support the [W3C XML Schema Part 1: Structures](#) and [XML Schema Part 2: Datatypes](#) recommendations.
- Classes in the [System.Xml.Xsl](#) namespace support XSLT transformations that conform to the [W3C XSLT 1.0](#) recommendation.

The XML classes in the .NET Framework provide these benefits:

- **Productivity.** [LINQ to XML \(C#\)](#) and [LINQ to XML \(Visual Basic\)](#) makes it easier to program with XML and provides a query experience that is similar to SQL.
- **Extensibility.** The XML classes in the .NET Framework are extensible through the use of abstract base classes and virtual methods. For example, you can create a derived class of the [XmlUrlResolver](#) class that stores the cache stream to the local disk.
- **Pluggable architecture.** The .NET Framework provides an architecture in which components can utilize one another, and data can be streamed between components. For example, a data store, such as an [XPathDocument](#) or [XmlDocument](#) object, can be transformed with the [XslCompiledTransform](#) class, and the output can then be streamed either into another store or returned as a stream from a web service.
- **Performance.** For better app performance, some of the XML classes in the .NET Framework support a streaming-based model with the following characteristics:
 - Minimal caching for forward-only, pull-model parsing ([XmlReader](#)).
 - Forward-only validation ([XmlReader](#)).
 - Cursor style navigation that minimizes node creation to a single virtual node while providing random access to the document ([XPathNavigator](#)).

For better performance whenever XSLT processing is required, you can use the [XPathDocument](#) class, which is an optimized, read-only store for XPath queries designed to work efficiently with the [XslCompiledTransform](#) class.

- **Integration with ADO.NET.** The XML classes and [ADO.NET](#) are tightly integrated to bring together relational data and XML. The [DataSet](#) class is an in-memory cache of data retrieved from a database. The [DataSet](#) class has the ability to read and write XML by using the [XmlReader](#) and [XmlWriter](#) classes, to persist its internal relational schema structure as XML schemas (XSD), and to infer the schema structure of an XML document.

In This Section

[XML Processing Options](#)

Discusses options for processing XML data.

[Processing XML Data In-Memory](#)

Discusses the three models for processing XML data in-memory: [LINQ to XML \(C#\)](#) and [LINQ to XML \(Visual Basic\)](#), the [XmlDocument](#) class (based on the W3C Document Object Model), and the [XPathDocument](#) class (based on the XPath data model).

[XSLT Transformations](#)

Describes how to use the XSLT processor.

[XML Schema Object Model \(SOM\)](#)

Describes the classes used for building and manipulating XML Schemas (XSD) by providing an [XmlSchema](#) class to load and edit a schema.

[XML Integration with Relational Data and ADO.NET](#)

Describes how the .NET Framework enables real-time, synchronous access to both the relational and hierarchical representations of data through the [DataSet](#) object and the [XmlDataDocument](#) object.

[Managing Namespaces in an XML Document](#)

Describes how the [XmlNamespaceManager](#) class is used to store and maintain namespace information.

[Type Support in the System.Xml Classes](#)

Describes how XML data types map to CLR types, how to convert XML data types, and other type support features in the [System.Xml](#) classes.

Serialization in .NET

5/2/2018 • 2 minutes to read • [Edit Online](#)

Serialization is the process of converting the state of an object into a form that can be persisted or transported. The complement of serialization is deserialization, which converts a stream into an object. Together, these processes allow data to be easily stored and transferred.

.NET features two serialization technologies:

- Binary serialization preserves type fidelity, which is useful for preserving the state of an object between different invocations of an application. For example, you can share an object between different applications by serializing it to the Clipboard. You can serialize an object to a stream, to a disk, to memory, over the network, and so forth. Remoting uses serialization to pass objects "by value" from one computer or application domain to another.
- XML serialization serializes only public properties and fields and does not preserve type fidelity. This is useful when you want to provide or consume data without restricting the application that uses the data. Because XML is an open standard, it is an attractive choice for sharing data across the Web. SOAP is likewise an open standard, which makes it an attractive choice.

In This Section

[Serialization How-to Topics](#)

Lists links to How-to topics contained in this section.

[Binary Serialization](#)

Describes the binary serialization mechanism that is included with the common language runtime.

[XML and SOAP Serialization](#)

Describes the XML and SOAP serialization mechanism that is included with the common language runtime.

[Serialization Tools](#)

These tools help develop serialization code.

[Serialization Samples](#)

The samples demonstrate how to do serialization.

Reference

[System.Xml.Serialization](#)

Contains classes that can be used to serialize objects into XML format documents or streams.

Developing for Multiple Platforms with the .NET Framework

3/8/2019 • 3 minutes to read • [Edit Online](#)

You can develop apps for both Microsoft and non-Microsoft platforms by using the .NET Framework and Visual Studio.

Options for cross-platform development

IMPORTANT

Because Portable Class Library projects target only a very specific subset of .NET implementations, we strongly discourage their use in new application development. The recommended replacement is a .NET Standard library, which targets all .NET implementations that support a specific version of the .NET Standard. For more information, see [.NET Standard](#).

To develop for multiple platforms, you can share source code or binaries, and you can make calls between .NET Framework code and Windows Runtime APIs.

IF YOU WANT TO...	USE...
Share source code between Windows Phone 8.1 and Windows 8.1 apps	<p>Shared projects (Universal Apps template in Visual Studio 2013, Update 2).</p> <ul style="list-style-type: none">- Currently no Visual Basic support.- You can separate platform-specific code by using <code># if</code> statements. <p>For details, see:</p> <ul style="list-style-type: none">- Start coding- Using Visual Studio to build Universal XAML Apps (blog post)- Using Visual Studio to Build XAML Converged Apps (video)

IF YOU WANT TO...	USE...
Share binaries between apps that target different platforms	<p>Portable Class Library projects for code that is platform-agnostic.</p> <ul style="list-style-type: none"> - This approach is typically used for code that implements business logic. - You can use Visual Basic or C#. - API support varies by platform. - Portable Class Library projects that target Windows 8.1 and Windows Phone 8.1 support Windows Runtime APIs and XAML. These features aren't available in older versions of the Portable Class Library. - If needed, you can abstract out platform-specific code by using interfaces or abstract classes. <p>For details, see:</p> <ul style="list-style-type: none"> - Portable Class Library - How to Make Portable Class Libraries Work for You (blog post) - Using Portable Class Library with MVVM - App Resources for Libraries That Target Multiple Platforms - .NET Portability Analyzer (Visual Studio extension)
Share source code between apps for platforms other than Windows 8.1 and Windows Phone 8.1	<p>Add as link feature.</p> <ul style="list-style-type: none"> - This approach is suitable for app logic that's common to both apps but not portable, for some reason. You can use this feature for C# or Visual Basic code. <p>For example, Windows Phone 8 and Windows 8 share Windows Runtime APIs, but Portable Class Libraries do not support Windows Runtime for those platforms. You can use <code>Add as link</code> to share common Windows Runtime code between a Windows Phone 8 app and a Windows Store app that targets Windows 8.</p> <p>For details, see:</p> <ul style="list-style-type: none"> - Share code with Add as Link - How to: Add Existing Items to a Project
Write Windows Store apps using the .NET Framework or call Windows Runtime APIs from .NET Framework code	<p>Windows Runtime APIs from your .NET Framework C# or Visual Basic code, and use the .NET Framework to create Windows Store apps. You should be aware of API differences between the two platforms. However, there are classes to help you work with those differences.</p> <p>For details, see:</p> <ul style="list-style-type: none"> - .NET Framework Support for Windows Store Apps and Windows Runtime - Passing a URI to the Windows Runtime - WindowsRuntimeStreamExtensions - WindowsRuntimeSystemExtensions

IF YOU WANT TO...	USE...
Build .NET Framework apps for non-Microsoft platforms	<p>Portable Class Library reference assemblies in the .NET Framework, and a Visual Studio extension or third-party tool such as Xamarin.</p> <p>For details, see:</p> <ul style="list-style-type: none"> - Portable Class Library now available on all platforms. Use JavaScript and HTML for cross-platform development	<p>Universal App templates in Visual Studio 2013, Update 2 to develop against Windows Runtime APIs for Windows 8.1 and Windows Phone 8.1. Currently, you can't use JavaScript and HTML with .NET Framework APIs to develop cross-platform apps.</p> <p>For details, see:</p> <ul style="list-style-type: none"> - JavaScript Project Templates - Porting a Windows Runtime app using JavaScript to Windows Phone

.NET Core Guide

1/4/2019 • 2 minutes to read • [Edit Online](#)

.NET Core is an [open-source](#), general-purpose development platform maintained by Microsoft and the .NET community on [GitHub](#). It's cross-platform (supporting Windows, macOS, and Linux) and can be used to build device, cloud, and IoT applications.

See [About .NET Core](#) to learn more about .NET Core, including its characteristics, supported languages and frameworks, and key APIs.

Check out [.NET Core Tutorials](#) to learn how to create a simple .NET Core application. It only takes a few minutes to get your first app up and running. If you want to try .NET Core in your browser, look at the [Numbers in C#](#) online tutorial.

Download .NET Core 2.2

Download the [.NET Core 2.2 SDK](#) to try .NET Core on your Windows, macOS, or Linux machine. Visit [microsoft/dotnet](#) if you prefer to use Docker containers.

All .NET Core versions are available at [.NET Core Downloads](#) if you're looking for another .NET Core version.

.NET Core 2.2

The latest version is [.NET Core 2.2](#). New features include: framework-dependent deployments, startup hooks, AAD authentication with Azure SQL, and support for Windows ARM32.

Create your first application

After installing the .NET Core SDK, open a command prompt. Type the following `dotnet` commands to create and run a C# application.

```
dotnet new console  
dotnet run
```

You should see the following output:

```
Hello World!
```

Support

.NET Core is [supported by Microsoft](#), on Windows, macOS and Linux. It's updated for security and quality several times a year, typically monthly.

.NET Core binary distributions are built and tested on Microsoft-maintained servers in Azure and supported just like any Microsoft product.

[Red Hat](#) supports .NET Core on Red Hat Enterprise Linux (RHEL). Red Hat builds .NET Core from source and makes it available in the [Red Hat Software Collections](#). Red Hat and Microsoft collaborate to ensure that .NET Core works well on RHEL.

About .NET Core

3/8/2019 • 6 minutes to read • [Edit Online](#)

.NET Core has the following characteristics:

- **Cross-platform:** Runs on Windows, macOS and Linux [operating systems](#).
- **Consistent across architectures:** Runs your code with the same behavior on multiple architectures, including x64, x86, and ARM.
- **Command-line tools:** Includes easy-to-use command-line tools that can be used for local development and in continuous-integration scenarios.
- **Flexible deployment:** Can be included in your app or installed side-by-side user- or machine-wide. Can be used with [Docker containers](#).
- **Compatible:** .NET Core is compatible with .NET Framework, Xamarin and Mono, via [.NET Standard](#).
- **Open source:** The .NET Core platform is open source, using MIT and Apache 2 licenses. .NET Core is a [.NET Foundation](#) project.
- **Supported by Microsoft:** .NET Core is supported by Microsoft, per [.NET Core Support](#).

Languages

C#, Visual Basic, and F# languages can be used to write applications and libraries for .NET Core. These languages are or can be integrated into your favorite text editors and IDEs, including [Visual Studio](#), [Visual Studio Code](#), Sublime Text and Vim. This integration is provided, in part, by the good folks from the [OmniSharp](#) and [Ionide](#) projects.

APIs

.NET Core exposes APIs for many scenarios, a few of which follow:

- Primitive types, such as [bool](#) and [int](#).
- Collections, such as [System.Collections.Generic.List<T>](#) and [System.Collections.Generic.Dictionary< TKey, TValue >](#).
- Utility types, such as [System.Net.Http.HttpClient](#), and [System.IO.FileStream](#).
- Data types, such as [System.Data.DataSet](#), and [DbSet](#).
- High performance types, such as [System.Numerics.Vector](#) and [Pipelines](#).

.NET Core provides compatibility with .NET Framework and Mono APIs by implementing the [.NET Standard](#) specification.

Frameworks

Multiple frameworks have been built on top of .NET Core:

- [ASP.NET Core](#)
- [Windows 10 Universal Windows Platform \(UWP\)](#)
- [Tizen](#)

Composition

.NET Core is composed of the following parts:

- The [.NET Core runtime](#), which provides a type system, assembly loading, a garbage collector, native interop and other basic services. [.NET Core framework libraries](#) provide primitive data types, app composition types and fundamental utilities.
- The [ASP.NET runtime](#), which provides a framework for building modern cloud based internet connected applications, such as web apps, IoT apps and mobile backends.
- The [.NET Core CLI tools](#) and language compilers ([Roslyn](#) and [F#](#)) that enable the .NET Core developer experience.
- The [dotnet tool](#), which is used to launch .NET Core apps and CLI tools. It selects the runtime and hosts the runtime, provides an assembly loading policy and launches apps and tools.

These components are distributed in the following ways:

- [.NET Core Runtime](#) -- includes the .NET Core runtime and framework libraries.
- [ASP.NET Core Runtime](#) -- includes ASP.NET Core and .NET Core runtime and framework libraries.
- [.NET Core SDK](#) -- includes the .NET CLI Tools, ASP.NET Core runtime, and .NET Core runtime and framework.

Open Source

.NET Core is open source ([MIT license](#)) and was contributed to the [.NET Foundation](#) by Microsoft in 2014. It is now one of the most active .NET Foundation projects. It can be freely adopted by individuals and companies, including for personal, academic or commercial purposes. Multiple companies use .NET Core as part of apps, tools, new platforms and hosting services. Some of these companies make significant contributions to .NET Core on GitHub and provide guidance on the product direction as part of the [.NET Foundation Technical Steering Group](#).

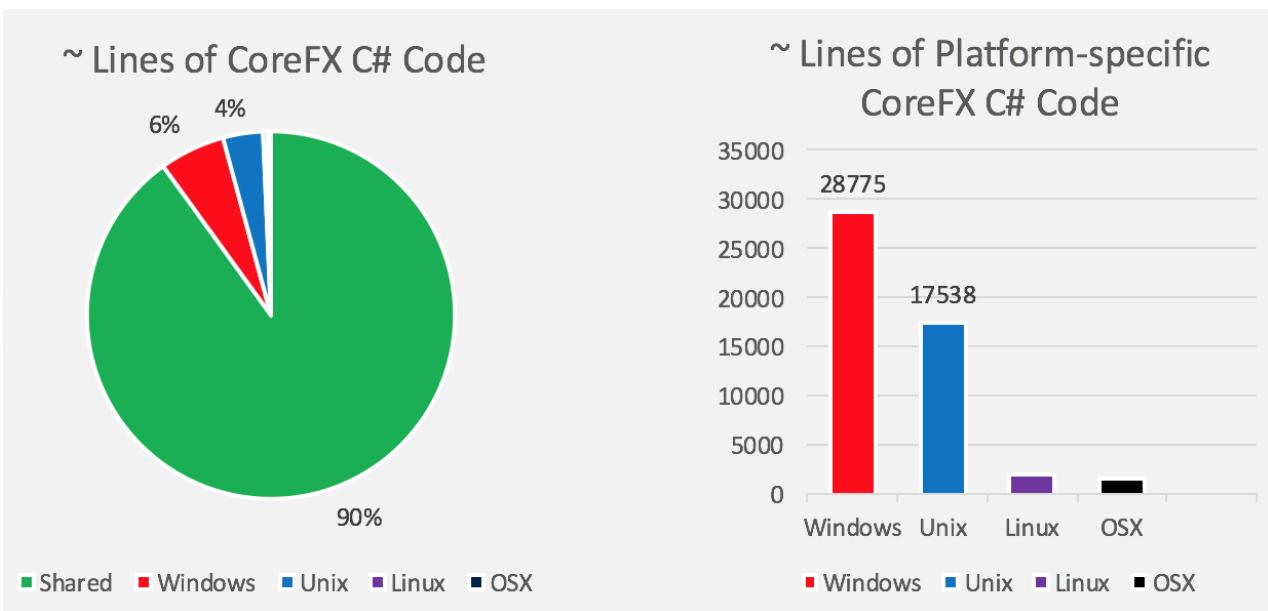

Designed for Adaptability

.NET Core has been built as a very similar but unique product relative to other .NET products. It has been designed to enable broad adaptability to new platforms and workloads. It has several OS and CPU ports available and may be ported to many more.

The product is broken into several pieces, enabling the various parts to be adapted to new platforms at different times. The runtime and platform-specific foundational libraries must be ported as a unit. Platform-agnostic libraries should work as-is on all platforms, by construction. There is a project bias to reducing platform-specific implementations to increase developer efficiency, preferring platform-neutral C# code whenever an algorithm or API can be implemented in-full or in-part that way.

People commonly ask how .NET Core is implemented in order to support multiple operating systems. They typically ask if there are separate implementations or if [conditional compilation](#) is used. It's both, with a strong bias towards conditional compilation.

You can see in the chart below that the vast majority of [CoreFX](#) is platform-neutral code that is shared across all platforms. Platform-neutral code can be implemented as a single portable assembly that is used on all platforms.

Windows and Unix implementations are similar in size. Windows has a larger implementation since CoreFX implements some Windows-only features, such as [Microsoft.Win32.Registry](#) but does not yet implement many Unix-only concepts. You will also see that the majority of the Linux and macOS implementations are shared across a Unix implementation, while the Linux- and macOS-specific implementations are roughly similar in size.

There are a mix of platform-specific and platform-neutral libraries in .NET Core. You can see the pattern in a few examples:

- [CoreCLR](#) is platform-specific. It builds on top of OS subsystems, like the memory manager and thread scheduler.
- [System.IO](#) and [System.Security.Cryptography.Algorithms](#) are platform-specific, given that storage and cryptography APIs are different on each OS.
- [System.Collections](#) and [System.Linq](#) are platform-neutral, given that they create and operate over data structures.

Comparisons to other .NET implementations

It is perhaps easiest to understand the size and shape of .NET Core by comparing it to existing .NET implementations.

Comparison with .NET Framework

.NET was first announced by Microsoft in 2000 and then evolved from there. The .NET Framework has been the primary .NET implementation produced by Microsoft during that nearly two decade period.

The major differences between .NET Core and the .NET Framework:

- **App-models** -- .NET Core does not support all the .NET Framework app-models. In particular, it doesn't support ASP.NET Web Forms and ASP.NET MVC, but it supports ASP.NET Core MVC. It was announced that [.NET Core 3 will support WPF and Windows Forms](#).
- **APIs** -- .NET Core contains a large subset of .NET Framework Base Class Library, with a different factoring (assembly names are different; members exposed on types differ in key cases). These differences require changes to port source to .NET Core in some cases (see [microsoft/dotnet-apiport](#)). .NET Core implements the [.NET Standard](#) API specification.
- **Subsystems** -- .NET Core implements a subset of the subsystems in the .NET Framework, with the goal of a simpler implementation and programming model. For example, Code Access Security (CAS) is not supported, while reflection is supported.
- **Platforms** -- The .NET Framework supports Windows and Windows Server while .NET Core also supports macOS and Linux.

- **Open Source** -- .NET Core is open source, while a [read-only subset of the .NET Framework](#) is open source.

While .NET Core is unique and has significant differences to the .NET Framework and other .NET implementations, it is straightforward to share code between these implementations, using either source or binary sharing techniques.

Comparison with Mono

Mono is the original cross-platform and [open source](#) .NET implementation, first shipping in 2004. It can be thought of as a community clone of the .NET Framework. The Mono project team relied on the open [.NET standards](#) (notably ECMA 335) published by Microsoft in order to provide a compatible implementation.

The major differences between .NET Core and Mono:

- **App-models** -- Mono supports a subset of the .NET Framework app-models (for example, Windows Forms) and some additional ones (for example, [Xamarin.iOS](#)) through the Xamarin product. .NET Core doesn't support these.
- **APIs** -- Mono supports a [large subset](#) of the .NET Framework APIs, using the same assembly names and factoring.
- **Platforms** -- Mono supports many platforms and CPUs.
- **Open Source** -- Mono and .NET Core both use the MIT license and are .NET Foundation projects.
- **Focus** -- The primary focus of Mono in recent years is mobile platforms, while .NET Core is focused on cloud and desktop workloads.

Get started with .NET Core

2/28/2019 • 2 minutes to read • [Edit Online](#)

This article provides information on getting started with .NET Core. .NET Core can be installed on Windows, Linux, and macOS. You can code in your favorite text editor and produce cross-platform libraries and applications.

If you're unsure what .NET Core is, or how it relates to other .NET technologies, start with the [What is .NET](#) overview. Put simply, .NET Core is an open-source, cross-platform, implementation of .NET.

Create an application

First, download and install the [.NET Core SDK](#) on your computer.

Next, open a terminal such as **PowerShell**, **Command Prompt**, or **bash**. Type the following `dotnet` commands to create and run a C# application.

```
dotnet new console --output sample1  
dotnet run --project sample1
```

You should see the following output:

```
Hello World!
```

Congratulations! You've created a simple .NET Core application. You can also use [Visual Studio Code](#), [Visual Studio 2017](#) (Windows only), or [Visual Studio for Mac](#) (macOS only), to create a .NET Core application.

Tutorials

You can get started developing .NET Core applications by following these step-by-step tutorials.

- [Windows](#)
- [Linux](#)
- [macOS](#)
- [Build a C# "Hello World" Application with .NET Core in Visual Studio 2017.](#)
- [Build a C# class library with .NET Core in Visual Studio 2017.](#)
- [Build a Visual Basic "Hello World" application with .NET Core in Visual Studio 2017.](#)
- [Build a class library with Visual Basic and .NET Core in Visual Studio 2017.](#)
- Watch a video on [how to install and use Visual Studio Code and .NET Core](#).
- Watch a video on [how to install and use Visual Studio 2017 and .NET Core](#).
- [Getting started with .NET Core using the command-line](#).

See the [Prerequisites for Windows development](#) article for a list of the supported Windows versions.

Get started with C# and Visual Studio Code

3/12/2019 • 4 minutes to read • [Edit Online](#)

.NET Core gives you a fast and modular platform for creating applications that run on Windows, Linux, and macOS. Use Visual Studio Code with the C# extension to get a powerful editing experience with full support for C# IntelliSense (smart code completion) and debugging.

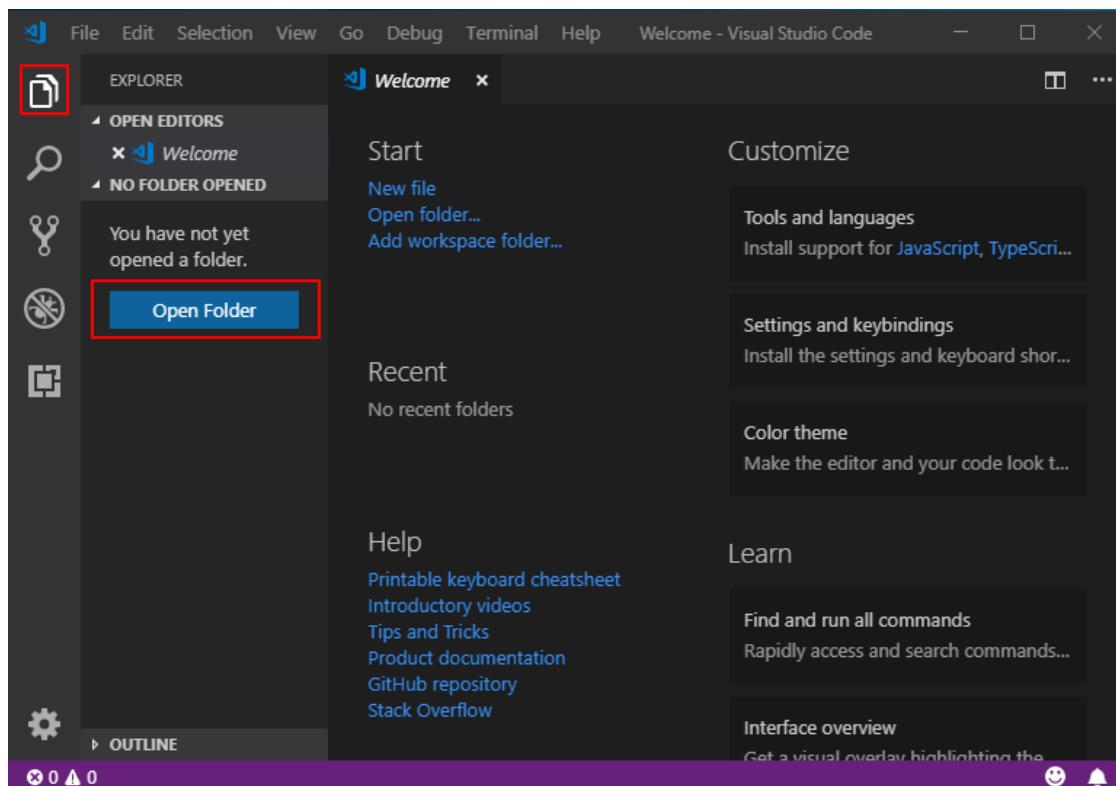

Prerequisites

1. Install [Visual Studio Code](#).
2. Install the [.NET Core SDK](#).
3. Install the [C# extension](#) for Visual Studio Code. For more information about how to install extensions on Visual Studio Code, see [VS Code Extension Marketplace](#).

Hello World

Let's get started with a simple "Hello World" program on .NET Core:

1. Open a project:
 - Open Visual Studio Code.
 - Click on the Explorer icon on the left menu and then click **Open Folder**.
 - Select **File > Open Folder** from the main menu to open the folder you want your C# project to be in and click **Select Folder**. For our example, we're creating a folder for our project named *HelloWorld*.

2. Initialize a C# project:

- Open the Integrated Terminal from Visual Studio Code by selecting **View > Integrated Terminal** from the main menu.

- In the terminal window, type `dotnet new console`.
- This command creates a `Program.cs` file in your folder with a simple "Hello World" program already written, along with a C# project file named `HelloWorld.csproj`.

The screenshot shows the Visual Studio Code interface. The Explorer sidebar on the left lists a project named 'HELLOWORLD' containing files like 'obj', 'HelloWorld.csproj', and 'Program.cs'. The Welcome panel is open in the center. A terminal window at the bottom is running a PowerShell session. The command `dotnet new console` is highlighted with a red box in the terminal output, which shows the standard .NET Core welcome message.

```
PS C:\Projects\HelloWorld> dotnet new console
Welcome to .NET Core!
-----
Learn more about .NET Core: https://aka.ms/dotnet-docs
Use 'dotnet --help' to see available commands or visit: https://aka.ms/dotnet-cli-docs
```

3. Resolve the build assets:

- For **.NET Core 1.x**, type `dotnet restore`. Running `dotnet restore` gives you access to the required .NET Core packages that are needed to build your project.

This screenshot is identical to the previous one, showing the Visual Studio Code interface with the terminal window running a PowerShell session. The command `dotnet restore` is highlighted with a red box, and the terminal output shows the restore process completed successfully.

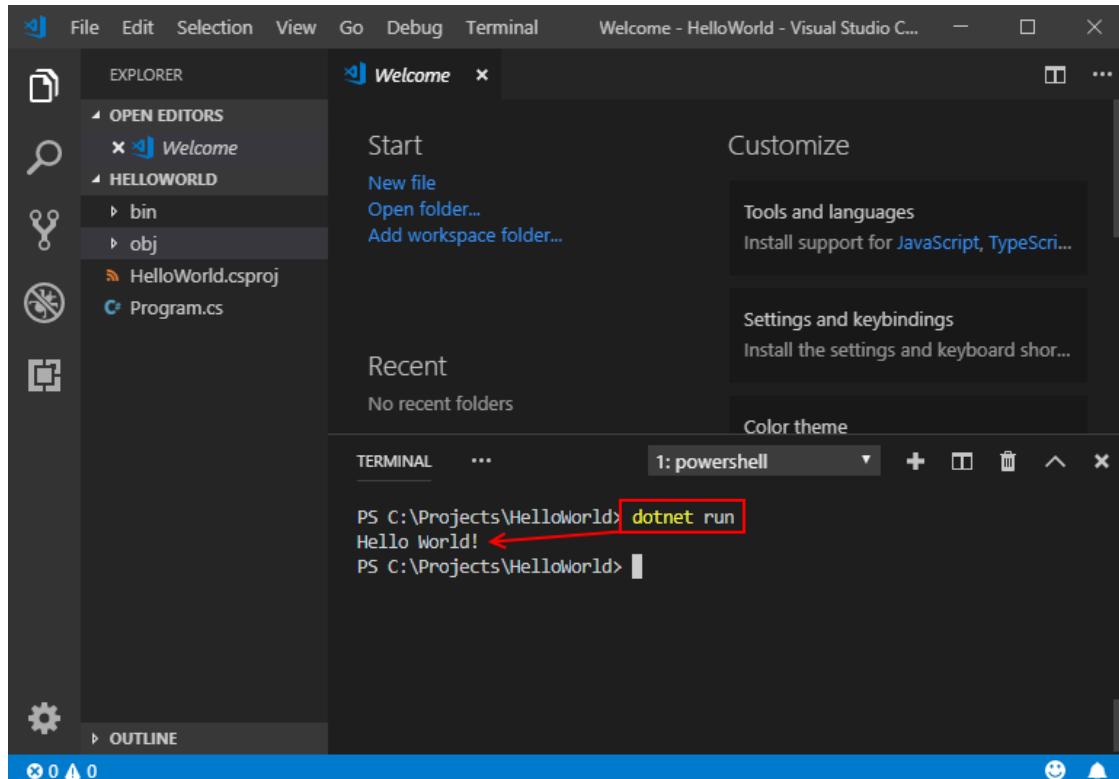

```
PS C:\Projects\HelloWorld> dotnet restore
Restore completed in 29,28 ms for C:\Projects\HelloWorld\HelloWorld.csproj.
PS C:\Projects\HelloWorld>
```

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

4. Run the "Hello World" program:

- Type `dotnet run`.

You can also watch a short video tutorial for further setup help on [Windows](#), [macOS](#), or [Linux](#).

Debug

- Open *Program.cs* by clicking on it. The first time you open a C# file in Visual Studio Code, [OmniSharp](#) loads in the editor.

File Edit Selection View Go Debug Terminal Program.cs - HelloWorld - Visual Studio C... — □ ×

EXPLORER OPEN EDITORS Program.cs HELLOWORLD .vscode bin obj HelloWorld.csproj Program.cs

Program.cs x

```
1 using System;

```

Ln 1, Col 1 Spaces: 4 UTF-8 with BOM CRLF C# ⚙️ 📡

- Visual Studio Code should prompt you to add the missing assets to build and debug your app. Select **Yes**.

- To open the Debug view, click on the Debugging icon on the left side menu.

File Edit Selection View Go Debug Terminal Program.cs - HelloWorld - Visual Studio C... — □ ×

DEBUG ▶ 🔍 ⚙️ ⏹

EXPLORER VARIABLES WATCH CALL STACK BREAKPOINTS

Program.cs x

```
1 using System;
2
3 namespace HelloWorld
4 {
5     0 references
6     class Program
7     {
8         0 references
9         static void Main(string[] args)
10        {
11            Console.WriteLine("Hello World!");
12        }
13    }
}
```

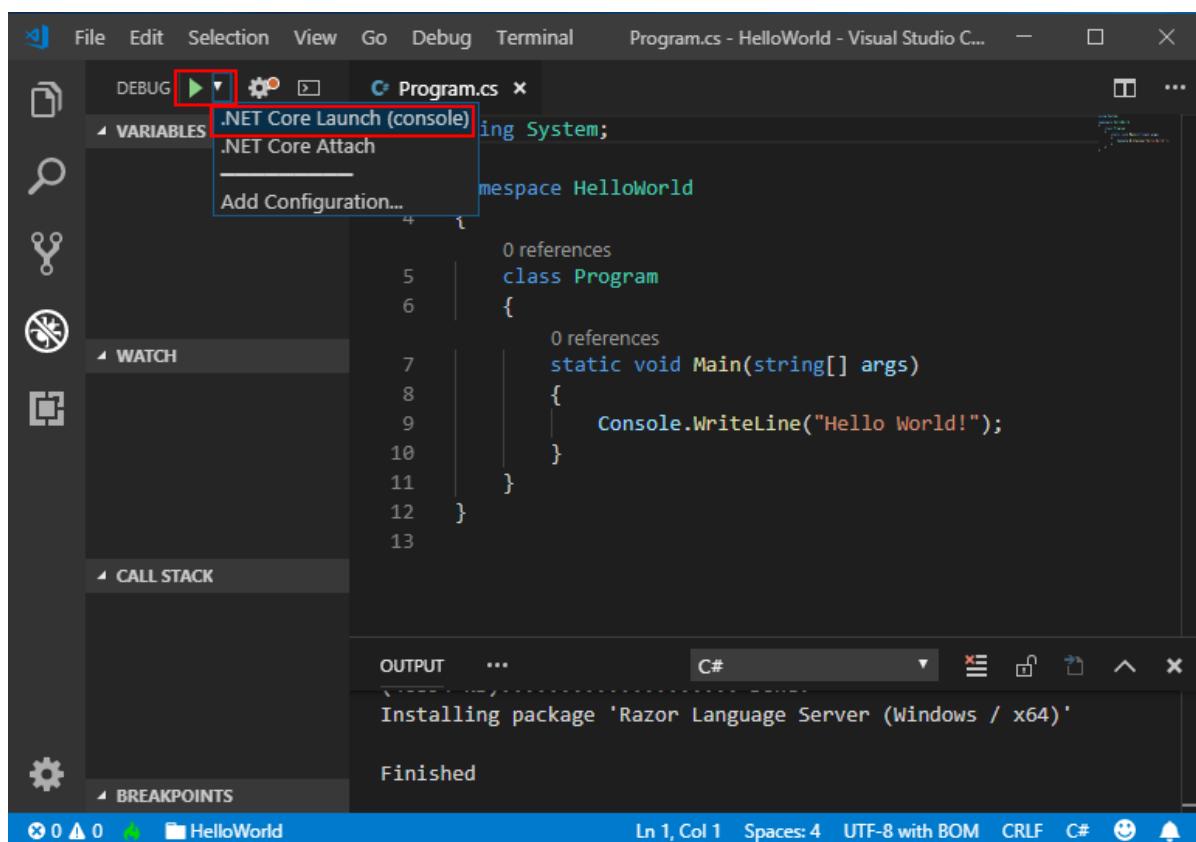

OUTPUT ... C# Installing package 'Razor Language Server (Windows / x64)'

```
Installing package 'Razor Language Server (Windows / x64)'

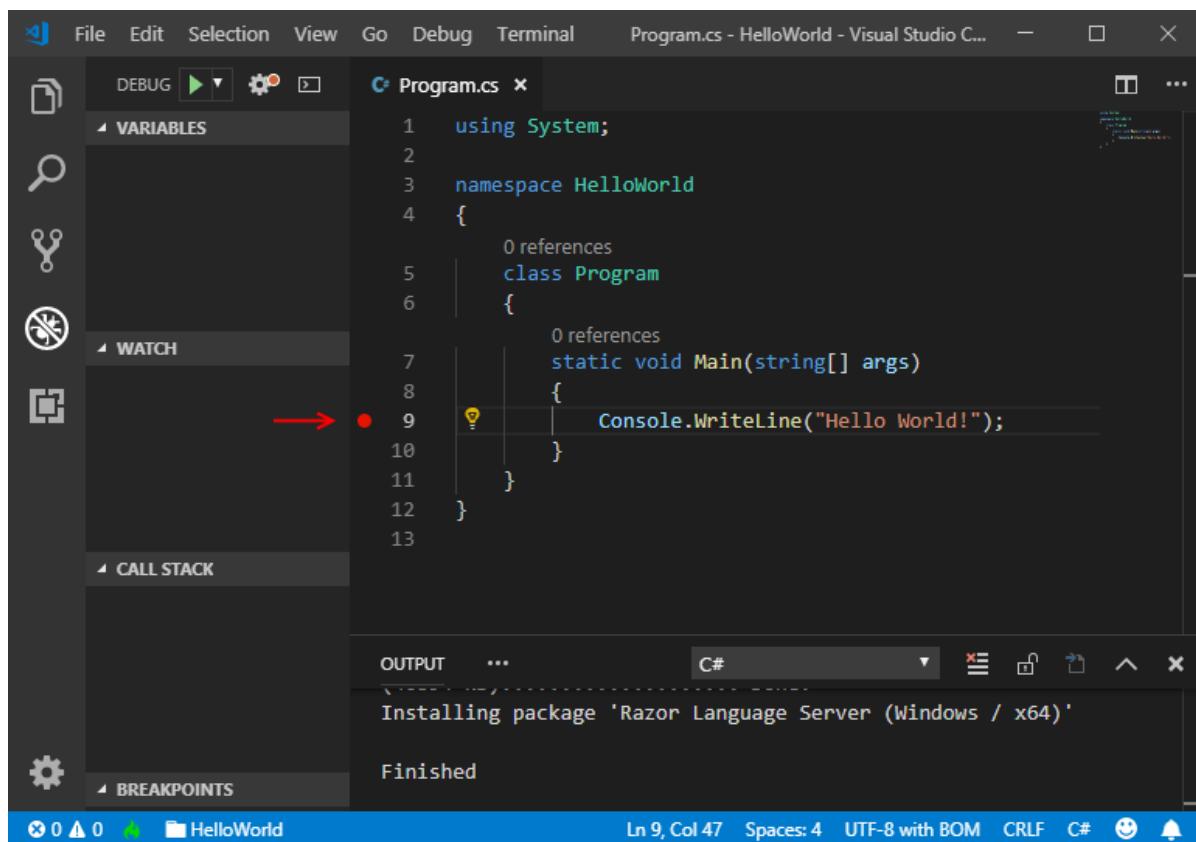

Finished
```

Ln 1, Col 1 Spaces: 4 UTF-8 with BOM CRLF C# ⚙️ 📡

4. Locate the green arrow at the top of the pane. Make sure the drop-down next to it has **.NET Core Launch (console)** selected.

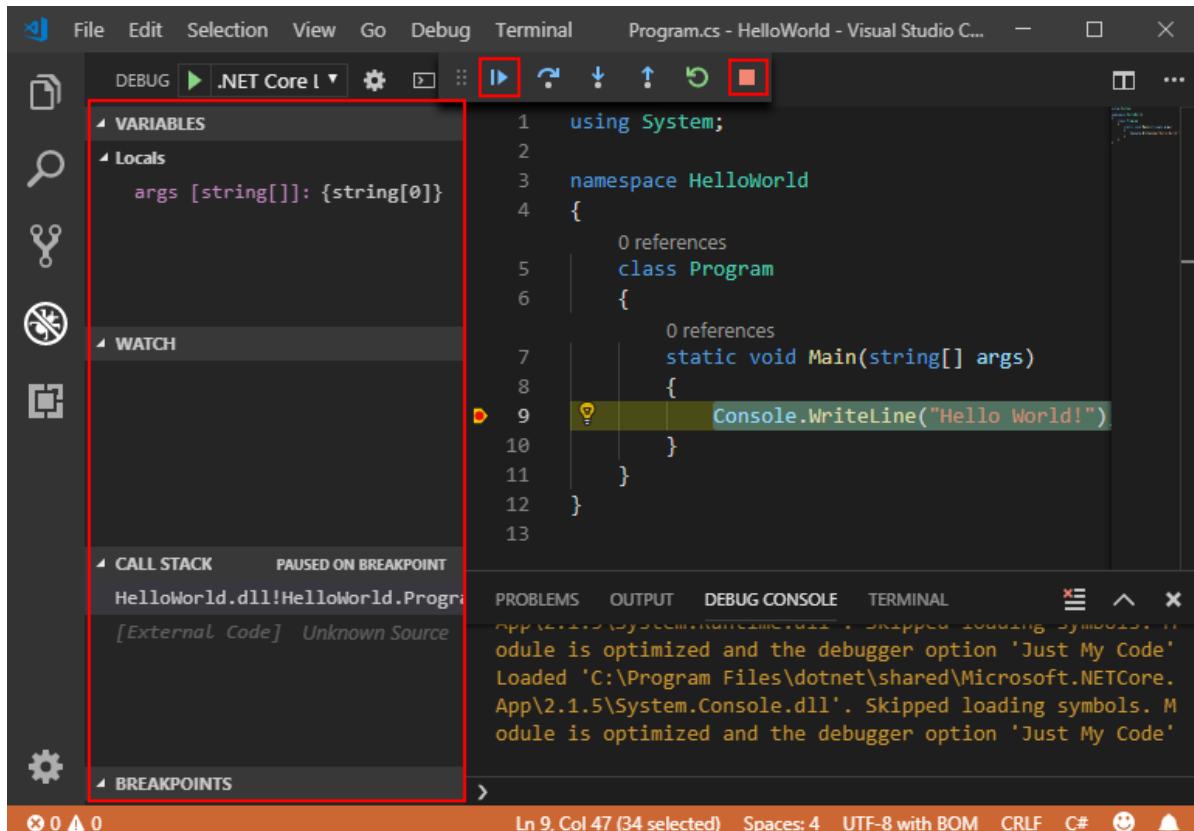

5. Add a breakpoint to your project by clicking on the **editor margin**, which is the space on the left of the line numbers in the editor, next to line 9, or move the text cursor onto line 9 in the editor and press F9.

6. To start debugging, select F5 or the green arrow. The debugger stops execution of your program when it reaches the breakpoint you set in the previous step.
- While debugging, you can view your local variables in the top left pane or use the debug console.

7. Select the blue arrow at the top to continue debugging, or select the red square at the top to stop.

TIP

For more information and troubleshooting tips on .NET Core debugging with OmniSharp in Visual Studio Code, see [Instructions for setting up the .NET Core debugger](#).

Add a class

1. To add a new class right-click in the VSCode Explorer and select **New File**. This adds a new file to the folder you have open in VSCode.
2. Name your file `Class1.cs`. You must save it with a `.cs` extension at the end for it to be recognized as a csharp file.
3. Add the code below to create your first class. Make sure to include the correct namespace so you can reference it from your `Program.cs` file.

```
using System;

namespace HelloWorld
{
    public class Class1
    {
        public string ReturnMessage()
        {
            return "Happy coding!";
        }
    }
}
```

4. Call your new class from your main method in `Program.cs` by adding the code below.

```
using System;

namespace HelloWorld
{
    class Program
    {
        static void Main(string[] args)
        {
            Class1 c1 = new Class1();
            Console.WriteLine($"Hello World! {c1.ReturnMessage()}");
        }
    }
}
```

5. Save your changes and run your program again. The new message should appear with the appended string.

```
> dotnet run
Hello World! Happy coding!
```

FAQ

I'm missing required assets to build and debug C# in Visual Studio Code. My debugger says "No Configuration."

The Visual Studio Code C# extension can generate assets to build and debug for you. Visual Studio Code prompts you to generate these assets when you first open a C# project. If you didn't generate assets then, you can still run this command by opening the Command Palette (**View > Command Palette**) and typing ">.NET: Generate Assets for Build and Debug". Selecting this generates the .vscode, launch.json, and tasks.json configuration files that you need.

Build a C# Hello World application with the .NET Core SDK in Visual Studio 2017

1/17/2019 • 3 minutes to read • [Edit Online](#)

This topic provides a step-by-step introduction to building, debugging, and publishing a simple .NET Core console application using C# in Visual Studio 2017. Visual Studio 2017 provides a full-featured development environment for building .NET Core applications. As long as the application doesn't have platform-specific dependencies, the application can run on any platform that .NET Core targets and on any system that has .NET Core installed.

Prerequisites

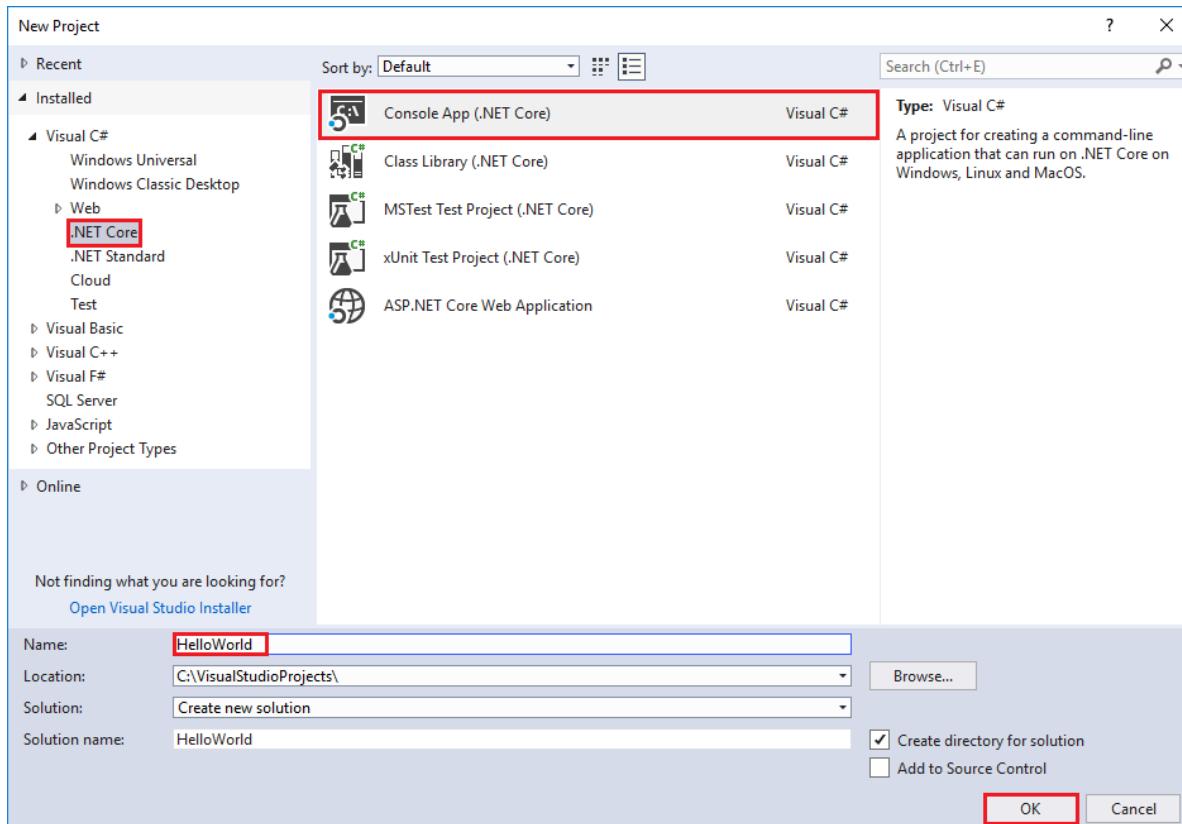

Visual Studio 2017 with the ".NET Core cross-platform development" workload installed. You can develop your app with either .NET Core 1.1 or .NET Core 2.0.

For more information, see the [Prerequisites for .NET Core on Windows](#) topic.

A simple Hello World application

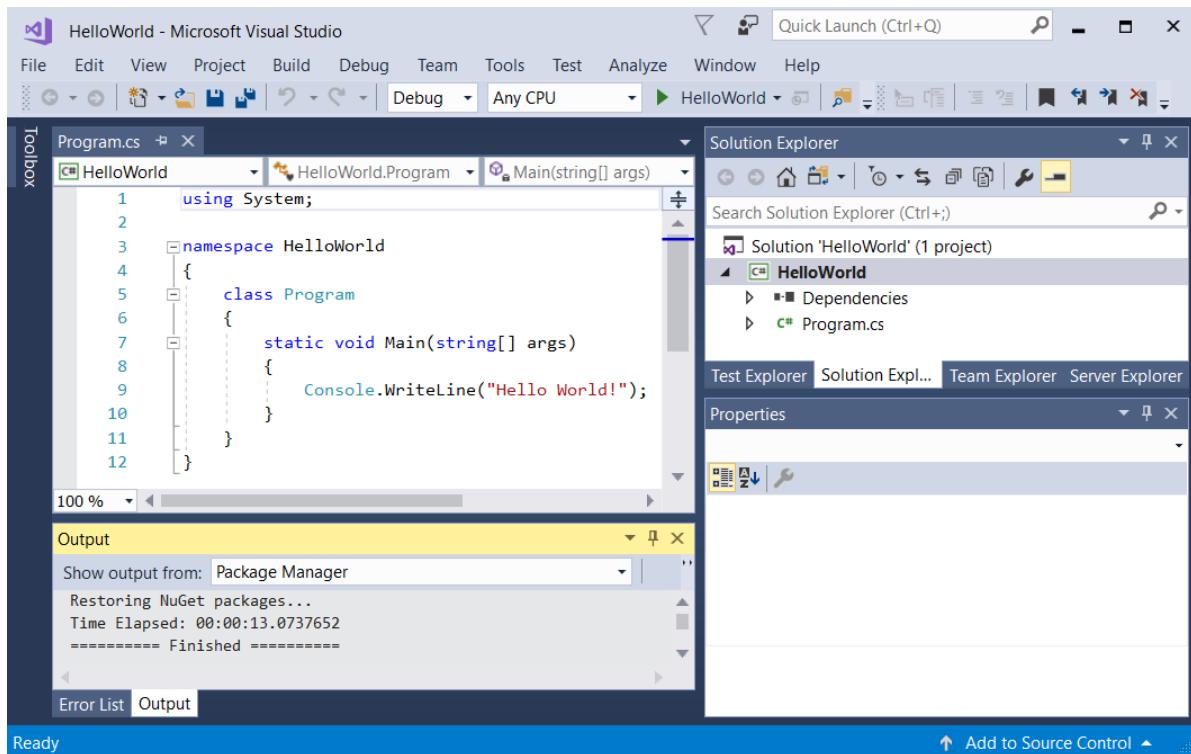

Begin by creating a simple "Hello World" console application. Follow these steps:

1. Launch Visual Studio 2017. Select **File > New > Project** from the menu bar. In the *New Project** dialog, select the **Visual C#** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "HelloWorld". Select the **OK** button.

2. Visual Studio uses the template to create your project. The C# Console Application template for .NET Core automatically defines a class, `Program`, with a single method, `Main`, that takes a `String` array as an argument. `Main` is the application entry point, the method that's called automatically by the runtime when it launches the application. Any command-line arguments supplied when the application is launched are

available in the `args` array.

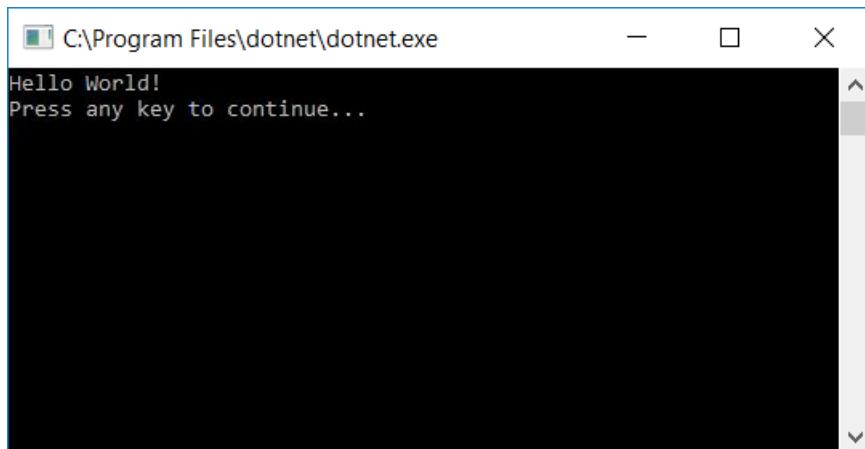

The template creates a simple "Hello World" application. It calls the `Console.WriteLine(String)` method to display the literal string "Hello World!" in the console window. By selecting the **HelloWorld** button with the green arrow on the toolbar, you can run the program in Debug mode. If you do, the console window is visible for only a brief time interval before it closes. This occurs because the `Main` method terminates and the application ends as soon as the single statement in the `Main` method executes.

3. To cause the application to pause before it closes the console window, add the following code immediately after the call to the `Console.WriteLine(String)` method:

```
Console.Write("Press any key to continue...");
Console.ReadKey(true);
```

This code prompts the user to press any key and then pauses the program until a key is pressed.

4. On the menu bar, select **Build > Build Solution**. This compiles your program into an intermediate language (IL) that's converted into binary code by a just-in-time (JIT) compiler.
5. Run the program by selecting the **HelloWorld** button with the green arrow on the toolbar.

6. Press any key to close the console window.

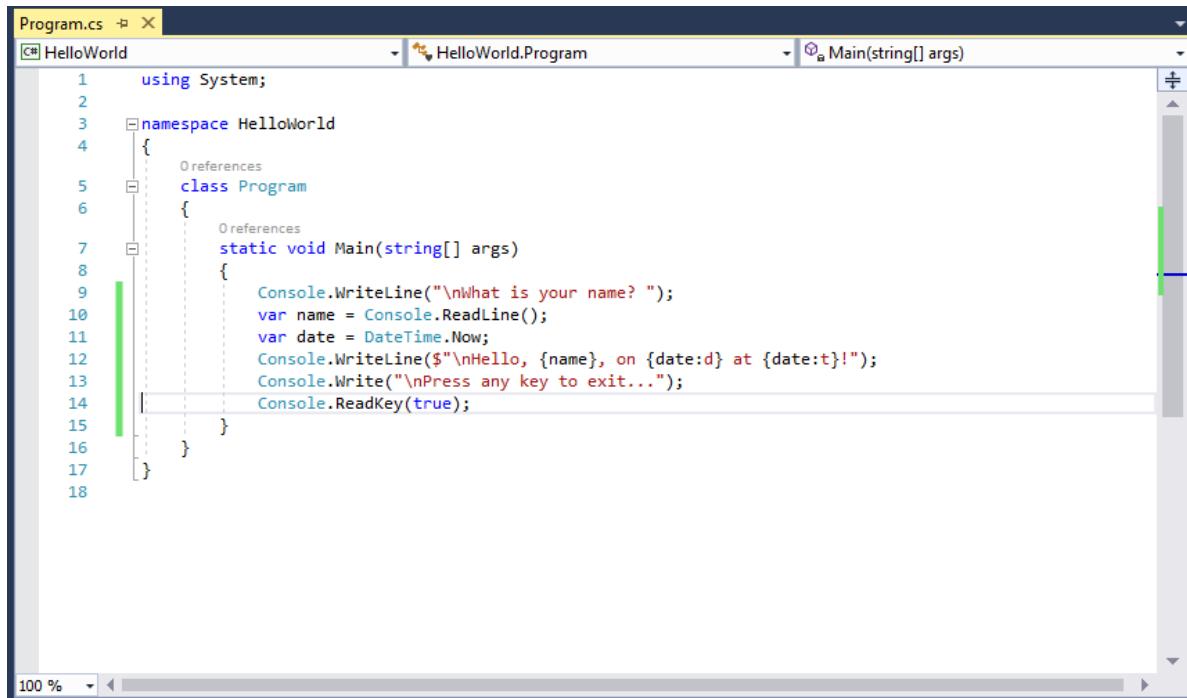

Enhancing the Hello World application

Enhance your application to prompt the user for their name and display it along with the date and time. To modify and test the program, do the following:

1. Enter the following C# code in the code window immediately after the opening bracket that follows the `static void Main(string[] args)` line and before the first closing bracket:

```
Console.WriteLine("\nWhat is your name? ");
var name = Console.ReadLine();
var date = DateTime.Now;
Console.WriteLine($"\\nHello, {name}, on {date:d} at {date:t}!");
Console.Write("\nPress any key to exit...");
Console.ReadKey(true);
```

This code replaces the existing `Console.WriteLine`, `Console.Write`, and `Console.ReadKey` statements.

```
Program.cs  X
HelloWorld  HelloWorld.Program  Main(string[] args)
1  using System;
2
3  namespace HelloWorld
4  {
5      class Program
6      {
7          static void Main(string[] args)
8          {
9              Console.WriteLine("\nWhat is your name? ");
10             var name = Console.ReadLine();
11             var date = DateTime.Now;
12             Console.WriteLine($"\\nHello, {name}, on {date:d} at {date:t}!");
13             Console.Write("\nPress any key to exit...");
14             Console.ReadKey(true);
15         }
16     }
17 }
18
```

This code displays "What is your name?" in the console window and waits until the user enters a string followed by the Enter key. It stores this string into a variable named `name`. It also retrieves the value of the `DateTime.Now` property, which contains the current local time, and assigns it to a variable named `date`. Finally, it uses an [interpolated string](#) to display these values in the console window.

2. Compile the program by choosing **Build > Build Solution**.
3. Run the program in Debug mode in Visual Studio by selecting the green arrow on the toolbar, pressing F5, or choosing the **Debug > Start Debugging** menu item. Respond to the prompt by entering a name and pressing the Enter key.

```
C:\Program Files\dotnet\dotnet.exe

What is your name?
Jack

Hello, Jack, on 8/1/2017 at 12:35 PM!

Press any key to exit...
```

4. Press any key to close the console window.

You've created and run your application. To develop a professional application, take some additional steps to make your application ready for release:

- For information on debugging your application, see [Debug your .NET Core Hello World application using Visual Studio 2017](#).
- For information on developing and publishing a distributable version of your application, see [Publish your .NET Core Hello World application with Visual Studio 2017](#).

Related topics

Instead of a console application, you can also build a class library with .NET Core and Visual Studio 2017. For a step-by-step introduction, see [Building a class library with C# and .NET Core in Visual Studio 2017](#).

You can also develop a .NET Core console app on Mac, Linux, and Windows by using [Visual Studio Code](#), a downloadable code editor. For a step-by-step tutorial, see [Getting Started with Visual Studio Code](#).

Build a Visual Basic Hello World application with the .NET Core SDK in Visual Studio 2017

3/14/2019 • 3 minutes to read • [Edit Online](#)

This topic provides a step-by-step introduction to building, debugging, and publishing a simple .NET Core console application using Visual Basic in Visual Studio 2017. Visual Studio 2017 provides a full-featured development environment for building .NET Core applications. As long as the application doesn't have platform-specific dependencies, the application can run on any platform that .NET Core targets and on any system that has .NET Core installed.

Prerequisites

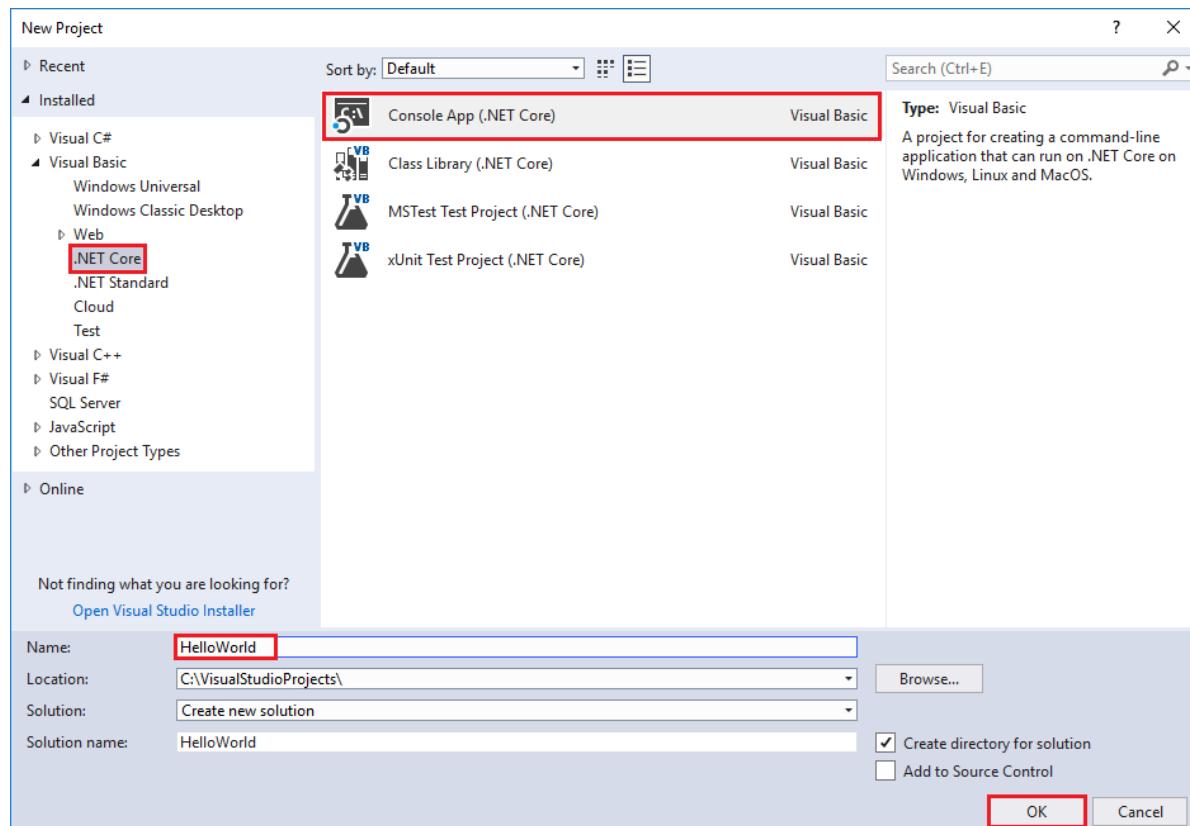

Visual Studio 2017 with the ".NET Core cross-platform development" workload installed. You can develop your app with .NET Core 2.0.

A simple Hello World application

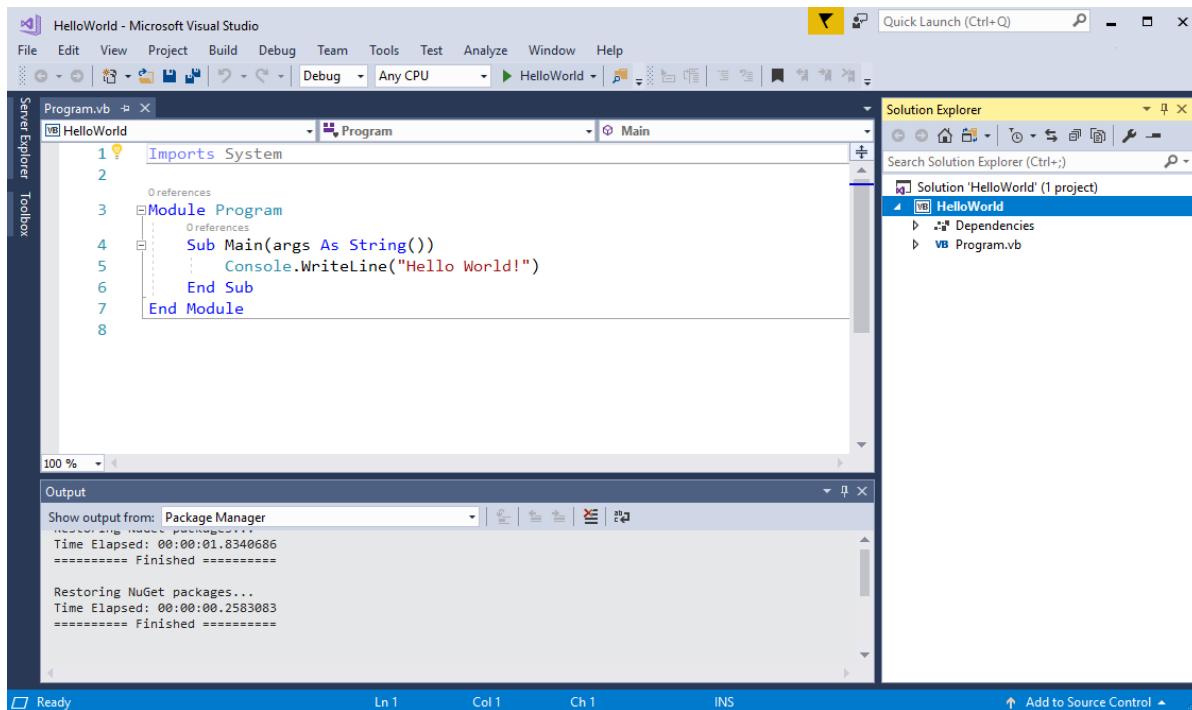

Begin by creating a simple "Hello World" console application. Follow these steps:

1. Launch Visual Studio 2017. Select **File > New > Project** from the menu bar. In the *New Project** dialog, select the **Visual Basic** node followed by the **.NET Core** node. Then select the **Console App (.NET Core)** project template. In the **Name** text box, type "HelloWorld". Select the **OK** button.

2. Visual Studio uses the template to create your project. The Visual Basic Console Application template for .NET Core automatically defines a class, `Program`, with a single method, `Main`, that takes a `String` array as an argument. `Main` is the application entry point, the method that's called automatically by the runtime

when it launches the application. Any command-line arguments supplied when the application is launched are available in the `args` array.

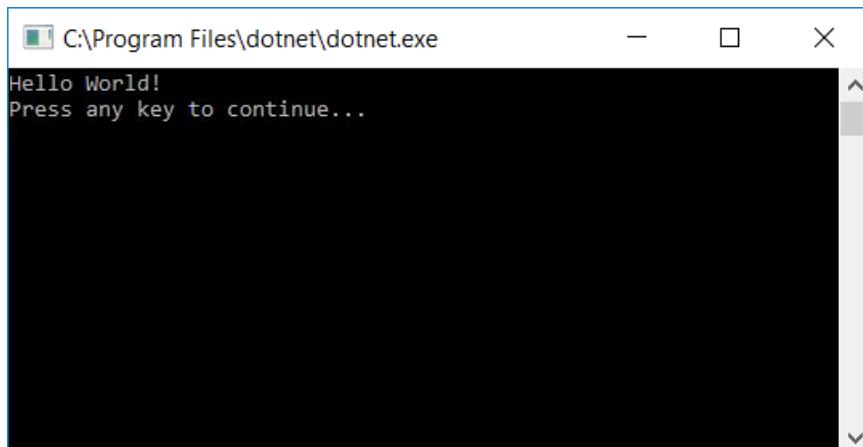

The template creates a simple "Hello World" application. It calls the `Console.WriteLine(String)` method to display the literal string "Hello World!" in the console window. By selecting the **HelloWorld** button with the green arrow on the toolbar, you can run the program in Debug mode. If you do, the console window is visible for only a brief time interval before it closes. This occurs because the `Main` method terminates and the application ends as soon as the single statement in the `Main` method executes.

3. To cause the application to pause before it closes the console window, add the following code immediately after the call to the `Console.WriteLine(String)` method:

```
Console.Write("Press any key to continue...")
Console.ReadKey(true)
```

This code prompts the user to press any key and then pauses the program until a key is pressed.

4. On the menu bar, select **Build > Build Solution**. This compiles your program into an intermediate language (IL) that's converted into binary code by a just-in-time (JIT) compiler.
5. Run the program by selecting the **HelloWorld** button with the green arrow on the toolbar.

6. Press any key to close the console window.

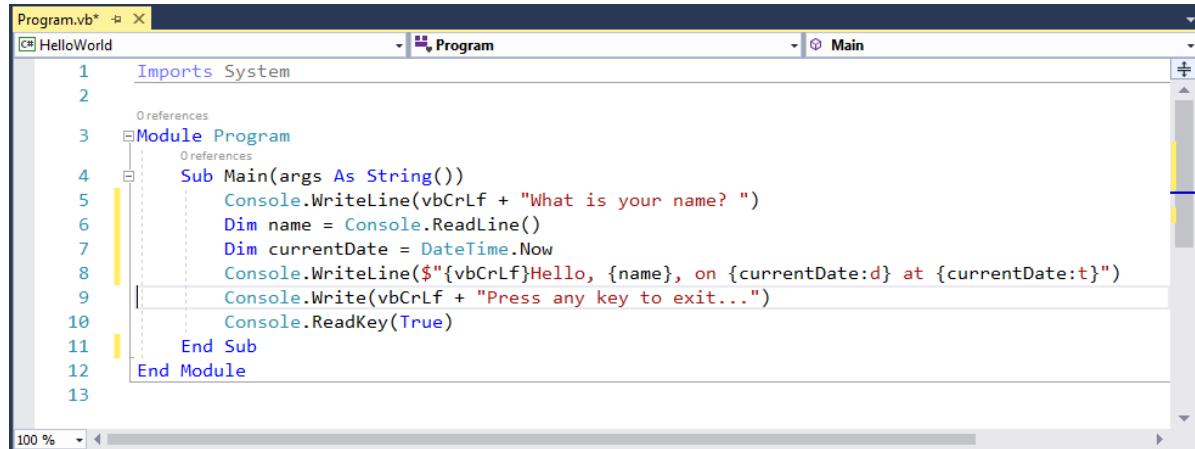

Enhancing the Hello World application

Enhance your application to prompt the user for his or her name and to display it along with the date and time. To modify and test the program, do the following:

1. Enter the following Visual Basic code in the code window immediately after the opening bracket that follows the `Sub Main(args As String())` line and before the first closing bracket:

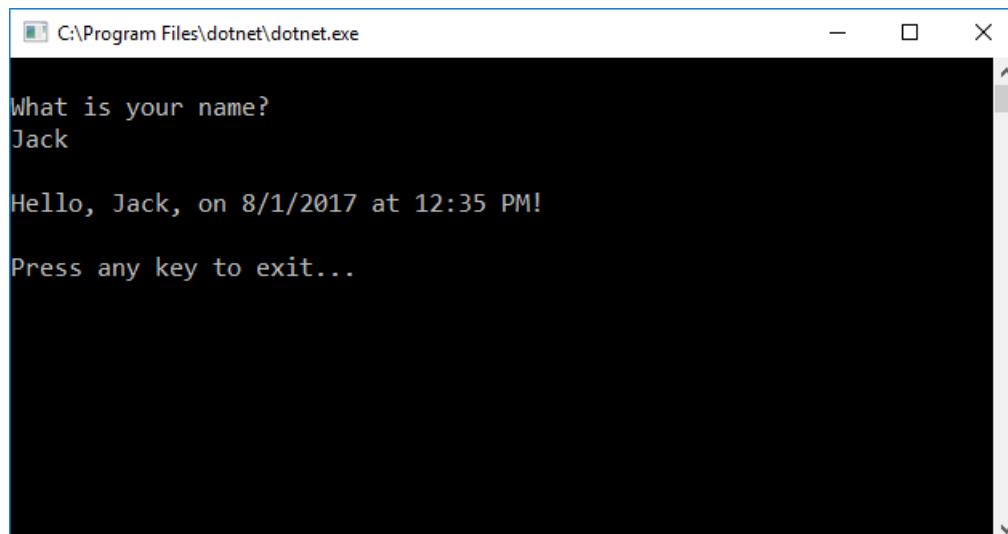

```
Console.WriteLine(vbCrLf + "What is your name? ")
Dim name = Console.ReadLine()
Dim currentDate = DateTime.Now
Console.WriteLine($"{vbCrLf}Hello, {name}, on {currentDate:d} at {currentDate:t}")
Console.Write(vbCrLf + "Press any key to exit... ")
Console.ReadKey(True)
```

This code replaces the existing `Console.WriteLine`, `Console.Write`, and `Console.ReadKey` statements.

This code displays "What is your name?" in the console window and waits until the user enters a string followed by the Enter key. It stores this string into a variable named `name`. It also retrieves the value of the `DateTime.Now` property, which contains the current local time, and assigns it to a variable named `currentDate`. Finally, it uses an [interpolated string](#) to display these values in the console window.

2. Compile the program by choosing **Build > Build Solution**.
3. Run the program in Debug mode in Visual Studio by selecting the green arrow on the toolbar, pressing F5, or choosing the **Debug > Start Debugging** menu item. Respond to the prompt by entering a name and pressing the Enter key.

4. Press any key to close the console window.

You've created and run your application. To develop a professional application, take some additional steps to make your application ready for release:

- To debug your application, see [Debug your .NET Core Hello World application using Visual Studio 2017](#).
- To publish a distributable version of your application, see [Publish your .NET Core Hello World application with Visual Studio 2017](#).

Related topics

Instead of a console application, you can also build a .NET Standard class library with Visual Basic, .NET Core, and Visual Studio 2017. For a step-by-step introduction, see [Build a .NET Standard library with Visual Basic and .NET Core SDK in Visual Studio 2017](#).

Debug your C# or Visual Basic .NET Core Hello World application using Visual Studio 2017

3/26/2019 • 11 minutes to read • [Edit Online](#)

So far, you've followed the steps in [Build a C# Hello World Application with .NET Core in Visual Studio 2017](#) or [Build a Visual Basic Hello World Application with .NET Core in Visual Studio 2017](#) to create and run a simple console application. Once you've written and compiled your application, you can begin testing it. Visual Studio includes a comprehensive set of debugging tools that you can use when testing and troubleshooting your application.

Debugging in Debug mode

Debug and *Release* are two of Visual Studio's default build configurations. The current build configuration is shown on the toolbar. The following toolbar image shows that Visual Studio is configured to compile your application in **Debug** mode.

You should always begin by testing your program in Debug mode. Debug mode turns off most compiler optimizations and provides richer information during the build process.

Setting a breakpoint

Run your program in Debug mode and try a few debugging features:

- C#
 - Visual Basic

1. A *breakpoint* temporarily interrupts the execution of the application *before* the line with the breakpoint is executed.

Set a breakpoint on the line that reads `Console.WriteLine($"\\nHello, {name}, on {date:d} at {date:t}!");` by clicking in the left margin of the code window on that line or by choosing the **Debug > Toggle Breakpoint** menu item with the line selected. As the following figure shows, Visual Studio indicates the line on which the breakpoint is set by highlighting it and displaying a red circle in its left margin.

A screenshot of the Visual Studio IDE showing the code editor for Program.cs. The code is a simple C# program that prompts the user for their name and prints a greeting. A red box highlights the line of code where the breakpoint is set:

```
1  using System;
2
3  namespace HelloWorld
4  {
5      class Program
6      {
7          static void Main(string[] args)
8          {
9              Console.WriteLine("\nWhat is your name? ");
10             var name = Console.ReadLine();
11             var date = DateTime.Now;
12             Console.WriteLine($"\\nHello, {name}, on {date:d} at {date:t}!");
13             Console.WriteLine("Press any key to exit... ");
14             Console.ReadKey(true);
15         }
16     }
17 }
18
```

2. Run the program in Debug mode by selecting the **HelloWorld** button with the green arrow on the toolbar, pressing F5, or choosing **Debug > Start Debugging**.
3. Enter a string in the console window when the program prompts for a name and press Enter.
4. Program execution stops when it reaches the breakpoint and before the `Console.WriteLine` method executes. The **Autos** window displays the values of variables that are used around the current line. The **Locals** window (which you can view by clicking the **Locals** tab) displays the values of variables that are defined in the currently executing method.

A screenshot of the Visual Studio IDE during debug mode. The code editor shows the same program as before, but the line 12 is now highlighted with a yellow background, indicating it is the current instruction. The **Autos** and **Call Stack** windows are open at the bottom of the screen.

Autos Window:

Name	Value	Type
DateTime.Now	{8/1/2017 12:50:03 PM}	System.DateTime
date	{8/1/2017 12:50:01 PM}	System.DateTime

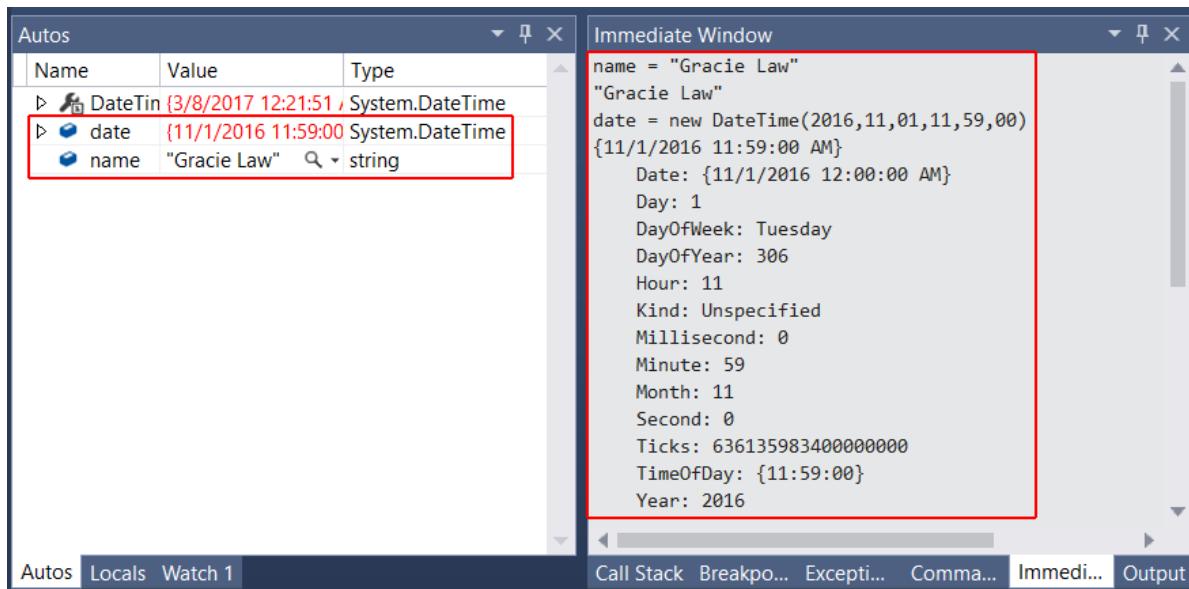

Call Stack Window:

Name
HelloWorld.dll!HelloWorld.Program.Main(string[] args) Line 12

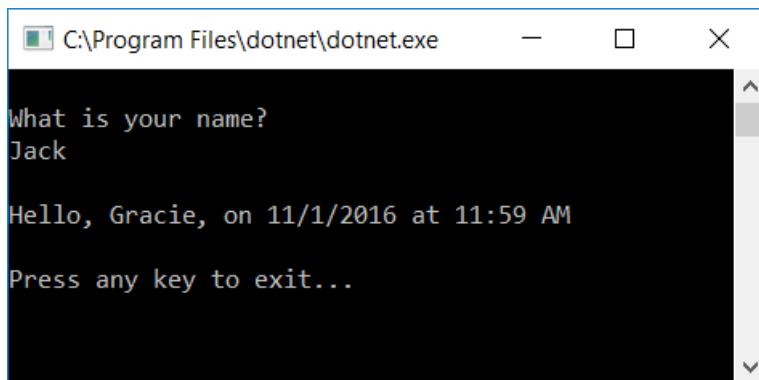

5. You can change the value of the variables to see how it affects your program. If the **Immediate Window** is not visible, display it by choosing the **Debug > Windows > Immediate** menu item. The **Immediate Window** lets you interact with the application you're debugging.
6. You can interactively change the values of variables. Enter `name = "Gracie"` in the **Immediate Window** and press the Enter key.

7. Enter `date = new DateTime(2016,11,01,11,59,00)` in the **Immediate Window** and press the Enter key.

The **Immediate Window** displays the value of the string variable and the properties of the `DateTime` value. In addition, the value of the variables is updated in the **Autos** and **Locals** windows.

8. Continue program execution by selecting the **Continue** button in the toolbar or by selecting the **Debug > Continue** menu item. The values displayed in the console window correspond to the changes you made in the **Immediate Window**.

9. Press any key to exit the application and end Debug mode.

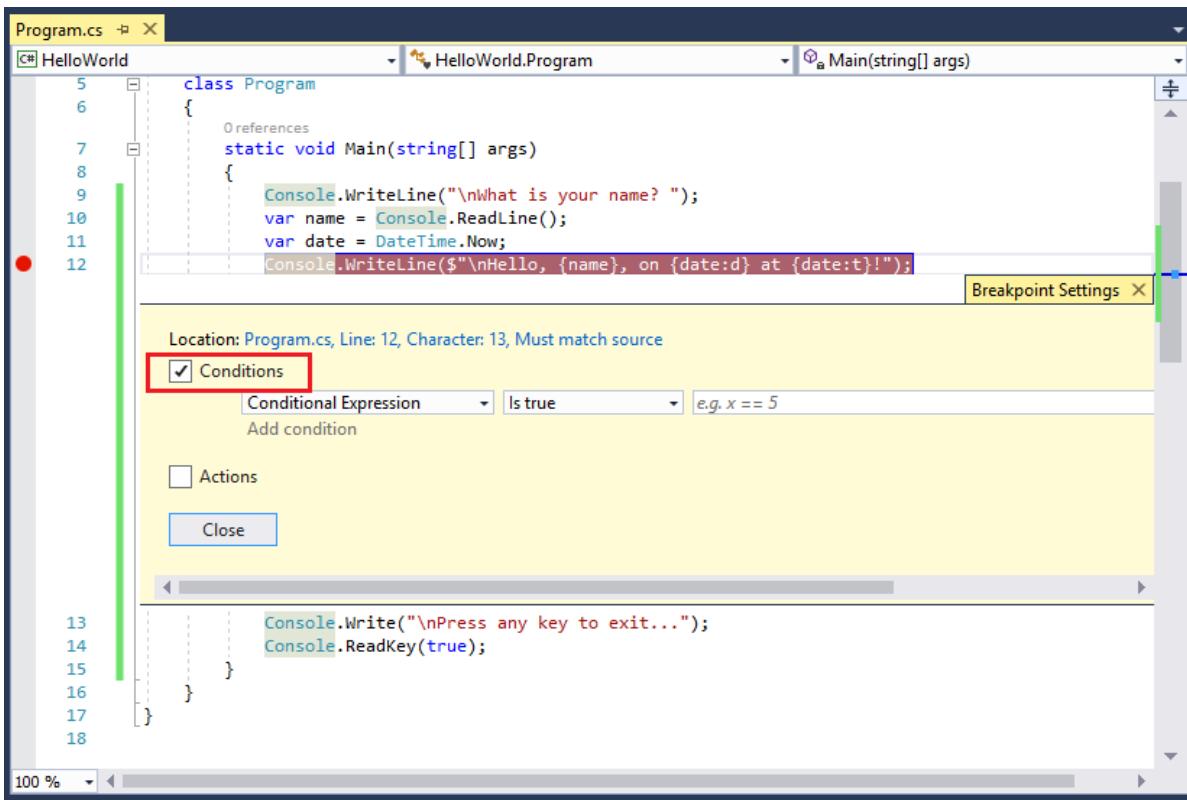

Setting a conditional breakpoint

Your program displays the string that the user enters. What happens if the user doesn't enter anything? You can test this with a useful debugging feature, the *conditional breakpoint*, which breaks program execution when one or more conditions are met.

To set a conditional breakpoint and test what happens when the user fails to enter a string, do the following:

- [C#](#)
- [Visual Basic](#)

1. Right-click on the red dot that represents the breakpoint. On the context menu, select **Conditions** to open the **Breakpoint Settings** dialog. Check the box for **Conditions**.

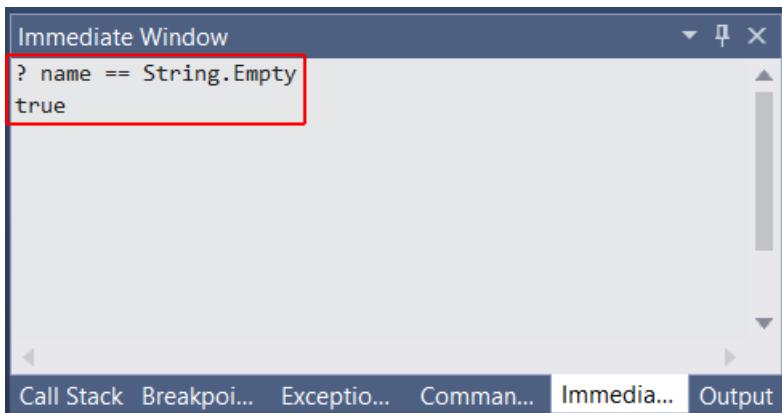

2. For the **Conditional Expression** replace "e.g. `x == 5`" with the following:

```
String.IsNullOrEmpty(name)
```

You're testing for a code condition, that the `String.IsNullOrEmpty(name)` method call is `true` either because `name` has not been assigned a value or because its value is an empty string (""). You can also specify a *hit count*, which interrupts program execution before a statement is executed a specified number of times, or a *filter condition*, which interrupts program execution based on such attributes as a thread identifier, process name, or thread name.

3. Select the **Close** button to close the dialog.
4. Run the program in Debug mode.
5. In the console window, press the Enter key when prompted to enter your name.
6. Because the condition we specified, `name` is either `null` or `String.Empty`, has been satisfied, program execution stops when it reaches the breakpoint and before the `Console.WriteLine` method executes.
7. Select the **Locals** window, which shows the values of variables that are local to the currently executing method, which is the `Main` method in your program. Observe that the value of the `name` variable is `""`, or `String.Empty`.
8. Confirm the value is an empty string by entering the following statement in the **Immediate Window**. The result is `true`.

```
? name == String.Empty
```

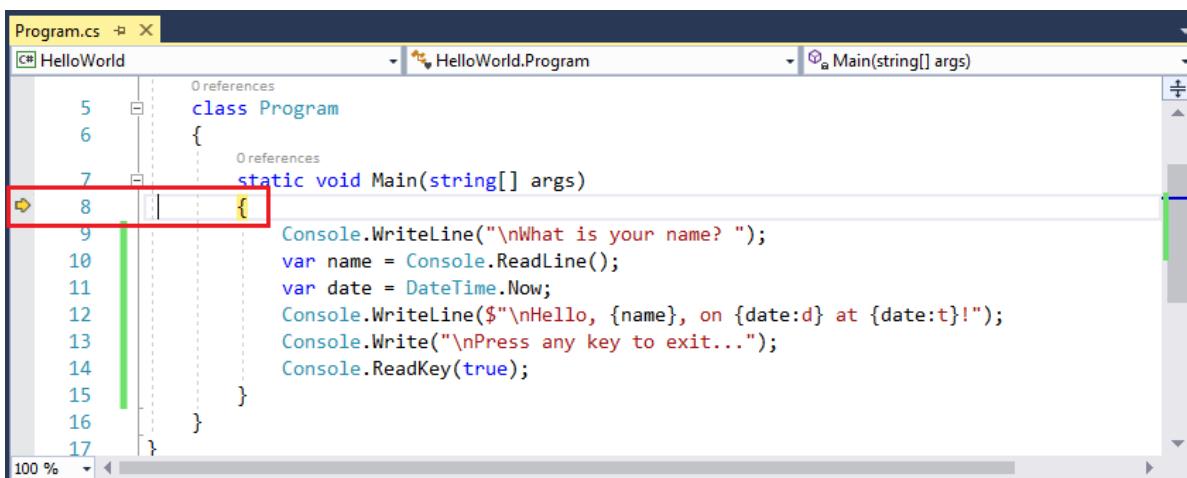

9. Select the **Continue** button on the toolbar to continue program execution.
10. Press any key to close the console window and exit Debug mode.
11. Clear the breakpoint by clicking on the dot in the left margin of the code window or by choosing the **Debug > Toggle Breakpoint** menu item with the row selected.

Stepping through a program

Visual Studio also allows you to step line by line through a program and monitor its execution. Ordinarily, you'd set a breakpoint and use this feature to follow program flow through a small part of your program code. Since your program is small, you can step through the entire program by doing the following:

- [C#](#)
- [Visual Basic](#)

1. On the menu bar, choose **Debug > Step Into** or press the F11 key. Visual Studio highlights and displays an arrow beside the next line of execution.

At this point, the **Autos** window shows that your program has defined only one variable, `args`. Because you haven't passed any command-line arguments to the program, its value is an empty string array. In addition, Visual Studio has opened a blank console window.

2. Select **Debug > Step Into** or press the F11 key. Visual Studio now highlights the next line of execution. As the figure shows, it has taken less than one millisecond to execute the code between the last statement and this one. `args` remains the only declared variable, and the console window remains blank.

```
Program.cs
C# HelloWorld
HelloWorld.Program
Main(string[] args)

5 class Program
6 {
7     static void Main(string[] args)
8     {
9         Console.WriteLine("\nWhat is your name? ");
10        var name = Console.ReadLine();
11        var date = DateTime.Now;
12        Console.WriteLine($"\\nHello, {name}, on {date:d} at {date:t}!");
13        Console.Write("\\nPress any key to exit...");
14        Console.ReadKey(true);
15    }
16 }
17 }
```

3. Select **Debug > Step Into** or press the F11 key. Visual Studio highlights the statement that includes the `name` variable assignment. The **Autos** window shows that `name` is `null`, and the console window displays the string "What is your name?".
4. Respond to the prompt by entering a string in the console window and pressing Enter. The console is unresponsive, and the string you enter isn't displayed in the console window, but the `Console.ReadLine` method will nevertheless capture your input.
5. Select **Debug > Step Into** or press the F11 key. Visual Studio highlights the statement that includes the `date` (in C#) or `currentDate` (in Visual Basic) variable assignment. The **Autos** window shows the `DateTime.Now` property value and the value returned by the call to the `Console.ReadLine` method. The console window also displays the string entered when the console prompted for input.
6. Select **Debug > Step Into** or press the F11 key. The **Autos** window shows the value of the `date` variable after the assignment from the `DateTime.Now` property. The console window is unchanged.
7. Select **Debug > Step Into** or press the F11 key. Visual Studio calls the `Console.WriteLine(String, Object, Object)` method. The values of the `date` (or `currentDate`) and `name` variables appear in the **Autos** window, and the console window displays the formatted string.
8. Select **Debug > Step Out** or press Shift and the F11 key. This stops step-by-step execution. The console window displays a message and waits for you to press a key.
9. Press any key to close the console window and exit Debug mode.

Building a Release version

Once you've tested the Debug build of your application, you should also compile and test the Release version. The Release version incorporates compiler optimizations that can sometimes negatively affect the behavior of an application. For example, compiler optimizations that are designed to improve performance can create race conditions in asynchronous or multithreaded applications.

To build and test the Release version of your console application, change the build configuration on the toolbar from **Debug** to **Release**.

When you press F5 or choose **Build Solution** from the **Build** menu, Visual Studio compiles the Release version of your console application. You can test it as you did the Debug version of the application.

Once you've finished debugging your application, the next step is to publish a deployable version of your application. For information on how to do this, see [Publish the Hello World application with Visual Studio 2017](#).

Publish your .NET Core Hello World application with Visual Studio 2017

1/17/2019 • 2 minutes to read • [Edit Online](#)

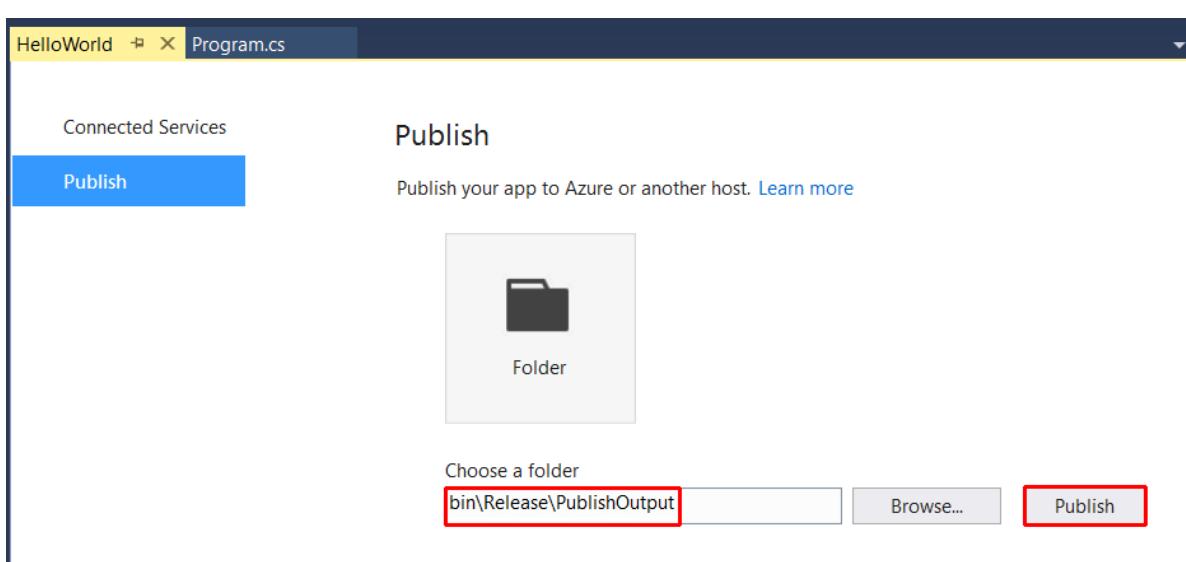

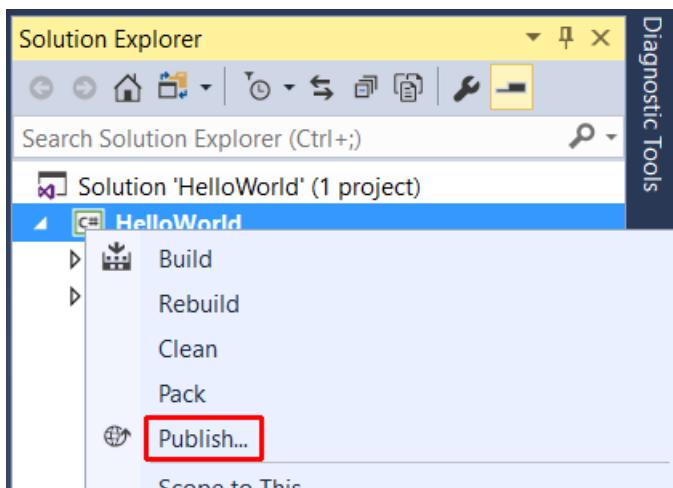

In [Build a C# Hello World application with .NET Core in Visual Studio 2017](#) or [Build a Visual Basic Hello World application with .NET Core in Visual Studio 2017](#), you built a Hello World console application. In [Debug your C# Hello World application with Visual Studio 2017](#), you tested it using the Visual Studio debugger. Now that you're sure that it works as expected, you can publish it so that other users can run it. Publishing creates the set of files that are needed to run your application, and you can deploy the files by copying them to a target machine.

To publish and run your application:

1. Make sure that Visual Studio is building the Release version of your application. If necessary, change the build configuration setting on the toolbar from **Debug** to **Release**.

2. Right-click on the **HelloWorld** project (not the HelloWorld solution) and select **Publish** from the menu. You can also select **Publish HelloWorld** from the main Visual Studio **Build** menu.

3. Open a console window. For example in the **Type here to search** text box in the Windows taskbar, enter

`Command Prompt` (or `cmd` for short), and open a console window by either selecting the **Command Prompt** desktop app or pressing Enter if it's selected in the search results.

4. Navigate to the published application in the `bin\release\PublishOutput` subdirectory of your application's project directory. As the following figure shows, the published output includes the following four files:

- `HelloWorld.deps.json`

The application's runtime dependencies file. It defines the .NET Core components and the libraries (including the dynamic link library that contains your application) needed to run your application. For more information, see [Runtime Configuration Files](#).

- `HelloWorld.dll`

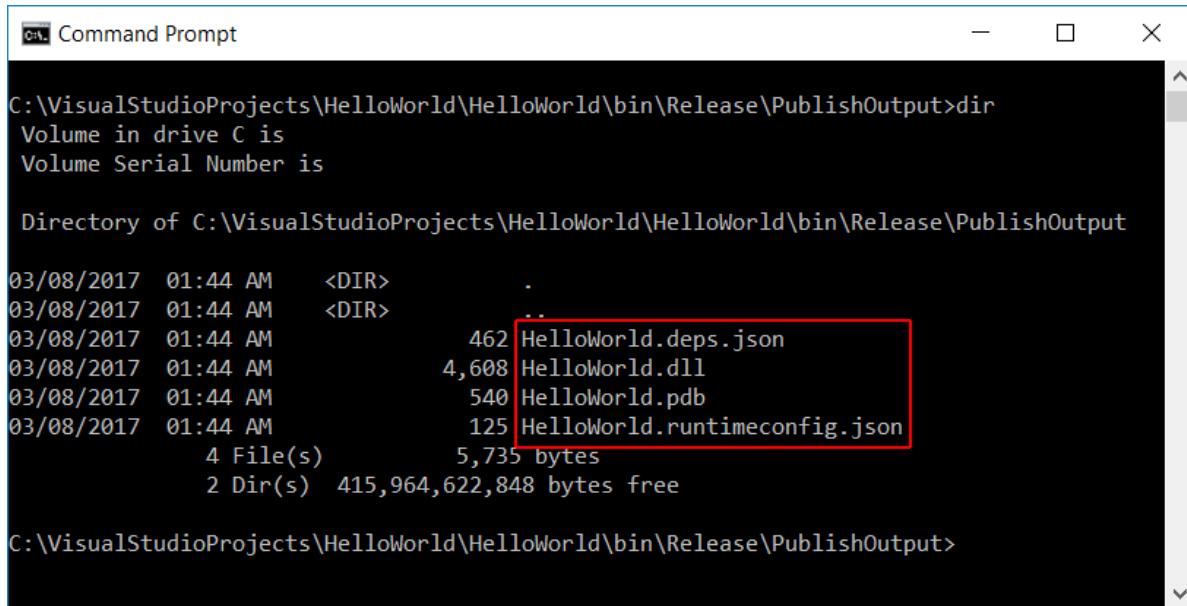

The file that contains your application. It is a dynamic link library that can be executed by entering the `dotnet HelloWorld.dll` command in a console window.

- `HelloWorld.pdb` (optional for deployment)

A file that contains debug symbols. You aren't required to deploy this file along with your application, although you should save it in the event that you need to debug the published version of your application.

- `HelloWorld.runtimeconfig.json`

The application's runtime configuration file. It identifies the version of .NET Core that your application was built to run on. For more information, see [Runtime Configuration Files](#).

The screenshot shows a Windows Command Prompt window titled "Command Prompt". The current directory is `C:\VisualStudioProjects\HelloWorld\HelloWorld\bin\Release\PublishOutput`. The user runs the `dir` command to list the files in the directory. The output shows the following files:

Date	Time	Type	Name	Size
03/08/2017	01:44 AM	<DIR>	.	
03/08/2017	01:44 AM	<DIR>	..	
03/08/2017	01:44 AM		HelloWorld.deps.json	462
03/08/2017	01:44 AM		HelloWorld.dll	4,608
03/08/2017	01:44 AM		HelloWorld.pdb	540
03/08/2017	01:44 AM		HelloWorld.runtimeconfig.json	125
		4 File(s)		5,735 bytes
		2 Dir(s)		415,964,622,848 bytes free

A red box highlights the `HelloWorld.deps.json`, `HelloWorld.dll`, `HelloWorld.pdb`, and `HelloWorld.runtimeconfig.json` files.

The publishing process creates a framework-dependent deployment, which is a type of deployment where the published application will run on any platform supported by .NET Core with .NET Core installed on the system. Users can run your application by issuing the `dotnet HelloWorld.dll` command from a console window.

For more information on publishing and deploying .NET Core applications, see [.NET Core Application Deployment](#).

Build a .NET Standard library with C# and the .NET Core SDK in Visual Studio 2017

1/17/2019 • 2 minutes to read • [Edit Online](#)

A *class library* defines types and methods that are called by an application. A class library that targets the .NET Standard 2.0 allows your library to be called by any .NET implementation that supports that version of the .NET Standard. When you finish your class library, you can decide whether you want to distribute it as a third-party component or whether you want to include it as a bundled component with one or more applications.

NOTE

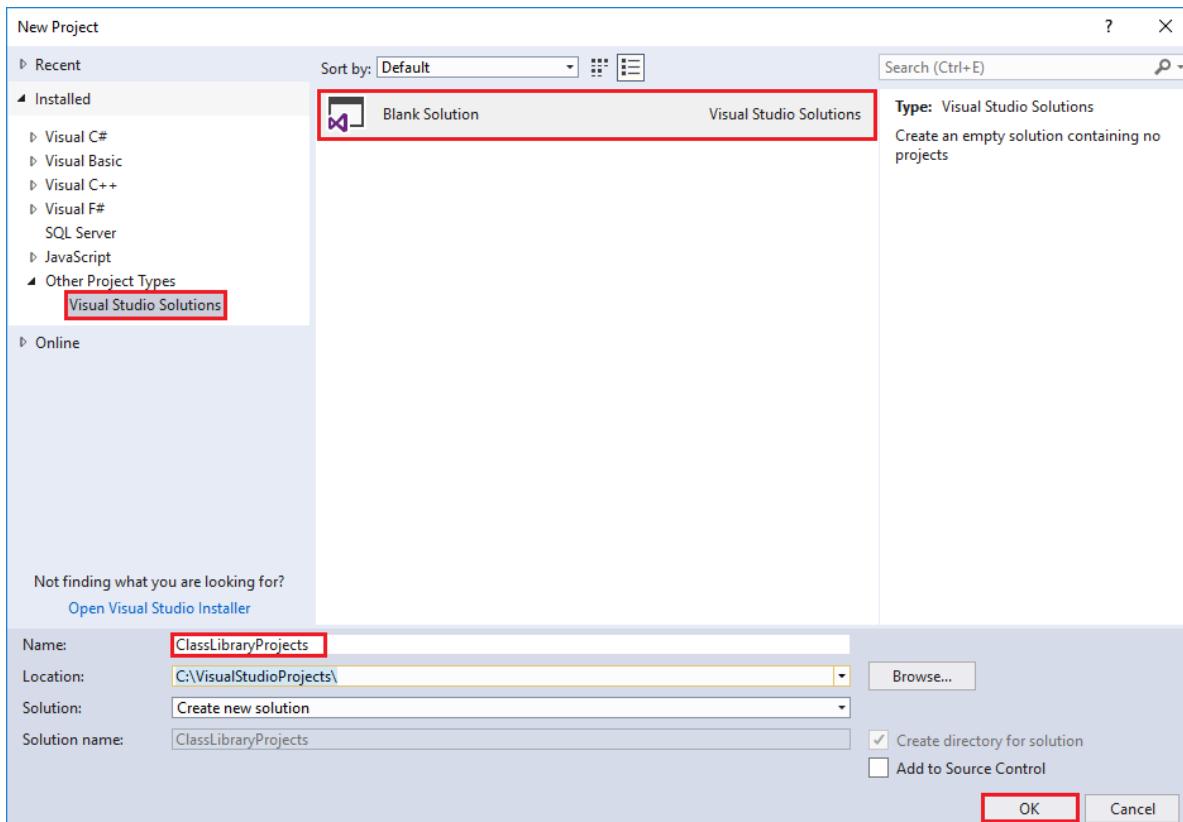

For a list of the .NET Standard versions and the platforms they support, see [.NET Standard](#).

In this topic, you'll create a simple utility library that contains a single string-handling method. You'll implement it as an [extension method](#) so that you can call it as if it were a member of the `String` class.

Creating a class library solution

Start by creating a solution for your class library project and its related projects. A Visual Studio Solution just serves as a container for one or more projects. To create the solution:

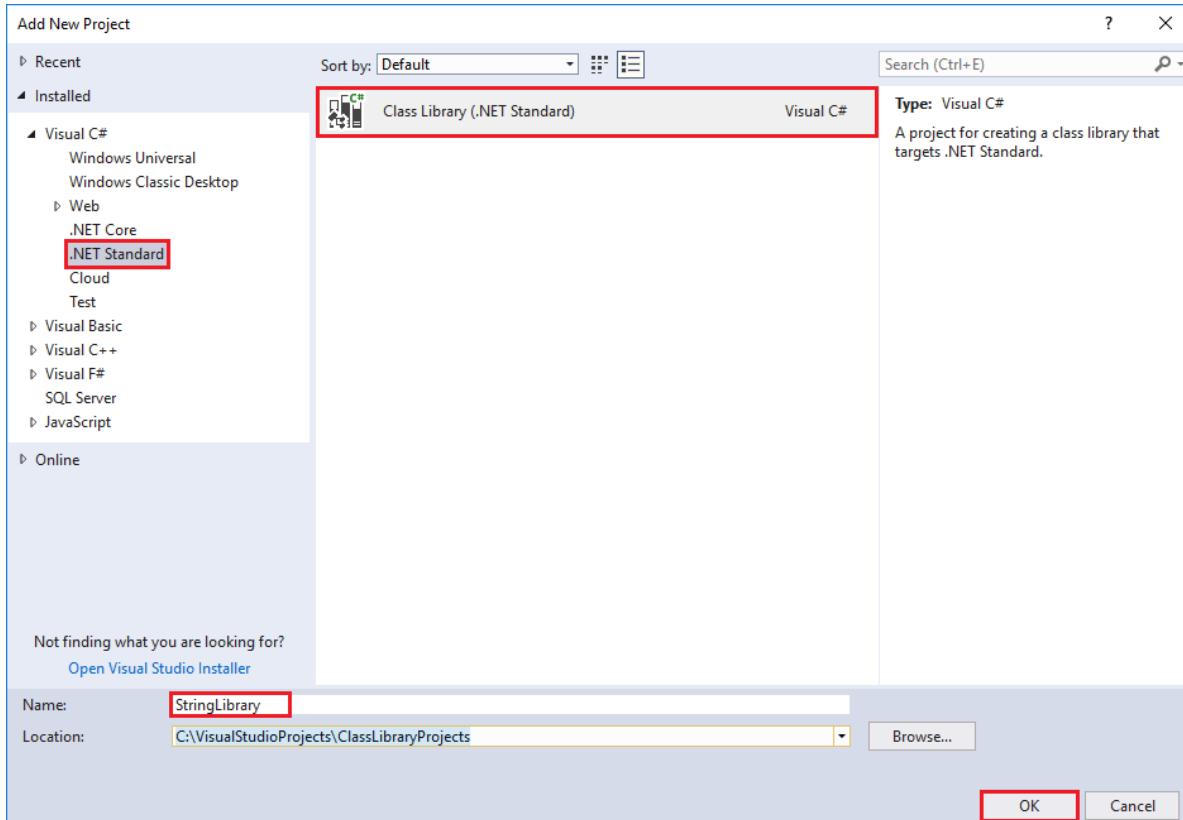

1. On the Visual Studio menu bar, choose **File > New > Project**.
 2. In the **New Project** dialog, expand the **Other Project Types** node, and select **Visual Studio Solutions**. Name the solution "ClassLibraryProjects" and select the **OK** button.

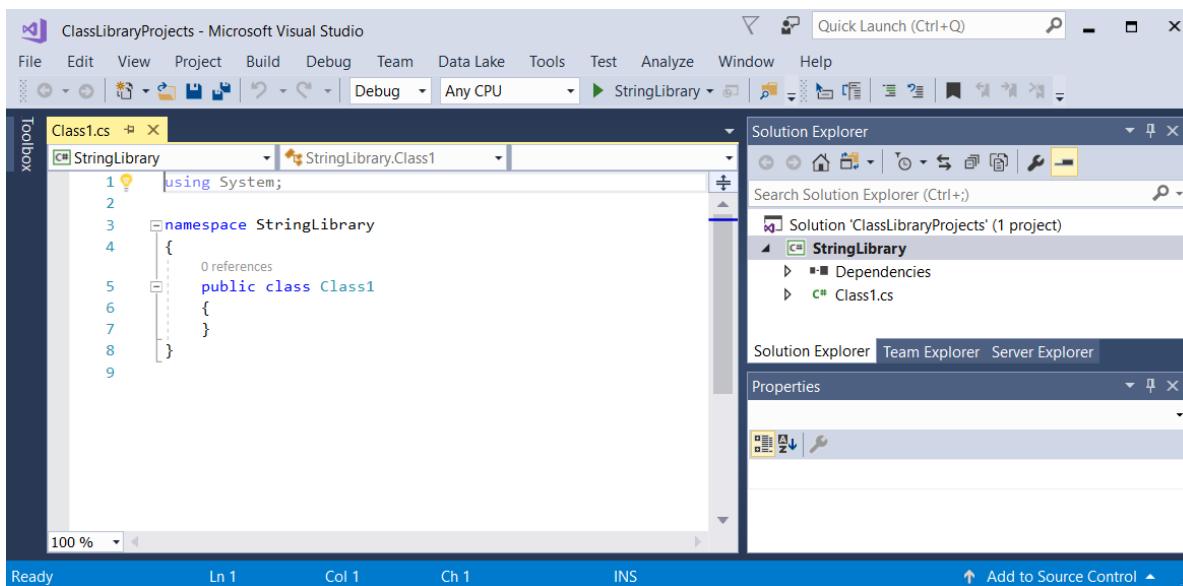

Creating the class library project

Create your class library project:

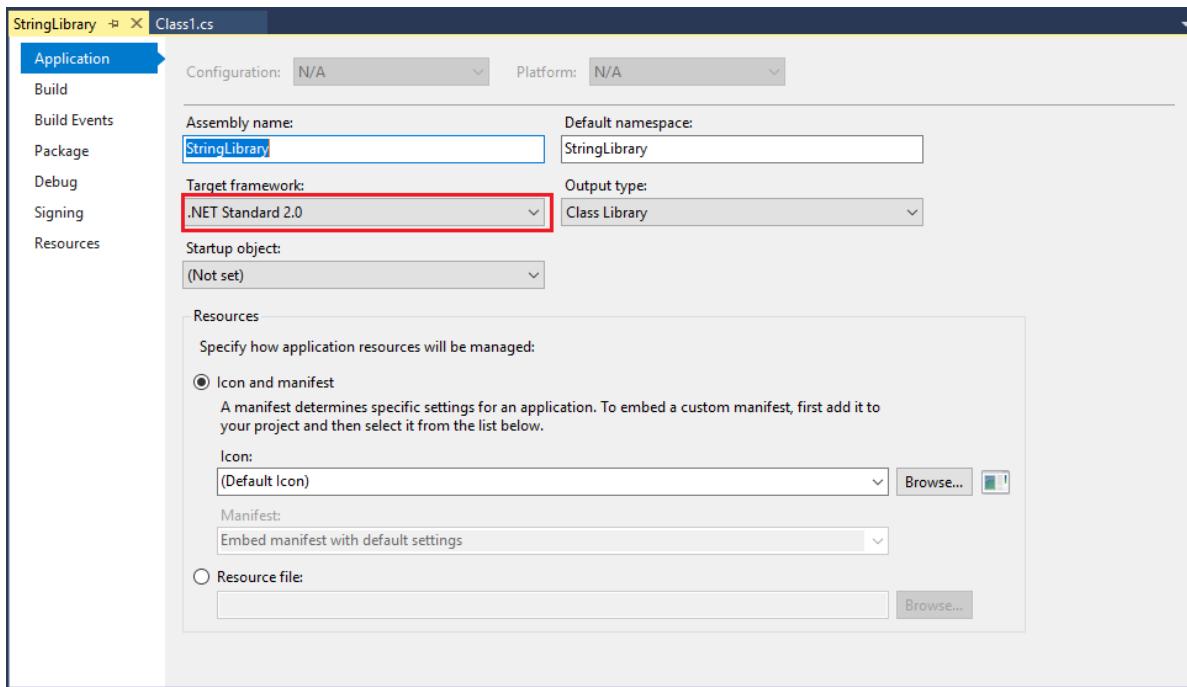

1. In **Solution Explorer**, right-click on the **ClassLibraryProjects** solution file and from the context menu, select **Add > New Project**.
2. In the **Add New Project** dialog, expand the **Visual C#** node, then select the **.NET Standard** node followed by the **Class Library (.NET Standard)** project template. In the **Name** text box, enter "StringLibrary" as the name of the project. Select **OK** to create the class library project.

The code window then opens in the Visual Studio development environment.

3. Check to make sure that our library targets the correct version of the .NET Standard. Right-click on the library project in the **Solution Explorer** windows, then select **Properties**. The **Target Framework** text box shows that we're targeting .NET Standard 2.0.

- Replace the code in the code window with the following code and save the file:

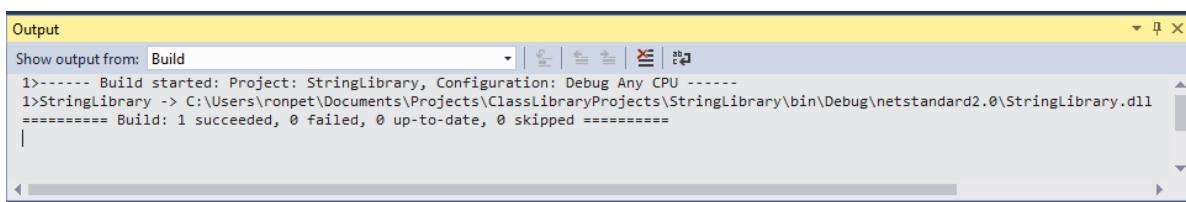

```
using System;

namespace UtilityLibraries
{
    public static class StringLibrary
    {
        public static bool StartsWithUpper(this String str)
        {
            if (String.IsNullOrWhiteSpace(str))
                return false;

            Char ch = str[0];
            return Char.IsUpper(ch);
        }
    }
}
```

The class library, `UtilityLibraries.StringLibrary`, contains a method named `StartsWithUpper`, which returns a `Boolean` value that indicates whether the current string instance begins with an uppercase character. The Unicode standard distinguishes uppercase characters from lowercase characters. The `Char.ToUpper(Char)` method returns `true` if a character is uppercase.

- On the menu bar, select **Build > Build Solution**. The project should compile without error.

Next step

You've successfully built the library. Because you haven't called any of its methods, you don't know whether it works as expected. The next step in developing your library is to test it by using a [Unit Test Project](#).

Build a .NET Standard library with Visual Basic and the .NET Core SDK in Visual Studio 2017

1/17/2019 • 2 minutes to read • [Edit Online](#)

A *class library* defines types and methods that are called by an application. A class library that targets the .NET Standard 2.0 allows your library to be called by any .NET implementation that supports that version of the .NET Standard. When you finish your class library, you can decide whether you want to distribute it as a third-party component or whether you want to include it as a bundled component with one or more applications.

NOTE

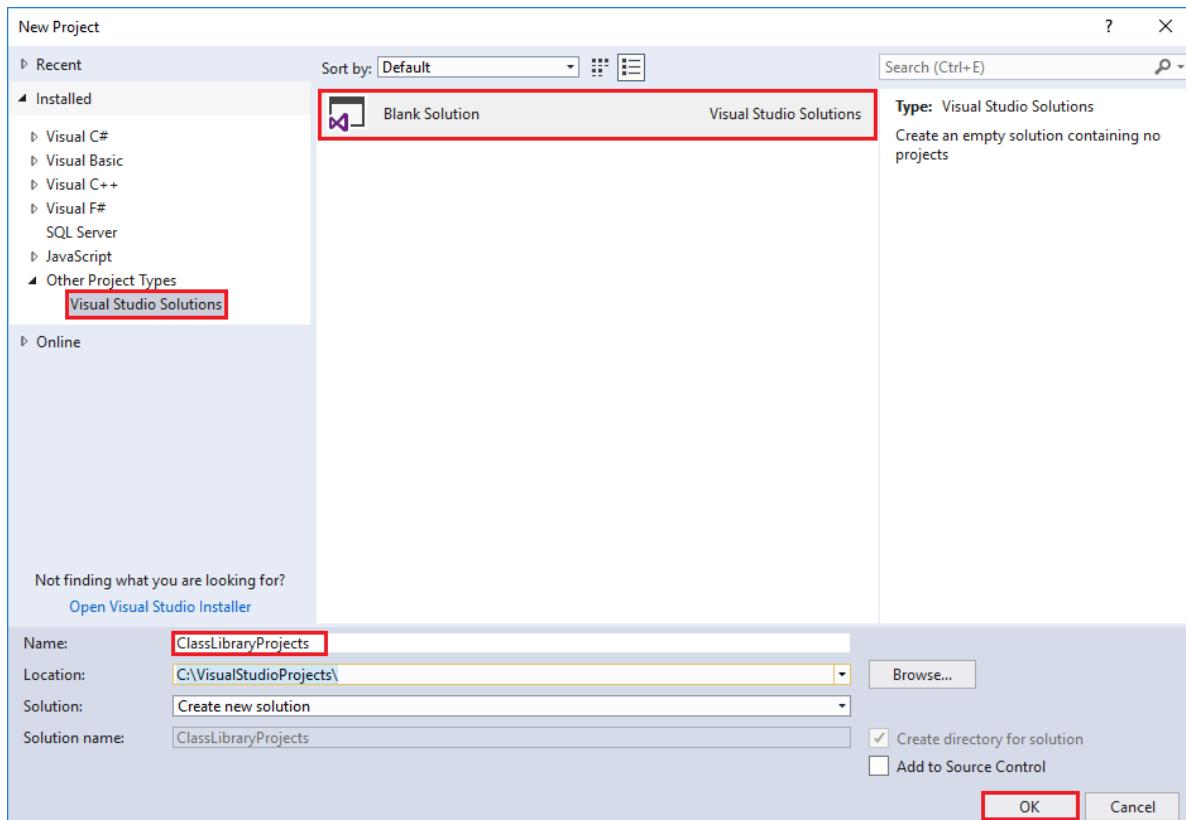

For a list of the .NET Standard versions and the platforms they support, see [.NET Standard](#).

In this topic, you'll create a simple utility library that contains a single string-handling method. You'll implement it as an [extension method](#) so that you can call it as if it were a member of the `String` class.

Creating a class library solution

Start by creating a solution for your class library project and its related projects. A Visual Studio Solution just serves as a container for one or more projects. To create the solution:

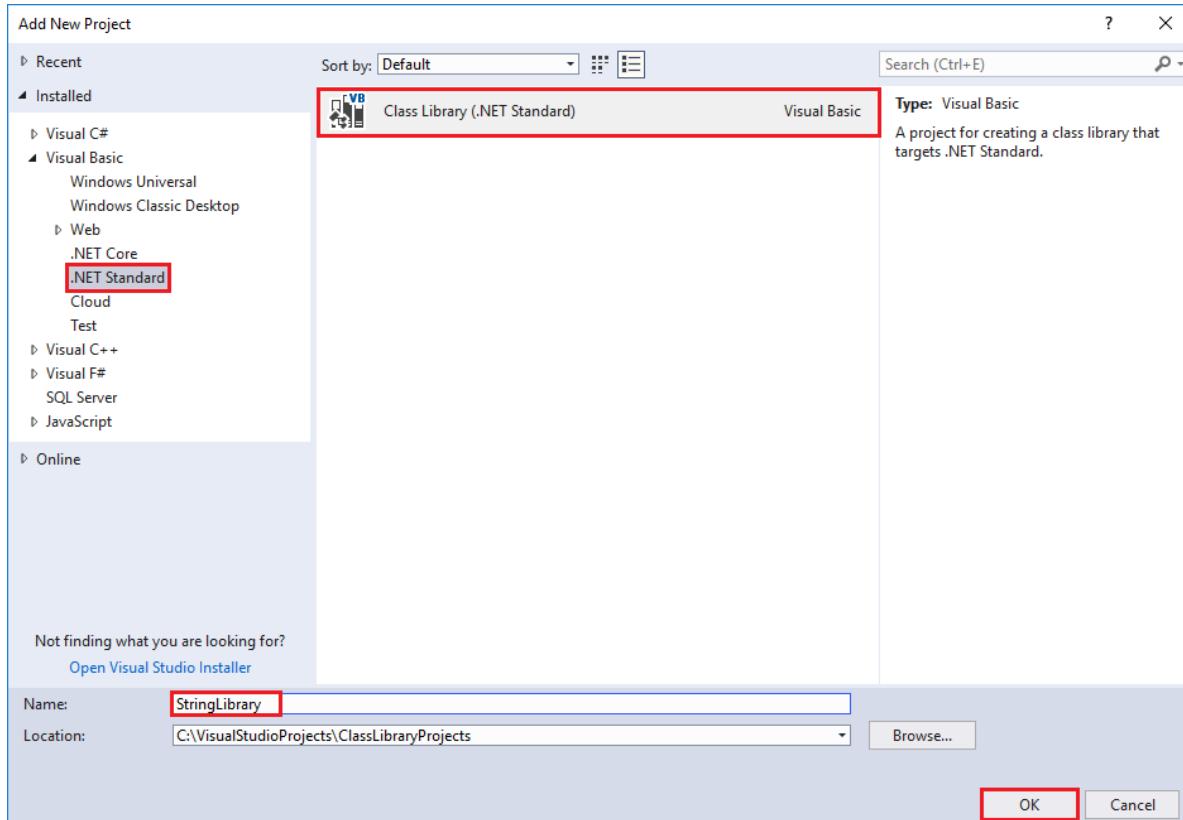

1. On the Visual Studio menu bar, choose **File > New > Project**.
 2. In the **New Project** dialog, expand the **Other Project Types** node, and select **Visual Studio Solutions**. Name the solution "ClassLibraryProjects" and select the **OK** button.

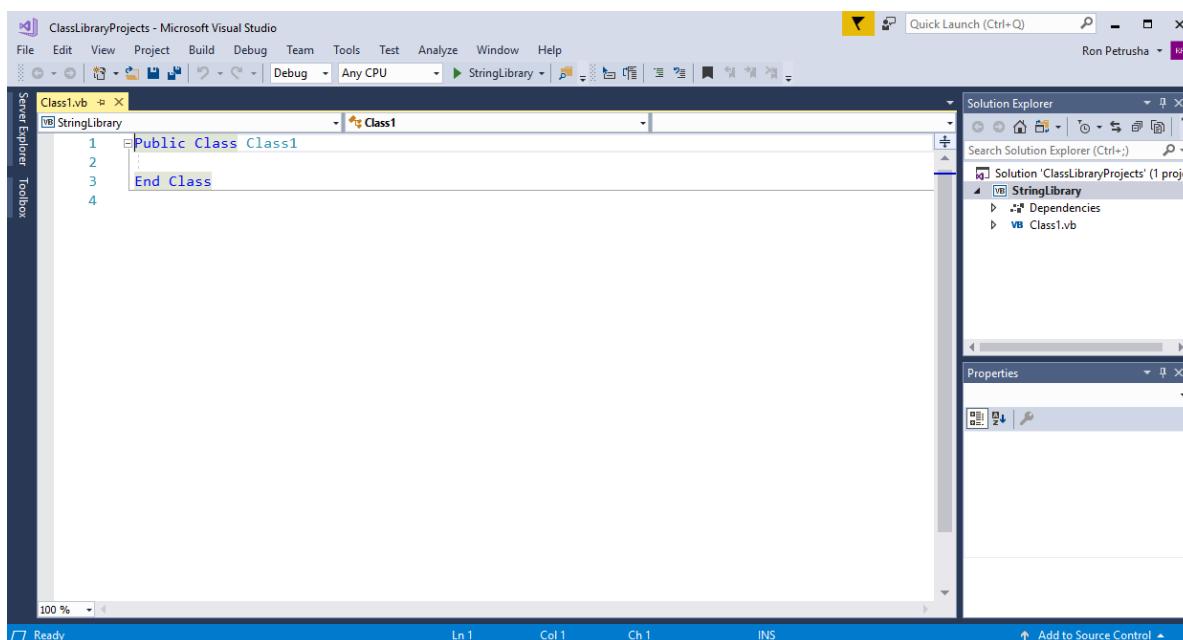

Creating the class library project

Create your class library project:

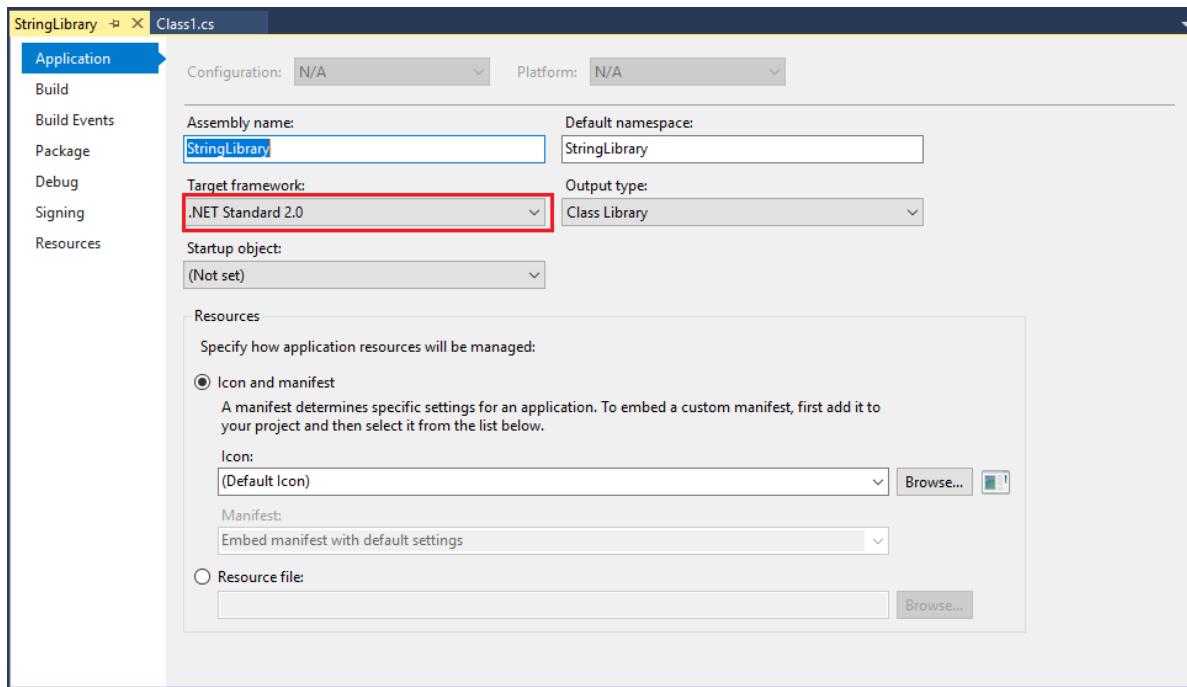

1. In **Solution Explorer**, right-click on the **ClassLibraryProjects** solution file and from the context menu, select **Add > New Project**.
2. In the **Add New Project** dialog, expand the **Visual Basic** node, then select the **.NET Standard** node followed by the **Class Library (.NET Standard)** project template. In the **Name** text box, enter "StringLibrary" as the name of the project. Select **OK** to create the class library project.

The code window then opens in the Visual Studio development environment.

3. Check to make sure that the library targets the correct version of the .NET Standard. Right-click on the library project in the **Solution Explorer** windows, then select **Properties**. The **Target Framework** text box shows that we're targeting .NET Standard 2.0.

- Also in the **Properties** dialog, clear the text in the **Root namespace** text box. For each project, Visual Basic automatically creates a namespace that corresponds to the project name, and any namespaces defined in source code files are parents of that namespace. We want to define a top-level namespace by using the `namespace` keyword.

- Replace the code in the code window with the following code and save the file:

```

Imports System.Runtime.CompilerServices

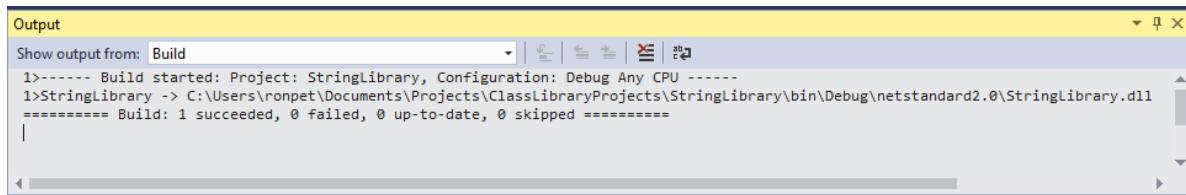

Namespace UtilityLibraries
    Public Module StringLibrary
        <Extension>
        Public Function StartsToUpper(str As String) As Boolean
            If String.IsNullOrWhiteSpace(str) Then
                Return False
            End If

            Dim ch As Char = str(0)
            Return Char.IsUpper(ch)
        End Function
    End Module
End Namespace

```

The class library, `UtilityLibraries.StringLibrary`, contains a method named `StartsToUpper`, which returns a `Boolean` value that indicates whether the current string instance begins with an uppercase character. The Unicode standard distinguishes uppercase characters from lowercase characters. The `Char.IsUpper(Char)` method returns `true` if a character is uppercase.

- On the menu bar, select **Build > Build Solution**. The project should compile without error.

Next step

You've successfully built the library. Because you haven't called any of its methods, you don't know whether it works as expected. The next step in developing your library is to test it by using a [Unit Test Project](#).

Test a .NET Standard library with .NET Core in Visual Studio 2017

3/1/2019 • 9 minutes to read • [Edit Online](#)

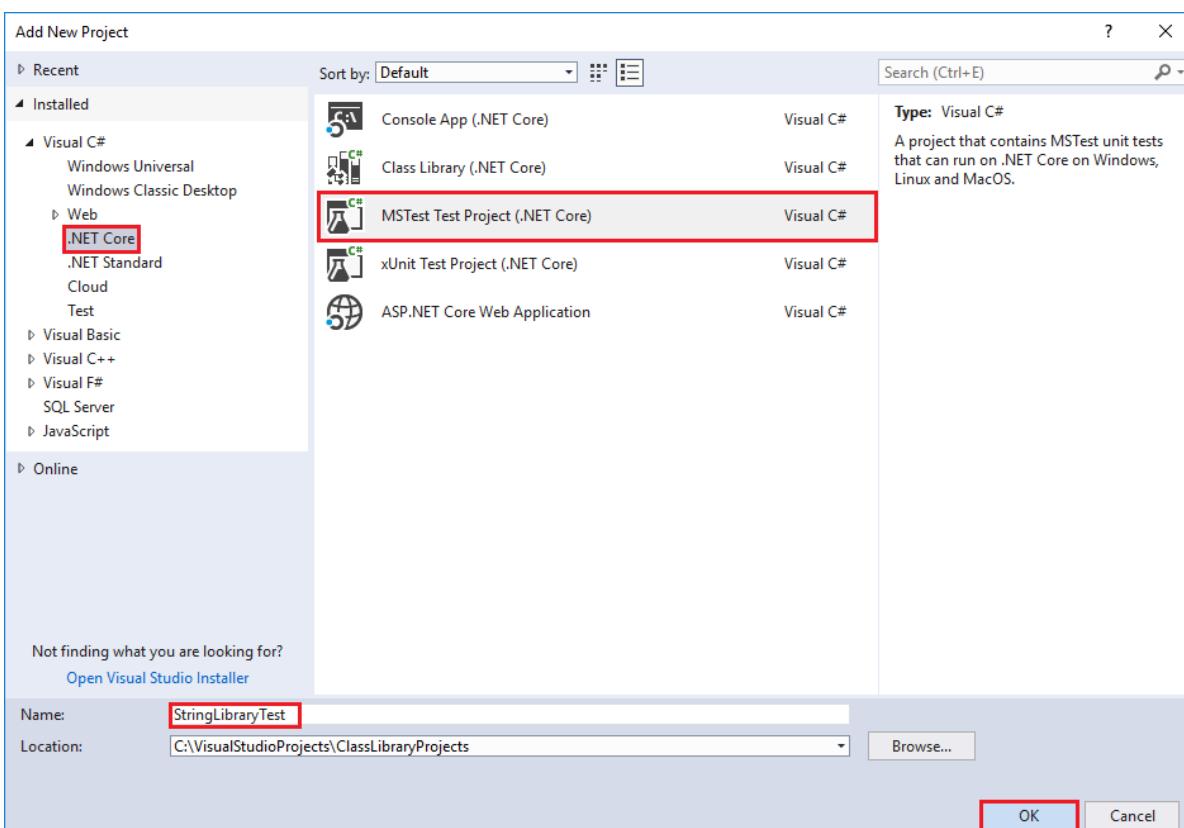

In [Build a .NET Standard library with C# and .NET Core in Visual Studio 2017](#) or [Build a .NET Standard library with Visual Basic and .NET Core in Visual Studio 2017](#), you created a simple class library that adds an extension method to the `String` class. Now, you'll create a unit test to make sure that it works as expected. You'll add your unit test project to the solution you created in the previous article.

Creating a unit test project

To create the unit test project, do the following:

- [C#](#)
- [Visual Basic](#)

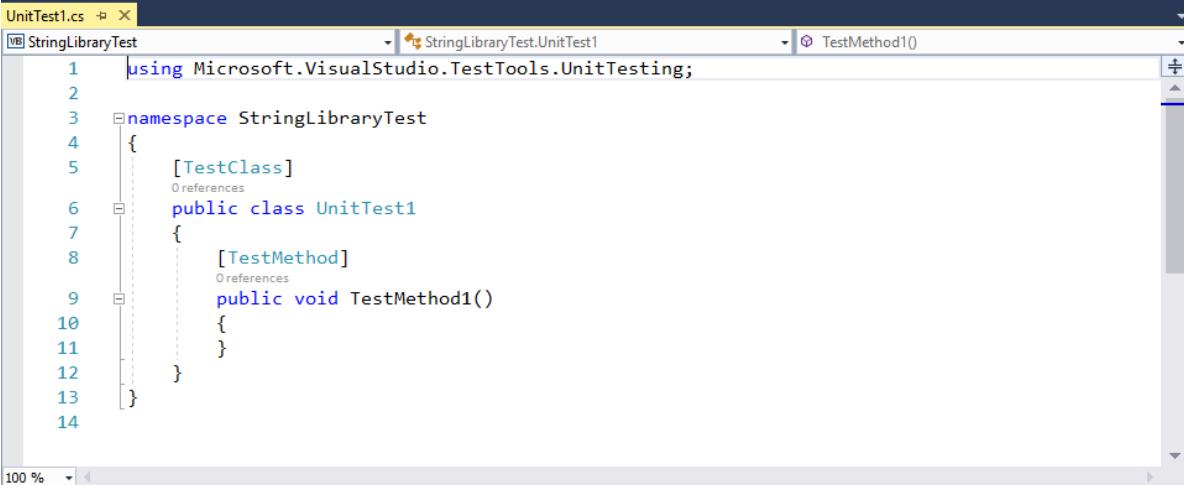

1. In **Solution Explorer**, open the context menu for the **ClassLibraryProjects** solution node and select **Add > New Project**.
2. In the **Add New Project** dialog, select the **Visual C#** node. Then select the **.NET Core** node followed by the **MSTest Test Project (.NET Core)** project template. In the **Name** text box, enter "StringLibraryTest" as the name of the project. Select **OK** to create the unit test project.

NOTE

In addition to an MSTest Test project, you can also use Visual Studio to create an xUnit test project for .NET Core.

3. Visual Studio creates the project and opens the `UnitTest1.cs` file in the code window.

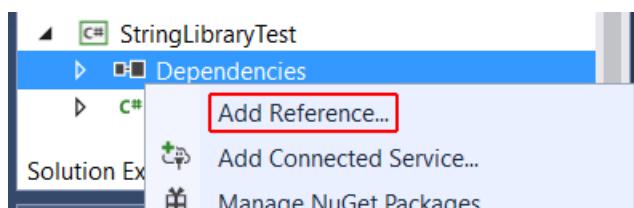

```
UnitTest1.cs
VB StringLibraryTest
1  using Microsoft.VisualStudio.TestTools.UnitTesting;
2
3  namespace StringLibraryTest
4  {
5      [TestClass]
6      public class UnitTest1
7      {
8          [TestMethod]
9          public void TestMethod1()
10         {
11         }
12     }
13 }
14
```

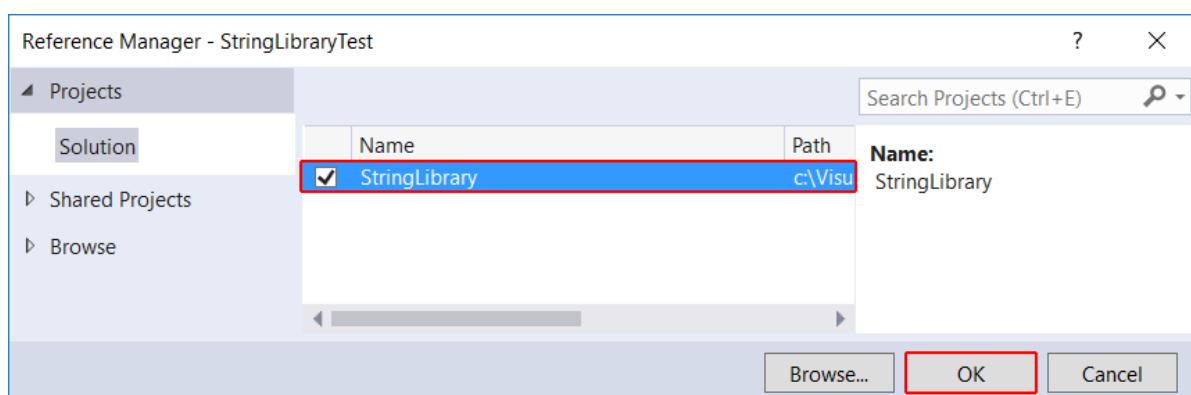

The source code created by the unit test template does the following:

- It imports the `Microsoft.VisualStudio.TestTools.UnitTesting` namespace, which contains the types used for unit testing.
- It applies the `TestClassAttribute` attribute to the `UnitTest1` class. Each test method in a test class tagged with the `[TestMethod]` attribute is executed automatically when the unit test is run.
- It applies the `TestMethodAttribute` attribute to define `TestMethod1` as a test method for automatic execution when the unit test is run.

4. In **Solution Explorer**, right-click the **Dependencies** node of the **StringLibraryTest** project and select **Add Reference** from the context menu.

5. In the **Reference Manager** dialog, expand the **Projects** node and check the box next to **StringLibrary**. Adding a reference to the `StringLibrary` assembly allows the compiler to find `StringLibrary` methods. Select the **OK** button. This adds a reference to your class library project, `StringLibrary`.

Adding and running unit test methods

When Visual Studio runs a unit test, it executes each method marked with the `TestMethodAttribute` attribute in a unit test class, the class to which the `TestClassAttribute` attribute is applied. A test method ends when the first failure is encountered or when all tests contained in the method have succeeded.

The most common tests call members of the [Assert](#) class. Many assert methods include at least two parameters, one of which is the expected test result and the other of which is the actual test result. Some of its most frequently called methods are shown in the table below.

ASSERT METHODS	FUNCTION
<code>Assert.AreEqual</code>	Verifies that two values or objects are equal. The assert fails if the values or objects are not equal.
<code>Assert.AreSame</code>	Verifies that two object variables refer to the same object. The assert fails if the variables refer to different objects.
<code>Assert.IsFalse</code>	Verifies that a condition is <code>false</code> . The assert fails if the condition is <code>true</code> .
<code>Assert.IsNotNull</code>	Verifies that an object is not <code>null</code> . The assert fails if the object is <code>null</code> .

You can also apply the [ExpectedExceptionAttribute](#) attribute to a test method. It indicates the type of exception a test method is expected to throw. The test fails if the specified exception is not thrown.

In testing the `StringLibrary.StartsWithUpper` method, you want to provide a number of strings that begin with an uppercase character. You expect the method to return `true` in these cases, so you can call the [IsTrue](#) method. Similarly, you want to provide a number of strings that begin with something other than an uppercase character. You expect the method to return `false` in these cases, so you can call the [IsFalse](#) method.

Since your library method handles strings, you also want to make sure that it successfully handles an [empty string](#) (`String.Empty`), a valid string that has no characters and whose [Length](#) is 0, and a `null` string that has not been initialized. If `StartsWithUpper` is called as an extension method on a `String` instance, it cannot be passed a `null` string. However, you can also call it directly as a static method and pass a single `String` argument.

You'll define three methods, each of which calls its [Assert](#) method repeatedly for each element in a string array. Because the test method fails as soon as it encounters the first failure, you'll call a method overload that allows you to pass a string that indicates the string value used in the method call.

To create the test methods:

- [C#](#)
- [Visual Basic](#)

1. In the `UnitTest1.cs` code window, replace the code with the following code:

```

using System;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using UtilityLibraries;

namespace StringLibraryTest
{
    [TestClass]
    public class UnitTest1
    {
        [TestMethod]
        public void TestStartsWithUpper()
        {
            // Tests that we expect to return true.
            string[] words = { "Alphabet", "Zebra", "ABC", "Αθήνα", "Москва" };
            foreach (var word in words)
            {
                bool result = word.StartsWithUpper();
                Assert.IsTrue(result,
                    String.Format("Expected for '{0}': true; Actual: {1}",
                    word, result));
            }
        }

        [TestMethod]
        public void TestDoesNotStartWithUpper()
        {
            // Tests that we expect to return false.
            string[] words = { "alphabet", "zebra", "abc", "αυτοκινητοβιομηχανία", "государство",
                "1234", ".", ";", " " };
            foreach (var word in words)
            {
                bool result = word.StartsWithUpper();
                Assert.IsFalse(result,
                    String.Format("Expected for '{0}': false; Actual: {1}",
                    word, result));
            }
        }

        [TestMethod]
        public void DirectCallWithNullOrEmpty()
        {
            // Tests that we expect to return false.
            string[] words = { string.Empty, null };
            foreach (var word in words)
            {
                bool result = StringLibrary.StartsWithUpper(word);
                Assert.IsFalse(result,
                    String.Format("Expected for '{0}': false; Actual: {1}",
                    word == null ? "<null>" : word, result));
            }
        }
    }
}

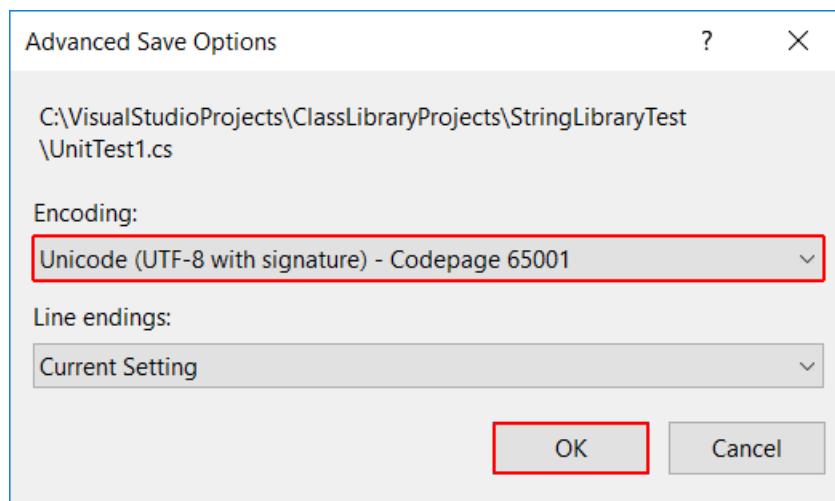

```

Note that your test of uppercase characters in the `TestStartsWithUpper` method includes the Greek capital letter alpha (U+0391) and the Cyrillic capital letter EM (U+041C), and the test of lowercase characters in the `TestDoesNotStartWithUpper` method includes the Greek small letter alpha (U+03B1) and the Cyrillic small letter Ghe (U+0433).

2. On the menu bar, select **File > Save UnitTest1.cs As**. In the **Save File As** dialog, select the arrow beside the **Save** button, and select **Save with Encoding**.

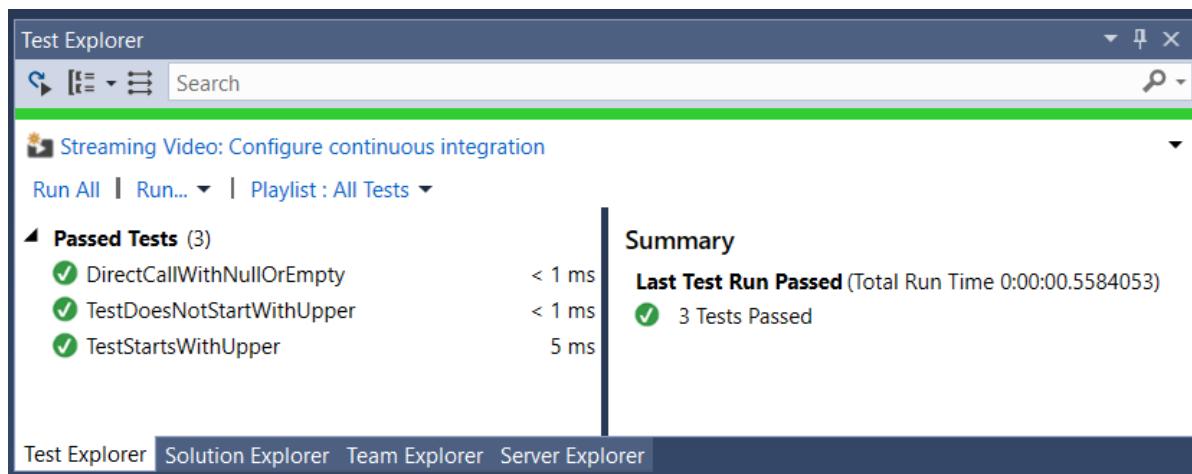

1. In the **Confirm Save As** dialog, select the **Yes** button to save the file.
2. In the **Advanced Save Options** dialog, select **Unicode (UTF-8 with signature) - Codepage 65001** from the **Encoding** drop-down list and select **OK**.

If you fail to save your source code as a UTF8-encoded file, Visual Studio may save it as an ASCII file. When that happens, the runtime doesn't accurately decode the UTF8 characters outside of the ASCII range, and the test results won't be accurate.

3. On the menu bar, select **Test > Run > All Tests**. The **Test Explorer** window opens and shows that the tests ran successfully. The three tests are listed in the **Passed Tests** section, and the **Summary** section reports the result of the test run.

Handling test failures

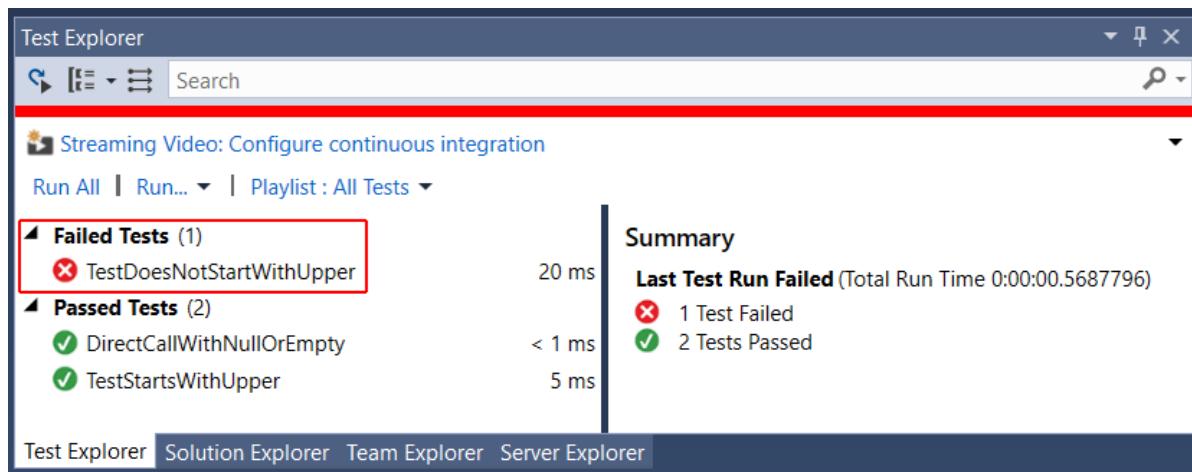

Your test run had no failures, but change it slightly so that one of the test methods fails:

1. Modify the `words` array in the `TestDoesNotStartWithUpper` method to include the string "Error". You don't need to save the file because Visual Studio automatically saves open files when a solution is built to run tests.

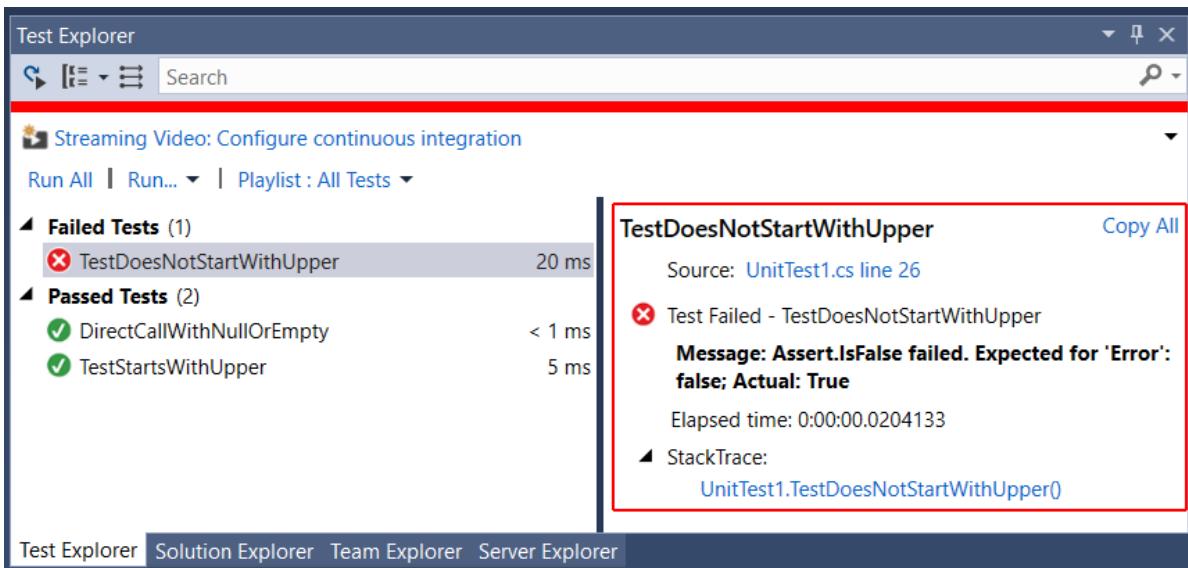

```
string[] words = { "alphabet", "Error", "zebra", "abc", "αυτοκινητοβιομηχανία", "государство",
    "1234", ".", ";", " " };
```

```
Dim words() As String = { "alphabet", "Error", "zebra", "abc", "αυτοκινητοβιομηχανία", "государство",
    "1234", ".", ";", " " }
```

2. Run the test by selecting **Test > Run > All Tests** from the menu bar. The **Test Explorer** window indicates that two tests succeeded and one failed.

3. In the **Failed Tests** section, select the failed test, `TestDoesNotStartWith`. The **Test Explorer** window displays the message produced by the assert: "Assert.IsFalse failed. Expected for 'Error': false; actual: True". Because of the failure, all strings in the array after "Error" were not tested.

4. Undo the modification you did in step 1 and remove the string "Error". Rerun the test and the tests will pass.

Testing the Release version of the library

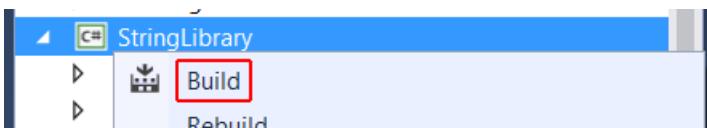

You've been running your tests against the Debug version of the library. Now that your tests have all passed and you've adequately tested your library, you should run the tests an additional time against the Release build of the library. A number of factors, including compiler optimizations, can sometimes produce different behavior between Debug and Release builds.

To test the Release build:

1. In the Visual Studio toolbar, change the build configuration from **Debug** to **Release**.

2. In **Solution Explorer**, right-click the **StringLibrary** project and select **Build** from the context menu to recompile the library.

3. Run the unit tests by choosing **Test > Run > All Tests** from the menu bar. The tests pass.

Now that you've finished testing your library, the next step is to make it available to callers. You can bundle it with one or more applications, or you can distribute it as a NuGet package. For more information, see [Consuming a .NET Standard Class Library](#).

Consume a .NET Standard library in Visual Studio 2017

1/17/2019 • 5 minutes to read • [Edit Online](#)

Once you've created a .NET Standard class library by following the steps in [Building a C# class library with .NET Core in Visual Studio 2017](#) or [Building a Visual Basic class library with .NET Core in Visual Studio 2017](#), tested it in [Testing a class library with .NET Core in Visual Studio 2017](#), and built a Release version of the library, the next step is to make it available to callers. You can do this in two ways:

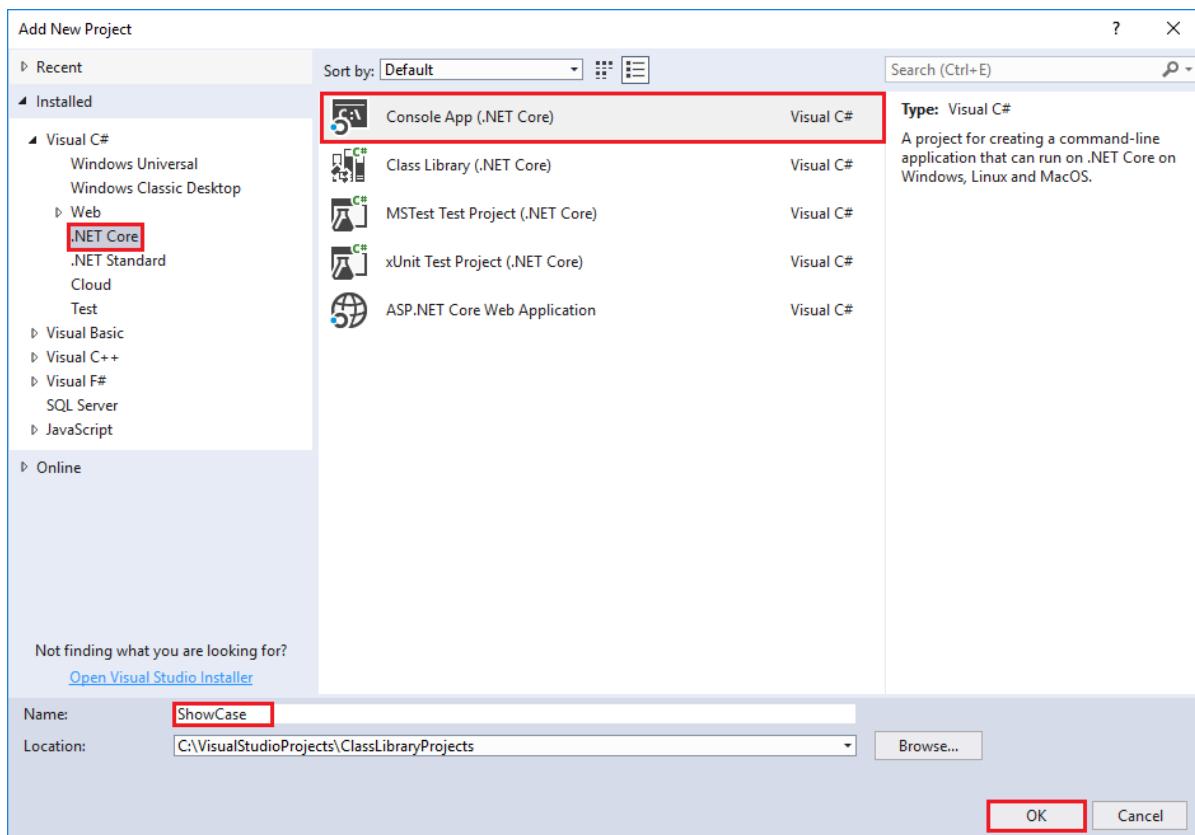

- If the library will be used by a single solution (for example, if it's a component in a single large application), you can include it as a project in your solution.
- If the library will be generally accessible, you can distribute it as a NuGet package.

Including a library as a project in a solution

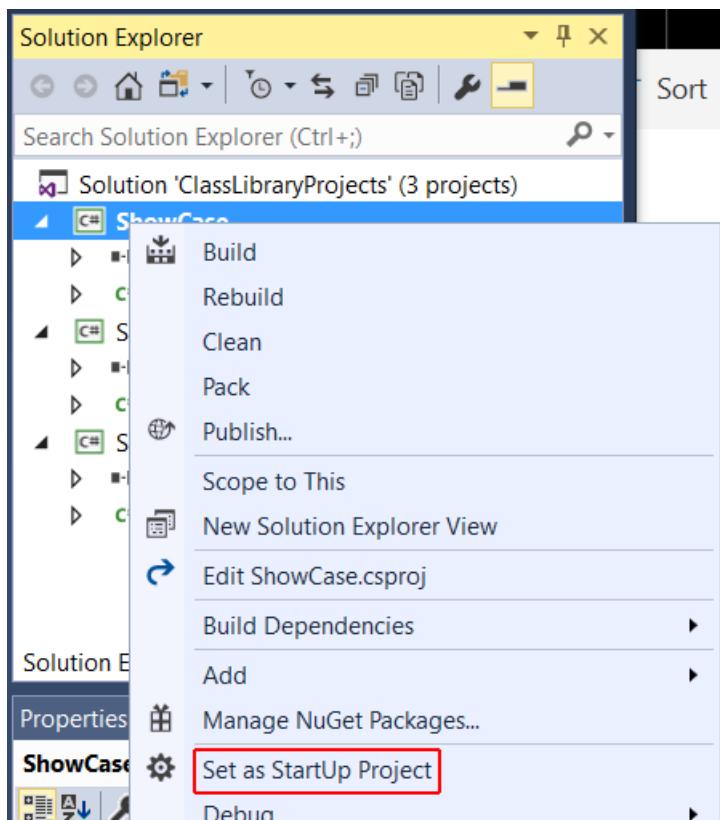

Just as you included unit tests in the same solution as your class library, you can include your application as part of that solution. For example, you can use your class library in a console application that prompts the user to enter a string and reports whether its first character is uppercase:

- [C#](#)
- [Visual Basic](#)

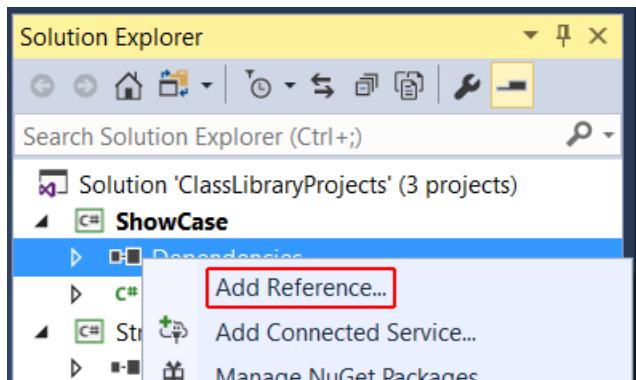

1. Open the `ClassLibraryProjects` solution you created in the [Building a C# Class Library with .NET Core in Visual Studio 2017](#) topic. In **Solution Explorer**, right-click the **ClassLibraryProjects** solution and select **Add > New Project** from the context menu.
2. In the **Add New Project** dialog, expand the **Visual C#** node and select the **.NET Core** node followed by the **Console App (.NET Core)** project template. In the **Name** text box, type "ShowCase", and select the **OK** button.

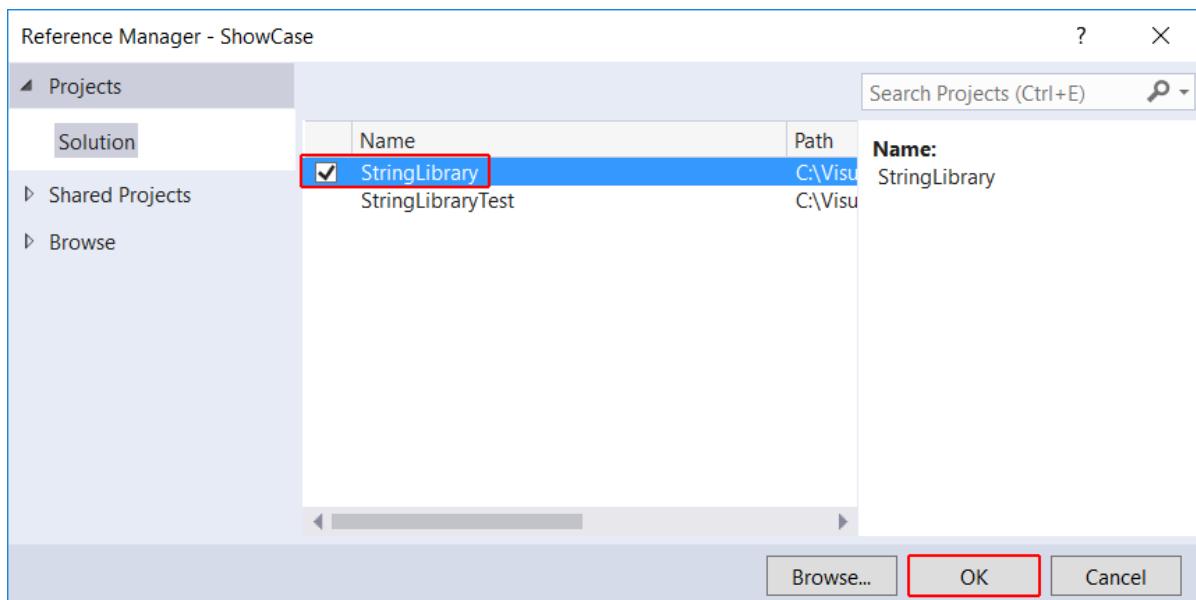

3. In **Solution Explorer**, right-click the **ShowCase** project and select **Set as StartUp Project** in the context menu.

4. Initially, your project doesn't have access to your class library. To allow it to call methods in your class library, you create a reference to the class library. In **Solution Explorer**, right-click the **ShowCase** project's **Dependencies** node and select **Add Reference**.

5. In the **Reference Manager** dialog, select **StringLibrary**, your class library project, and select the **OK** button.

6. In the code window for the *Program.cs* file, replace all of the code with the following code:

```

using System;
using UtilityLibraries;

class Program
{
    static void Main(string[] args)
    {
        int row = 0;

        do
        {
            if (row == 0 || row >= 25)
                ResetConsole();

            string input = Console.ReadLine();
            if (String.IsNullOrEmpty(input)) break;
            Console.WriteLine($"Input: {input} {"Begins with uppercase? ,30}: " +
                $"{{(input.StartsWithUpper()) ? "Yes" : "No"}}\n");
            row += 3;
        } while (true);
        return;
    }

    // Declare a ResetConsole local method
    void ResetConsole()
    {
        if (row > 0) {
            Console.WriteLine("Press any key to continue...");
            Console.ReadKey();
        }
        Console.Clear();
        Console.WriteLine("\nPress <Enter> only to exit; otherwise, enter a string and press
<Enter>:\n");
        row = 3;
    }
}

```

The code uses the `row` variable to maintain a count of the number of rows of data written to the console window. Whenever it is greater than or equal to 25, the code clears the console window and displays a message to the user.

The program prompts the user to enter a string. It indicates whether the string starts with an uppercase character. If the user presses the Enter key without entering a string, the application terminates, and the console window closes.

7. If necessary, change the toolbar to compile the **Debug** release of the `ShowCase` project. Compile and run the program by selecting the green arrow on the **ShowCase** button.

You can debug and publish the application that uses this library by following the steps in [Debugging your Hello World application with Visual Studio 2017](#) and [Publishing your Hello World Application with Visual Studio 2017](#).

Distributing the library in a NuGet package

You can make your class library widely available by publishing it as a NuGet package. Visual Studio does not support the creation of NuGet packages. To create one, you use the [dotnet command line utility](#):

1. Open a console window. For example in the **Ask me anything** text box in the Windows taskbar, enter `Command Prompt` (or `cmd` for short), and open a console window by either selecting the **Command Prompt** desktop app or pressing Enter if it's selected in the search results.

2. Navigate to your library's project directory. Unless you've reconfigured the typical file location, it's in the `Documents\Visual Studio 2017\Projects\ClassLibraryProjects\StringLibrary` directory. The directory contains your source code and a project file, `StringLibrary.csproj`.
3. Issue the command `dotnet pack --no-build`. The `dotnet` utility generates a package with a `.nupkg` extension.

TIP

If the directory that contains `dotnet.exe` is not in your PATH, you can find its location by entering `where dotnet.exe` in the console window.

For more information on creating NuGet packages, see [How to Create a NuGet Package with Cross Platform Tools](#).

Prerequisites for .NET Core on Windows

12/20/2018 • 4 minutes to read • [Edit Online](#)

This article shows the supported OS versions in order to run .NET Core applications on Windows. The supported OS versions and dependencies that follow apply to the three ways of developing .NET Core apps on Windows:

- [Command line](#)
- [Visual Studio](#)
- [Visual Studio Code](#)

Also, if you're developing on Windows using Visual Studio 2017, the [Prerequisites with Visual Studio 2017](#) section goes in more detail about minimum versions supported for .NET Core development.

.NET Core supported Windows versions

.NET Core is supported on the following versions of:

- Windows 7 SP1
- Windows 8.1
- Windows 10 Anniversary Update (version 1607) or later versions
- Windows Server 2008 R2 SP1 (Full Server or Server Core)
- Windows Server 2012 SP1 (Full Server or Server Core)
- Windows Server 2012 R2 (Full Server or Server Core)
- Windows Server 2016 or later versions (Full Server, Server Core, or Nano Server)

.NET Core supported operating systems

The following articles have a complete list of .NET Core supported operating systems per version:

- [.NET Core 3.0 \(Preview\)](#)
- [.NET Core 2.2](#)
- [.NET Core 2.1](#)
- [.NET Core 1.0](#)

For download links and more information, see [.NET downloads](#) to download the latest version or [.NET downloads archive](#) for older versions.

.NET Core dependencies

.NET Core 1.1 and earlier versions require the Visual C++ Redistributable when running on Windows versions earlier than Windows 10 and Windows Server 2016. This dependency is automatically installed by the .NET Core installer.

[Microsoft Visual C++ 2015 Redistributable Update 3](#) must be manually installed when:

- Installing .NET Core with the [installer script](#).
- Deploying a self-contained .NET Core application.
- Building the product from source.
- Installing .NET Core via a *.zip* file. This can include build/CI/CD servers.

NOTE

For Windows 8.1 and earlier versions, or Windows Server 2012 R2 and earlier versions:

Make sure that your Windows installation is up-to-date and includes [KB2999226](#), which can be installed through Windows Update. If you don't have this update installed, you'll see an error like the following when you launch a .NET Core application:

```
The program can't start because api-ms-win-crt-runtime-1-1-0.dll is missing from your computer. Try  
reinstalling the program to fix this problem.
```

For Windows 7 or Windows Server 2008 R2:

In addition to KB2999226, make sure you also have [KB2533623](#) installed. If you don't have this update installed, you'll see an error similar to the following when you launch a .NET Core application:

```
The library hostfxr.dll was found, but loading it from C:\<path_to_app>\hostfxr.dll failed.
```

Prerequisites for .NET Core 3.0 Preview 1

.NET Core 3.0 Preview 1 has the same prerequisites as other versions of .NET Core. However, if you want to use Visual Studio to create .NET Core 3.0 projects, you must use the [Visual Studio 2019 Preview](#). Visual Studio 2019 Preview can be installed side-by-side with other versions of Visual Studio without conflict.

Prerequisites with Visual Studio 2017

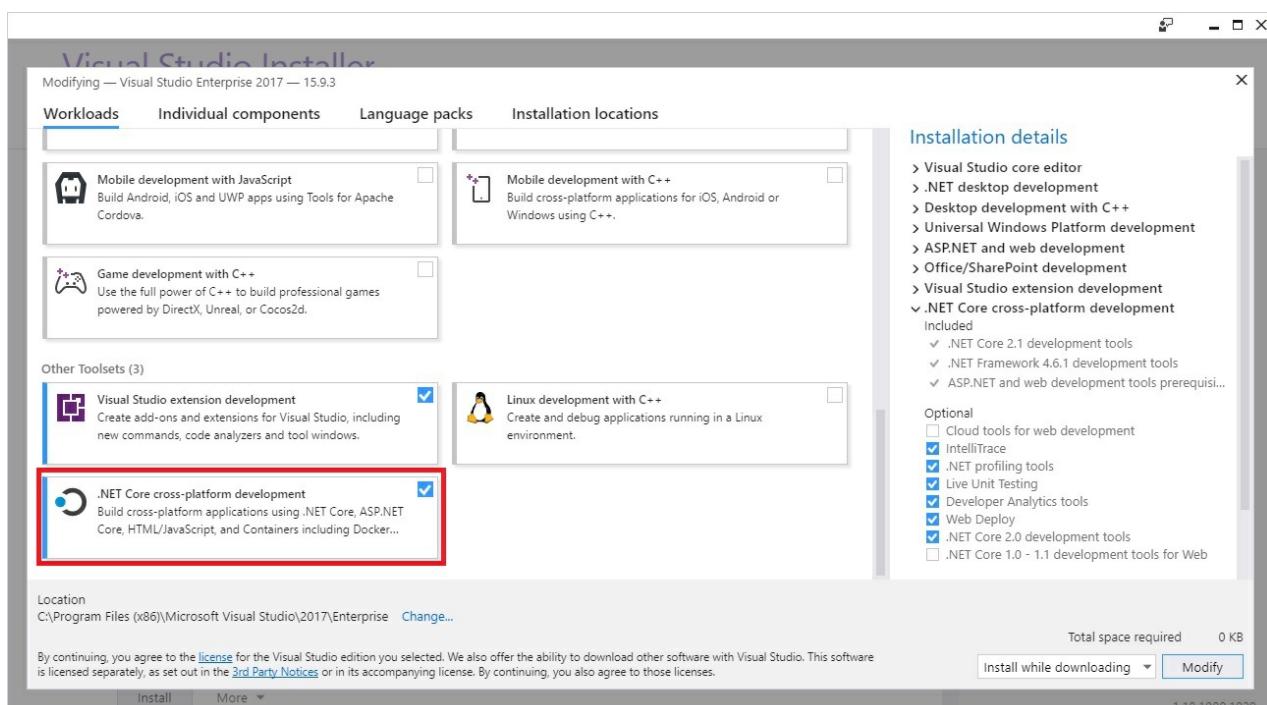

You can use any editor to develop .NET Core applications using the .NET Core SDK. Visual Studio 2017 provides an integrated development environment for .NET Core apps on Windows.

You can read more about the changes in Visual Studio 2017 in the [release notes](#).

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

To develop .NET Core apps in Visual Studio 2017 using the .NET Core 2.2 SDK:

1. [Download and install Visual Studio 2017 version 15.9.0 or higher](#) with the **.NET Core cross-platform development** workload (in the **Other Toolsets** section) selected.

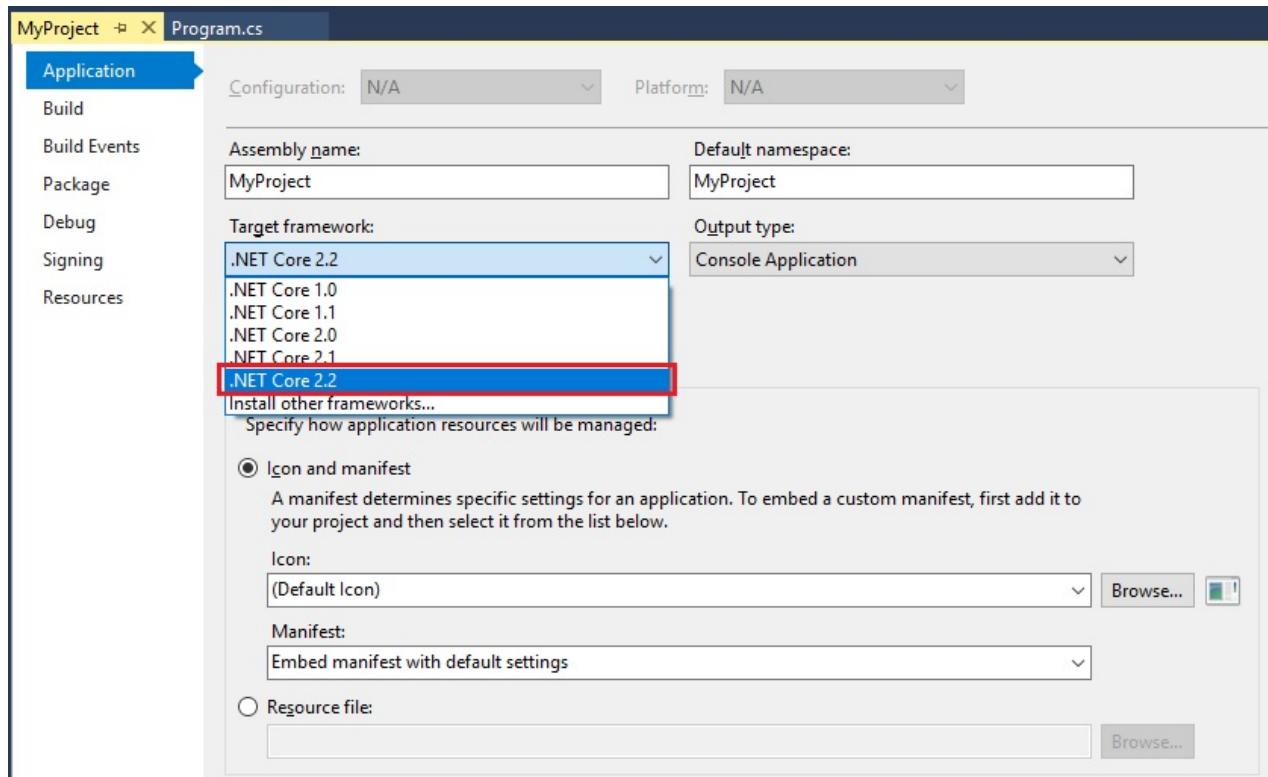

After the **.NET Core cross-platform development** toolset is installed, Visual Studio usually installs a previous

version of the .NET Core SDK. For example, Visual Studio 2017 15.9 uses .NET Core 2.1 SDK by default after the workload is installed.

To update Visual Studio to use .NET Core 2.2 SDK:

1. Install the [.NET Core 2.2 SDK](#).
2. If you want your project to use the latest .NET Core runtime, retarget existing or new .NET Core projects to .NET Core 2.2 using the following instructions:
 - On the **Project** menu, choose **Properties**.
 - In the **Target framework** selection menu, set the value to **.NET Core 2.2**.

Once you have Visual Studio configured with .NET Core 2.2 SDK, you can do the following actions:

- Open, build, and run existing .NET Core 1.x and 2.x projects.
- Retarget .NET Core 1.x and 2.x projects to .NET Core 2.2, build, and run.
- Create new .NET Core 2.2 projects.

TIP

To verify your Visual Studio version:

- On the **Help** menu, choose **About Microsoft Visual Studio**.
- In the **About Microsoft Visual Studio** dialog, verify the version number.
 - For .NET Core 3.0 Preview 1 apps, Visual Studio 2019 Preview 1 or higher.
 - For .NET Core 2.2 apps, Visual Studio 2017 version 15.9 or higher.
 - For .NET Core 2.1 apps, Visual Studio 2017 version 15.7 or higher.
 - For .NET Core 1.x apps, Visual Studio 2017 version 15.0 or higher.

Prerequisites for .NET Core on macOS

1/10/2019 • 3 minutes to read • [Edit Online](#)

This article shows you the supported macOS versions and .NET Core dependencies that you need to develop, deploy, and run .NET Core applications on macOS machines. The supported OS versions and dependencies that follow apply to the three ways of developing .NET Core apps on a Mac: via the [command-line with your favorite editor](#), [Visual Studio Code](#), and [Visual Studio for Mac](#).

Supported macOS versions

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)
- [.NET Core 3.0 Preview 1](#)

.NET Core 2.x is supported on the following versions of macOS:

- macOS 10.12 "Sierra" and later versions

See [.NET Core 2.1 Supported OS Versions](#) and [.NET Core 2.2 Supported OS Versions](#) for the complete list of .NET Core 2.1 and .NET Core 2.2 supported operating systems, distributions and versions, out of support OS versions, and lifecycle policy links.

For download links and more information, see [.NET Core 2.2 downloads](#) or [.NET Core 2.1 downloads](#).

.NET Core dependencies

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)
- [.NET Core 3.0 Preview 1](#)

Download and install the .NET Core SDK from [.NET Downloads](#). If you have problems with the installation on macOS, consult the [Known issues](#) topic for the version you have installed.

Increase the maximum open file limit (.NET Core versions before .NET Core SDK 2.0.2)

In older .NET Core versions (before .NET Core SDK 2.0.2), the default open file limit on macOS may not be sufficient for some .NET Core workloads, such as restoring projects or running unit tests.

You can increase this limit by following these steps:

1. Using a text editor, create a new file `/Library/LaunchDaemons/limit.maxfiles.plist`, and save the file with this content:

```
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE plist PUBLIC "-//Apple//DTD PLIST 1.0//EN" "http://www.apple.com/DTDs/PropertyList-1.0.dtd">
<plist version="1.0">
<dict>
<key>Label</key>
<string>limit.maxfiles</string>
<key>ProgramArguments</key>
<array>
<string>launchctl</string>
<string>limit</string>
<string>maxfiles</string>
<string>2048</string>
<string>4096</string>
</array>
<key>RunAtLoad</key>
<true/>
<key>ServiceIPC</key>
<false/>
</dict>
</plist>
```

2. In a terminal window, run the following command:

```
echo 'ulimit -n 2048' | sudo tee -a /etc/profile
```

3. Reboot your Mac to apply these settings.

Visual Studio for Mac

You can use any editor to develop .NET Core applications using the .NET Core SDK. However, if you want to develop .NET Core applications on a Mac in an integrated development environment, you can use [Visual Studio for Mac](#).

.NET Core development on macOS with Visual Studio for Mac requires:

- A supported version of the macOS operating system
- OpenSSL (.NET Core 1.x only; .NET Core 2.x uses security services available natively in macOS)
- .NET Core SDK for Mac
- [Visual Studio for Mac](#)

Prerequisites for .NET Core on Linux

1/26/2019 • 4 minutes to read • [Edit Online](#)

This article shows the dependencies needed to develop .NET Core applications on Linux. The supported Linux distributions/versions, and dependencies that follow apply to the two ways of developing .NET Core apps on Linux:

- [Command-line with your favorite editor](#)
- [Visual Studio Code](#)

NOTE

The .NET Core SDK package is not required for production servers/environments. Only the .NET Core runtime package is needed for apps deployed to production environments. The .NET Core runtime is deployed with apps as part of a self-contained deployment, however, it must be deployed for Framework-dependent deployed apps separately. For more information about framework-dependent and self-contained deployment types, see [.NET Core application deployment](#). Also see [Self-contained Linux applications](#) for specific guidelines.

Supported Linux versions

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)
- [.NET Core 3.0 Preview 1](#)

.NET Core 2.x treats Linux as a single operating system. There is a single Linux build (per chip architecture) for supported Linux distributions.

For download links and more information, see [.NET Core 2.2 downloads](#) or [.NET Core 2.1 downloads](#).

.NET Core 2.x is supported on the following Linux distributions/versions:

- Red Hat Enterprise Linux 7, 6 - 64-bit ([x86_64](#) or [amd64](#))
- CentOS 7 - 64-bit ([x86_64](#) or [amd64](#))
- Oracle Linux 7 - 64-bit ([x86_64](#) or [amd64](#))
- Fedora 28, 27 - 64-bit ([x86_64](#) or [amd64](#))
- Debian 9 (64-bit, [arm32](#)), 8.7 or later versions - 64-bit ([x86_64](#) or [amd64](#))
- Ubuntu 18.04 (64-bit, [arm32](#)), 16.04, 14.04 - 64-bit ([x86_64](#) or [amd64](#))
- Linux Mint 18, 17 - 64-bit ([x86_64](#) or [amd64](#))
- openSUSE 42.3 or later versions - 64-bit ([x86_64](#) or [amd64](#))
- SUSE Enterprise Linux (SLES) 12 Service Pack 2 or later - 64-bit ([x86_64](#) or [amd64](#))
- Alpine Linux 3.7 or later versions - 64-bit ([x86_64](#) or [amd64](#))

See [.NET Core 2.1 Supported OS Versions](#) and [.NET Core 2.2 Supported OS Versions](#) for the complete list of .NET Core 2.1 and .NET Core 2.2 supported operating systems, distributions and versions, out of support OS versions, and lifecycle policy links.

Linux distribution dependencies

The following are intended to be examples. The exact versions and names may vary slightly on your Linux

distribution of choice.

Ubuntu

Ubuntu distributions require the following libraries installed:

- libltng-ust0
- libcurl3 (for 14.x and 16.x)
- libcurl4 (for 18.x)
- libssl1.0.0
- libkrb5-3
- zlib1g
- libicu52 (for 14.x)
- libicu55 (for 16.x)
- libicu57 (for 17.x)
- libicu60 (for 18.x)

For versions earlier than .NET Core 2.1, following dependencies are also required:

- libunwind8
- libuuid1

CentOS and Fedora

CentOS distributions require the following libraries installed:

- ltng-ust
- libcurl
- openssl-libs
- krb5-libs
- libicu
- zlib

Fedora users: If your openssl's version >= 1.1, you'll need to install compat-openssl10.

For versions earlier than .NET Core 2.1, following dependencies are also required:

- libunwind
- libuid

For more information about the dependencies, see [Self-contained Linux applications](#).

Installing .NET Core dependencies with the native installers

.NET Core native installers are available for supported Linux distributions/versions. The native installers require admin (sudo) access to the server. The advantage of using a native installer is that all of the .NET Core native dependencies are installed. Native installers also install the .NET Core SDK system-wide.

On Linux, there are two installer package choices:

- Using a feed-based package manager, such as apt-get for Ubuntu, or yum for CentOS/RHEL.
- Using the packages themselves, DEB or RPM.

Scripting Installs with the .NET Core installer script

The [dotnet-install scripts](#) are used to perform a non-admin install of the CLI toolchain and the shared runtime. You can download the script from <https://dot.net/v1/dotnet-install.sh>.

The script defaults to installing the latest "LTS" version, which is currently .NET Core 1.1. To install .NET Core 2.1, run the script with the following switch:

```
./dotnet-install.sh -c Current
```

The installer bash script is used in automation scenarios and non-admin installations. This script also reads PowerShell switches, so they can be used with the script on Linux/OS X systems.

Troubleshoot

If you have problems with a .NET Core installation on a supported Linux distribution/version, consult the following topics for your installed distributions/versions:

- [.NET Core 3.0 known issues](#)
- [.NET Core 2.2 known issues](#)
- [.NET Core 2.1 known issues](#)
- [.NET Core 1.1 known issues](#)
- [.NET Core 1.0 known issues](#)

What's new in .NET Core

2/7/2019 • 2 minutes to read • [Edit Online](#)

This page provides a summary of new features in each release of .NET Core starting with .NET Core 2.0. The following links provide detailed information on the major features added in each release.

- [.NET Core 3.0 \(Preview 2\)](#)
- [.NET Core 2.2](#)
- [.NET Core 2.1](#)
- [.NET Core 2.0](#)

See also

- [What's new in ASP.NET Core 2.0](#)

What's new in .NET Core 3.0 (Preview 2)

3/8/2019 • 23 minutes to read • [Edit Online](#)

This article describes what is new in .NET Core 3.0 (preview 2). One of the biggest enhancements is support for Windows desktop applications (Windows only). By utilizing a .NET Core 3.0 SDK component called Windows Desktop, you can port your Windows Forms and Windows Presentation Foundation (WPF) applications. To be clear, the Windows Desktop component is only supported and included on Windows. For more information, see the section [Windows desktop](#) below.

.NET Core 3.0 adds support for C# 8.0.

[Download and get started with .NET Core 3.0 Preview 2](#) right now on Windows, Mac and Linux. You can see complete details of the release in the [.NET Core 3.0 Preview 2 release notes](#).

For more information about what was released with each version, see the following announcements:

- [.NET Core 3.0 Preview 1 announcement](#)
- [.NET Core 3.0 Preview 2 announcement](#)

C# 8

.NET Core 3.0 supports C# 8, and as of .NET Core 3.0 Preview 2, supports these new features. For more information about C# 8.0 features, see the following blog posts:

- [Do more with patterns in C# 8.0](#)
- [Take C# 8.0 for a spin](#)
- [Building C# 8.0](#)

Ranges and indices

The new `Index` type can be used for indexing. You can create one from an `int` that counts from the beginning, or with a prefix `^` operator (C#) that counts from the end:

```
Index i1 = 3; // number 3 from beginning
Index i2 = ^4; // number 4 from end
int[] a = { 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 };
Console.WriteLine($"{a[i1]}, {a[i2]}"); // "3, 6"
```

There is also a `Range` type, which consists of two `Index` values, one for the start and one for the end, and can be written with a `x..y` range expression (C#). You can then index with a `Range` in order to produce a slice:

```
var slice = a[i1..i2]; // { 3, 4, 5 }
```

Async streams

The `IAsyncEnumerable<T>` type is a new asynchronous version of `IEnumerable<T>`. The language lets you `await foreach` over `IAsyncEnumerable<T>` to consume their elements, and use `yield return` to them to produce elements.

The following example demonstrates both production and consumption of async streams. The `foreach` statement is async and itself uses `yield return` to produce an async stream for callers. This pattern (using `yield return`) is the recommended model for producing async streams.

```

async IAsyncEnumerable<int> GetBigResultsAsync()
{
    await foreach (var result in GetResultsAsync())
    {
        if (result > 20) yield return result;
    }
}

```

In addition to being able to `await foreach`, you can also create async iterators, for example, an iterator that returns an `IAsyncEnumerable/IAsyncEnumerator` that you can both `await` and `yield` in. For objects that need to be disposed, you can use `IAsyncDisposable`, which various BCL types implement, such as `Stream` and `Timer`.

NOTE

You need .NET Core 3.0 Preview 2 to use async streams if you want to develop with either Visual Studio 2019 Preview 2 or the latest preview of the [C# extension for Visual Studio Code](#). If you are using .NET Core 3.0 Preview 2 at the command line, then everything will work as expected.

Using Declarations

Using declarations are a new way to ensure your object is properly disposed. A *using declaration* keeps the object alive while it is still in scope. Once the object becomes out of scope, it is automatically disposed. This will reduce nested *using statements* and make your code cleaner.

```

static void Main(string[] args)
{
    using var options = Parse(args);
    if (options["verbose"]) { WriteLine("Logging..."); }

} // options disposed here

```

Switch Expressions

Switch expressions are a cleaner way of doing a *switch statement* but, since it's an expression, returns a value. *Switch expressions* are also fully integrated with pattern matching, and use the discard pattern, `_`, to represent the `default` value.

You can see the syntax for *switch expressions* in the following example:

```

static string Display(object o) => o switch
{
    Point { X: 0, Y: 0 }      => "origin",
    Point { X: var x, Y: var y } => $"({x}, {y})",
    _                         => "unknown"
};

```

There are two patterns at play in this example. `o` first matches with the `Point` type pattern and then with the property pattern inside the curly braces. The `_` describes the discard pattern, which is the same as `default` for *switch statements*.

Patterns enable you to write declarative code that captures your intent instead of procedural code that implements tests for it. The compiler becomes responsible for implementing that boring procedural code and is guaranteed to always do it correctly.

There will still be cases where *switch statements* will be a better choice than *switch expressions* and patterns can be used with both syntax styles.

For more information, see [Do more with patterns in C# 8.0](#).

IEEE Floating-point improvements

Floating point APIs are in the process of being updated to comply with [IEEE 754-2008 revision](#). The goal of these changes is to expose all "required" operations and ensure that they are behaviorally compliant with the IEEE spec.

Parsing and formatting fixes:

- Correctly parse and round inputs of any length.
- Correctly parse and format negative zero.
- Correctly parse Infinity and NaN by performing a case-insensitive check and allowing an optional preceding `+` where applicable.

New Math APIs have:

- `BitIncrement/BitDecrement`
Corresponds to the `nextUp` and `nextDown` IEEE operations. They return the smallest floating-point number that compares greater or lesser than the input (respectively). For example, `Math.BitIncrement(0.0)` would return `double.Epsilon`.
- `MaxMagnitude/MinMagnitude`
Corresponds to the `maxNumMag` and `minNumMag` IEEE operations, they return the value that is greater or lesser in magnitude of the two inputs (respectively). For example, `Math.MaxMagnitude(2.0, -3.0)` would return `-3.0`.
- `ILogB`
Corresponds to the `logB` IEEE operation which returns an integral value, it returns the integral base-2 log of the input parameter. This is effectively the same as `floor(log2(x))`, but done with minimal rounding error.
- `ScaleB`
Corresponds to the `scaleB` IEEE operation which takes an integral value, it returns effectively `x * pow(2, n)`, but is done with minimal rounding error.
- `Log2`
Corresponds to the `log2` IEEE operation, it returns the base-2 logarithm. It minimizes rounding error.
- `FusedMultiplyAdd`
Corresponds to the `fma` IEEE operation, it performs a fused multiply add. That is, it does `(x * y) + z` as a single operation, there-by minimizing the rounding error. An example would be
`FusedMultiplyAdd(1e308, 2.0, -1e308)` which returns `1e308`. The regular `(1e308 * 2.0) - 1e308` returns `double.PositiveInfinity`.
- `CopySign`
Corresponds to the `copySign` IEEE operation, it returns the value of `x`, but with the sign of `y`.

.NET Platform Dependent Intrinsics

APIs have been added that allow access to certain perf-oriented CPU instructions, such as the **SIMD** or **Bit Manipulation instruction** sets. These instructions can help achieve big performance improvements in certain scenarios, such as processing data efficiently in parallel. In addition to exposing the APIs for your programs to use, the .NET libraries have begun using these instructions to improve performance.

The following CoreCLR PRs demonstrate a few of the intrinsics, either via implementation or use:

- [Implement simple SSE2 hardware intrinsics](#)
- [Implement the SSE hardware intrinsics](#)
- [Arm64 Base HW Intrinsics](#)
- [Use TZCNT and LZCNT for Locate{First|Last}Found{Byte|Char}](#)

For more information, see [.NET Platform Dependent Intrinsics](#), which defines an approach for defining this hardware infrastructure, allowing Microsoft, chip vendors, or any other company or individual to define hardware/chip APIs that should be exposed to .NET code.

Default executables

.NET Core will now build [framework-dependent executables](#) by default. This is new for applications that use a globally installed version of .NET Core. Until now, only [self-contained deployments](#) would produce an executable.

During `dotnet build` or `dotnet publish`, an executable is created provided that matches the environment and platform of the SDK you are using. You can expect the same things with these executables as you would other native executables, such as:

- You can double-click on the executable.
- You can launch the application from a command prompt directly, such as `myapp.exe` on Windows, and `./myapp` on Linux and macOS.

Build copies dependencies

`dotnet build` now copies NuGet dependencies for your application from the NuGet cache to the build output folder. Previously, dependencies were only copied as part of `dotnet publish`.

There are some operations, like linking and razor page publishing that will still require publishing.

Local dotnet tools

WARNING

There was a change in .NET Core Local Tools between .NET Core 3.0 Preview 1 and .NET Core 3.0 Preview 2. If you tried out local tools in Preview 1 by running a command like `dotnet tool restore` or `dotnet tool install`, you need to delete your local tools cache folder before local tools will work correctly in Preview 2. This folder is located at:

On mac, Linux: `rm -r $HOME/.dotnet/toolResolverCache`

On Windows: `rmdir /s %USERPROFILE%\.dotnet\toolResolverCache`

If you do not delete this folder, you will receive an error.

While .NET Core 2.1 supported global tools, .NET Core 3.0 now has local tools. Local tools are similar to global tools but are associated with a particular location on disk. This enables per-project and per-repository tooling. Any tool installed locally isn't available globally. Tools are distributed as NuGet packages.

Local tools rely on a manifest file name `dotnet-tools.json` in your current directory. This manifest file defines the tools to be available at that folder and below. By creating this manifest file at the root of your repository, you ensure anyone cloning your code can restore and use the tools that are needed to successfully work with your code.

To create a `dotnet-tools.json` manifest file, use:

```
dotnet new tool-manifest
```

Add a new tool to the local manifest with:

```
dotnet tool install <packageId>
```

You can also list the tools in the local manifest with:

```
dotnet tool list
```

To see what tools are installed globally, use:

```
dotnet tool list -g
```

When the local tools manifest file is available, but the tools defined in the manifest have not been installed, use the following command to automatically download and install those tools:

```
dotnet tool restore
```

Run a local tool with the following command:

```
dotnet tool run <tool-command-name>
```

When a local tool is run, dotnet searches for a manifest up the current directory structure. When a tool manifest file is found, it is searched for the requested tool. If the tool is found in the manifest, but not the cache, the user receives an error and needs to run `dotnet tool restore`.

To remove a tool from the local tool manifest file, run the following command:

```
dotnet tool uninstall <packageId>
```

The tool manifest file is designed to allow hand editing – which you might do to update the required version for working with the repository. Here is an example `dotnet-tools.json` file:

```
{
  "version": 1,
  "isRoot": true,
  "tools": {
    "dotnetsay": {
      "version": "2.1.4",
      "commands": [
        "dotnetsay"
      ]
    },
    "t-rex": {
      "version": "1.0.103",
      "commands": [
        "t-rex"
      ]
    }
  }
}
```

For both global and local tools, a compatible version of the runtime is required. Many tools currently on NuGet.org target .NET Core Runtime 2.1. To install those globally or locally, you would still need to install the [NET Core 2.1 Runtime](#).

Windows desktop

Starting with .NET Core 3.0 Preview 1, you can build Windows desktop applications using WPF and Windows Forms. These frameworks also support using modern controls and Fluent styling from the Windows UI XAML Library (WinUI) via [XAML islands](#).

The Windows Desktop component is part of the Windows .NET Core 3.0 SDK.

You can create a new WPF or Windows Forms app with the following `dotnet` commands:

```
dotnet new wpf  
dotnet new winforms
```

Visual Studio 2019 Preview 2 adds **New Project** templates for .NET Core 3.0 Windows Forms and WPF.

Designers are still not yet supported. And you can open, launch, and debug these projects in Visual Studio 2019.

Visual Studio 2017 15.9 adds the ability to [enable .NET Core previews](#), but you need to turn that feature on, and it's not a supported scenario.

The new projects are the same as existing .NET Core projects, with a couple additions. Here is the comparison of the basic .NET Core console project and a basic Windows Forms and WPF project.

In a .NET Core console project, the project uses the `Microsoft.NET.Sdk` SDK and declares a dependency on .NET Core 3.0 via the `netcoreapp3.0` target framework. To create a Windows Desktop app, use the

`Microsoft.NET.Sdk.WindowsDesktop` SDK and choose which UI framework to use:

```
-<Project Sdk="Microsoft.NET.Sdk">  
+<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">  
  <PropertyGroup>  
    <OutputType>Exe</OutputType>  
    <TargetFramework>netcoreapp3.0</TargetFramework>  
  +  <UseWPF>true</UseWPF>  
  </PropertyGroup>  
</Project>
```

To choose Windows Forms over WPF, set `UseWindowsForms` instead of `UseWPF`:

```
<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">  
  <PropertyGroup>  
    <OutputType>Exe</OutputType>  
    <TargetFramework>netcoreapp3.0</TargetFramework>  
  -  <UseWPF>true</UseWPF>  
  +  <UseWindowsForms>true</UseWindowsForms>  
  </PropertyGroup>  
</Project>
```

Both `useWPF` and `UseWindowsForms` can be set to `true` if the app uses both frameworks, for example when a Windows Forms dialog is hosting a WPF control.

Please share your feedback on the [dotnet/winforms](#), [dotnet/wpf](#) and [dotnet/core](#) repos.

MSIX Deployment for Windows Desktop

[MSIX](#) is a new Windows app package format. It can be used to deploy .NET Core 3.0 desktop applications to Windows 10.

The [Windows Application Packaging Project](#), available in Visual Studio 2019 Preview 2, allows you to create MSIX packages with [self-contained](#) .NET Core applications.

Note: The .NET Core project file must specify the supported runtimes in the `<RuntimeIdentifiers>` property:

```
<RuntimeIdentifiers>win-x86;win-x64</RuntimeIdentifiers>
```

Fast built-in JSON support

The .NET ecosystem has relied on [Json.NET](#) and other popular JSON libraries, which continue to be good choices. **Json.NET** uses .NET strings as its base datatype, which are UTF-16 under the hood.

The new built-in JSON support is high-performance, low allocation, and based on `Span<byte>`. Three new main JSON-related types have been added to .NET Core 3.0 the `System.Text.Json` namespace.

Utf8JsonReader

`System.Text.Json.Utf8JsonReader` is a high-performance, low allocation, forward-only reader for UTF-8 encoded JSON text, read from a `ReadOnlySpan<byte>`. The `Utf8JsonReader` is a foundational, low-level type, that can be leveraged to build custom parsers and deserializers. Reading through a JSON payload using the new `Utf8JsonReader` is 2x faster than using the reader from **Json.NET**. It does not allocate until you need to actualize JSON tokens as (UTF-16) strings.

This new API will include the following components:

- In Preview 1: JSON reader (sequential access)
- Coming next: JSON writer, DOM (random access), poco serializer, poco deserializer

Here is the basic reader loop for the `Utf8JsonReader` that can be used as a starting point:

```

using System.Text.Json;

public static void Utf8JsonReaderLoop(ReadOnlySpan<byte> dataUtf8)
{
    var json = new Utf8JsonReader(dataUtf8, isFinalBlock: true, state: default);

    while (json.Read())
    {
        JsonTokenType tokenType = json.TokenType;
        ReadOnlySpan<byte> valueSpan = json.ValueSpan;
        switch (tokenType)
        {
            case JsonTokenType.StartObject:
            case JsonTokenType.EndObject:
                break;
            case JsonTokenType.StartArray:
            case JsonTokenType.EndArray:
                break;
            case JsonTokenType.PropertyName:
                break;
            case JsonTokenType.String:
                string valueString = json.GetStringValue();
                break;
            case JsonTokenType.Number:
                if (!json.TryGetInt32Value(out int valueInteger))
                {
                    throw new FormatException();
                }
                break;
            case JsonTokenType.True:
            case JsonTokenType.False:
                bool valueBool = json.GetBooleanValue();
                break;
            case JsonTokenType.Null:
                break;
            default:
                throw new ArgumentException();
        }
    }

    dataUtf8 = dataUtf8.Slice((int)json.BytesConsumed);
    JsonReaderState state = json.CurrentState;
}

```

Utf8JsonWriter

`System.Text.Json.Utf8JsonWriter` provides a high-performance, non-cached, forward-only way to write UTF-8 encoded JSON text from common .NET types like `String`, `Int32`, and `DateTime`. Like the reader, the writer is a foundational, low-level type, that can be leveraged to build custom serializers. Writing a JSON payload using the new `Utf8JsonWriter` is 30-80% faster than using the writer from **Json.NET** and does not allocate.

Here is a sample usage of the `Utf8JsonWriter` that can be used as a starting point:

```

static int WriteJson(IBufferWriter<byte> output, long[] extraData)
{
    var json = new Utf8JsonWriter(output, state: default);

    json.WriteStartObject();

    json.WriteNumber("age", 15, escape: false);
    json.WriteString("date", DateTime.Now);
    json.WriteString("first", "John");
    json.WriteString("last", "Smith");

    json.WriteStartArray("phoneNumbers", escape: false);
    json.WriteStringValue("425-000-1212", escape: false);
    json.WriteStringValue("425-000-1213");
    json.WriteEndArray();

    json.WriteStartObject("address");
    json.WriteString("street", "1 Microsoft Way");
    json.WriteString("city", "Redmond");
    json.WriteNumber("zip", 98052);
    json.WriteEndObject();

    json.WriteStartArray("ExtraArray");
    for (var i = 0; i < extraData.Length; i++)
    {
        json.WriteNumberValue(extraData[i]);
    }
    json.WriteEndArray();

    json.WriteEndObject();

    json.Flush(isFinalBlock: true);

    return (int)json.BytesWritten;
}

```

The `Utf8JsonWriter` accepts `IBufferWriter<byte>` as the output location to synchronously write the json data into, and you as the caller need to provide a concrete implementation. The platform does not currently include an implementation of this interface. For an example of `IBufferWriter<byte>`, see <https://gist.github.com/ahsonkhan/c76a1cc4dc7107537c3fd0079a68b35>

JsonDocument

`System.Text.Json.JsonDocument` is built on top of the `Utf8JsonReader`. The `JsonDocument` provides the ability to parse JSON data and build a read-only Document Object Model (DOM) that can be queried to support random access and enumeration. The JSON elements that compose the data can be accessed via the `JsonElement` type which is exposed by the `JsonDocument` as a property called `RootElement`. The `JsonElement` contains the JSON array and object enumerators along with APIs to convert JSON text to common .NET types. Parsing a typical JSON payload and accessing all its members using the `JsonDocument` is 2-3x faster than **Json.NET** with very little allocations for data that is reasonably sized (i.e. < 1 MB).

Here is a sample usage of the `JsonDocument` and `JsonElement` that can be used as a starting point:

```

static double ParseJson()
{
    const string json = " [ { \"name\": \"John\" }, [ \"425-000-1212\", 15 ], { \"grades\": [ 90, 80, 100, 75 ] } ]";

    double average = -1;

    using (JsonDocument doc = JsonDocument.Parse(json))
    {
        JsonElement root = doc.RootElement;
        JsonElement info = root[1];

        string phoneNumber = info[0].GetString();
        int age = info[1].GetInt32();

        JsonElement grades = root[2].GetProperty("grades");

        double sum = 0;
        foreach (JsonElement grade in grades.EnumerateArray())
        {
            sum += grade.GetInt32();
        }

        int numberOfCourses = grades.GetArrayLength();
        average = sum / numberOfCourses;
    }

    return average;
}

```

Assembly Unloadability

Assembly unloadability is a new capability of `AssemblyLoadContext`. This new feature is largely transparent from an API perspective, exposed with just a few new APIs. It enables a loader context to be unloaded, releasing all memory for instantiated types, static fields and for the assembly itself. An application should be able to load and unload assemblies via this mechanism forever without experiencing a memory leak.

This new capability can be used for scenarios similar to:

- Plugin scenarios where dynamic plugin loading and unloading is required.
- Dynamically compiling, running and then flushing code. Useful for web sites, scripting engines, etc.
- Loading assemblies for introspection (like `ReflectionOnlyLoad`), although `MetadataLoadContext` (released in Preview 1) will be a better choice in many cases.

For more information, see the [Using Unloadability](#) document.

Assembly unloading requires significant care to ensure that all references to managed objects from outside a loader context are understood and managed. When the loader context is requested to be unloaded, any outside references need to have been unreferenced so that the loader context is self-consistent only to itself.

Assembly unloadability was provided in the .NET Framework by Application Domains (AppDomains), which are not supported with .NET Core. AppDomains had both benefits and limitations compared to this new model. Consider this new loader model to be more flexible and higher performant when compared to AppDomains.

Windows Native Interop

Windows offers a rich native API, in the form of flat C APIs, COM, and WinRT. Since .NET Core 1.0, **P/Invoke** has been supported. Now with .NET Core 3.0, support for the ability to **CoCreate COM APIs** and **Activate WinRT APIs** has been added.

You can see an example of using COM with the [Excel Demo source code](#).

Type: SequenceReader

In .NET Core 3.0, `System.Buffers.SequenceReader` has been added which can be used as a reader for `ReadOnlySequence<T>`. This allows easy, high performance, low allocation parsing of `System.IO.Pipelines` data that can cross multiple backing buffers.

The following example breaks an input `Sequence` into valid `CR/LF` delimited lines:

```
private static ReadOnlySpan<byte> CRLF => new byte[] { (byte)'\r', (byte)'\n' };

public static void ReadLines(ReadOnlySequence<byte> sequence)
{
    SequenceReader<byte> reader = new SequenceReader<byte>(sequence);

    while (!reader.End)
    {
        if (!reader.TryReadToAny(out ReadOnlySpan<byte> line, CRLF, advancePastDelimiter:false))
        {
            // Couldn't find another delimiter
            // ...
        }

        if (!reader.IsNext(CRLF, advancePast: true))
        {
            // Not a good CR/LF pair
            // ...
        }

        // line is valid, process
        ProcessLine(line);
    }
}
```

Type: MetadataLoadContext

The `MetadataLoadContext` type has been added that enables reading assembly metadata without affecting the caller's application domain. Assemblies are read as data, including assemblies built for different architectures and platforms than the current runtime environment. `MetadataLoadContext` overlaps with the `ReflectionOnlyLoad`, which is only available in the .NET Framework.

`MetadataLoadContext` is available in the [System.Reflection.MetadataLoadContext package](#). It is a .NET Standard 2.0 package.

The `MetadataLoadContext` exposes APIs similar to the `AssemblyLoadContext` type, but is not based on that type. Much like `AssemblyLoadContext`, the `MetadataLoadContext` enables loading assemblies within an isolated assembly loading universe. `MetadataLoadContext` APIs return `Assembly` objects, enabling the use of familiar reflection APIs. Execution-oriented APIs, such as `MethodBase.Invoke`, are not allowed and will throw `InvalidOperationException`.

The following sample demonstrates how to find concrete types in an assembly that implements a given interface:

```

var paths = new string[] {@"C:\myapp\mscorlib.dll", @"C:\myapp\myapp.dll"};
var resolver = new PathAssemblyResolver(paths);
using (var lc = new MetadataLoadContext(resolver))
{
    Assembly a = lc.LoadFromAssemblyName("myapp");
    Type myInterface = a.GetType("MyApp.IPluginInterface");
    foreach (Type t in a.GetTypes())
    {
        if (t.IsClass && myInterface.IsAssignableFrom(t))
            Console.WriteLine($"Class {t.FullName} implements IPluginInterface");
    }
}

```

Scenarios for `MetadataLoadContext` include design-time features, build-time tooling, and runtime light-up features that need to inspect a set of assemblies as data and have all file locks and memory freed after inspection is performed.

The `MetadataLoadContext` has a resolver class passed to its constructor. The resolver's job is to load an `Assembly` given its `AssemblyName`. The resolver class derives from the abstract `MetadataAssemblyResolver` class. An implementation of the resolver for path-based scenarios is provided with `PathAssemblyResolver`.

The [MetadataLoadContext tests](#) demonstrate many use cases. The [Assembly tests](#) are a good place to start.

TLS 1.3 & OpenSSL 1.1.1 on Linux

.NET Core will now take advantage of [TLS 1.3 support in OpenSSL 1.1.1](#), when it is available in a given environment. There are multiple benefits of TLS 1.3, per the [OpenSSL team](#):

- Improved connection times due to a reduction in the number of round trips required between the client and server.
- Improved security due to the removal of various obsolete and insecure cryptographic algorithms and encryption of more of the connection handshake.

.NET Core 3.0 Preview 1 is capable of utilizing **OpenSSL 1.1.1**, **OpenSSL 1.1.0**, or **OpenSSL 1.0.2** (whatever the best version found is, on a Linux system). When **OpenSSL 1.1.1** is available the `SslStream` and `HttpClient` types will use **TLS 1.3** when using `SslProtocols.None` (system default protocols), assuming both the client and server support **TLS 1.3**.

The following sample demonstrates .NET Core 3.0 Preview 1 on Ubuntu 18.10 connecting to <https://www.cloudflare.com>:

```

using System;
using System.Net.Security;
using System.Net.Sockets;
using System.Threading.Tasks;

namespace tlstest
{
    class Program
    {
        static async Task Main()
        {
            using (TcpClient tcpClient = new TcpClient())
            {
                string targetHost = "www.cloudflare.com";

                await tcpClient.ConnectAsync(targetHost, 443);

                using (SslStream sslStream = new SslStream(tcpClient.GetStream()))
                {
                    await sslStream.AuthenticateAsClientAsync(targetHost);
                    await Console.Out.WriteLineAsync($"Connected to {targetHost} with
{sslStream.SslProtocol}");
                }
            }
        }
    }
}

```

```

user@comp-ubuntu1810:~/tlstest$ dotnet run
Connected to www.cloudflare.com with Tls13
user@comp-ubuntu1810:~/tlstest$ openssl version
OpenSSL 1.1.1  11 Sep 2018

```

IMPORTANT

Windows and macOS do not yet support **TLS 1.3**. .NET Core 3.0 will support **TLS 1.3** on these operating systems when support becomes available.

Cryptography

Support has been added for **AES-GCM** and **AES-CCM** ciphers, implemented via

`System.Security.Cryptography.AesGcm` and `System.Security.Cryptography.AesCcm`. These algorithms are both [Authenticated Encryption with Association Data \(AEAD\) algorithms](#), and the first Authenticated Encryption (AE) algorithms added to .NET Core.

The following code demonstrates using **AesGcm** cipher to encrypt and decrypt random data.

The code for **AesCcm** would look almost identical (only the class variable names would be different).

```

// key should be: pre-known, derived, or transported via another channel, such as RSA encryption
byte[] key = new byte[16];
RandomNumberGenerator.Fill(key);

byte[] nonce = new byte[12];
RandomNumberGenerator.Fill(nonce);

// normally this would be your data
byte[] dataToEncrypt = new byte[1234];
byte[] associatedData = new byte[333];
RandomNumberGenerator.Fill(dataToEncrypt);
RandomNumberGenerator.Fill(associatedData);

// these will be filled during the encryption
byte[] tag = new byte[16];
byte[] ciphertext = new byte[dataToEncrypt.Length];

using (AesGcm aesGcm = new AesGcm(key))
{
    aesGcm.Encrypt(nonce, dataToEncrypt, ciphertext, tag, associatedData);
}

// tag, nonce, ciphertext, associatedData should be sent to the other part

byte[] decryptedData = new byte[ciphertext.Length];

using (AesGcm aesGcm = new AesGcm(key))
{
    aesGcm.Decrypt(nonce, ciphertext, tag, decryptedData, associatedData);
}

// do something with the data
// this should always print that data is the same
Console.WriteLine($"AES-GCM: Decrypted data is {(dataToEncrypt.SequenceEqual(decryptedData) ? "the same as" : "different than")} original data.");

```

Cryptographic Key Import/Export

.NET Core 3.0 Preview 1 supports the import and export of asymmetric public and private keys from standard formats, without needing to use an X.509 certificate.

All key types (RSA, DSA, ECDsa, ECDiffieHellman) support the **X.509 SubjectPublicKeyInfo** format for public keys, and the **PKCS#8 PrivateKeyInfo** and **PKCS#8 EncryptedPrivateKeyInfo** formats for private keys. RSA additionally supports **PKCS#1 RSAPublicKey** and **PKCS#1 RSAPrivatekey**. The export methods all produce DER-encoded binary data, and the import methods expect the same. If a key is stored in the text-friendly PEM format, the caller will need to base64-decode the content before calling an import method.

```

using System;
using System.IO;
using System.Security.Cryptography;

namespace rsakeyprint
{
    class Program
    {
        static void Main(string[] args)
        {
            using (RSA rsa = RSA.Create())
            {
                byte[] keyBytes = File.ReadAllBytes(args[0]);
                rsa.ImportRSAPrivateKey(keyBytes, out int bytesRead);

                Console.WriteLine($"Read {bytesRead} bytes, {keyBytes.Length-bytesRead} extra byte(s) in
file.");
                RSAParameters rsaParameters = rsa.ExportParameters(true);
                Console.WriteLine(BitConverter.ToString(rsaParameters.D));
            }
        }
    }
}

```

```

user@comp-ubuntu1810:~/rsakeyprint$ echo Making a small key to save on screen space.

```

PKCS#8 files can be inspected with the `System.Security.Cryptography.Pkcs.Pkcs8PrivateKeyInfo` class.

PFX/PKCS#12 files can be inspected and manipulated with `System.Security.Cryptography.Pkcs.Pkcs12Info` and `System.Security.Cryptography.Pkcs.Pkcs12Builder`, respectively.

SerialPort for Linux

.NET Core 3.0 now supports `System.IO.Ports.SerialPort` on Linux.

Previously, .NET Core only supported using the `SerialPort` type on Windows.

More BCL Improvements

The `Span<T>`, `Memory<T>`, and related types that were introduced in .NET Core 2.1, have been optimized in .NET

Core 3.0. Common operations such as span construction, slicing, parsing, and formatting now perform better.

Additionally, types like `String` have seen under-the-cover improvements to make them more efficient when used as keys with `Dictionary< TKey, TValue >` and other collections. No code changes are required to benefit from these improvements.

The following improvements are also new in .NET Core 3 Preview 1:

- Brotli support built in to `HttpClient`
- `ThreadPool.UnsafeQueueWorkItem(IThreadPoolWorkItem)`
- `Unsafe.Unbox`
- `CancellationToken.Unregister`
- Complex arithmetic operators
- Socket APIs for TCP keep alive
- `StringBuilder.GetChunks`
- `IPEndPoint` parsing
- `RandomNumberGenerator.GetInt32`

Tiered compilation

[Tiered compilation](#) is on by default with .NET Core 3.0. It is a feature that enables the runtime to more adaptively use the Just-In-Time (JIT) compiler to get better performance, both at startup and to maximize throughput.

This feature was added as an opt-in feature in [.NET Core 2.1](#) and then was enabled by default in [.NET Core 2.2 Preview 2](#). Subsequently, it has been reverted back to opt in with the .NET Core 2.2 release.

ARM64 Linux support

Support has been added for ARM64 for Linux. The primary use case for ARM64 is currently with IoT scenarios.

Alpine, Debian and Ubuntu Docker images are available for [.NET Core for ARM64](#).

Please check [.NET Core ARM64 Status](#) for more information.

NOTE

ARM64 Windows support isn't yet available.

Install .NET Core 3.0 Previews on Linux with Snap

Snap is the preferred way to install and try .NET Core previews on [Linux distributions that support Snap](#).

After configuring Snap on your system, run the following command to install the [.NET Core SDK 3.0 Preview SDK](#).

```
sudo snap install dotnet-sdk --beta --classic
```

When .NET Core is installed using the Snap package, the default .NET Core command is `dotnet-sdk.dotnet`, as opposed to just `dotnet`. The benefit of the namespaced command is that it will not conflict with a globally installed .NET Core version you may have. This command can be aliased to `dotnet` with:

```
sudo snap alias dotnet-sdk.dotnet dotnet
```

Some distros require an additional step to enable access to the SSL certificate. See our [Linux Setup](#) for details.

GPIO Support for Raspberry Pi

Two new packages have been released to NuGet that you can use for GPIO programming.

- [System.Device.Gpio](#)
- [IoT.Device.Bindings](#)

The GPIO Packages includes APIs for GPIO, SPI, I2C and PWM devices. The IoT bindings package includes [device bindings](#) for various chips and sensors, the same ones available at [dotnet/iot - src/devices](#).

The updated serial port APIs that were announced as part of .NET Core 3.0 Preview 1 are not part of these packages but are available as part of the .NET Core platform.

Platform Support

.NET Core 3 will be supported on the following operating systems:

- Windows Client: 7, 8.1, 10 (1607+)
- Windows Server: 2012 R2 SP1+
- macOS: 10.12+
- RHEL: 6+
- Fedora: 26+
- Ubuntu: 16.04+
- Debian: 9+
- SLES: 12+
- openSUSE: 42.3+
- Alpine: 3.8+

Chip support follows:

- x64 on Windows, macOS, and Linux
- x86 on Windows
- ARM32 on Windows and Linux
- ARM64 on Linux

For Linux, ARM32 is supported on Debian 9+ and Ubuntu 16.04+. For ARM64, it is the same as ARM32 with the addition of Alpine 3.8. These are the same versions of those distros as is supported for X64.

Docker images for .NET Core 3.0 are available at [microsoft/dotnet on Docker Hub](#). Microsoft is currently in the process of adopting [Microsoft Container Registry \(MCR\)](#) and it is expected that the final .NET Core 3.0 images will only be published to MCR.

What's new in .NET Core 2.2

3/8/2019 • 4 minutes to read • [Edit Online](#)

.NET Core 2.2 includes enhancements in application deployment, event handling for runtime services, authentication to Azure SQL databases, JIT compiler performance, and code injection prior to the execution of the `Main` method.

New deployment mode

Starting with .NET Core 2.2, you can deploy [framework-dependent executables](#), which are `.exe` files instead of `.dll` files. Functionally similar to framework-dependent deployments, framework-dependent executables (FDE) still rely on the presence of a shared system-wide version of .NET Core to run. Your app contains only your code and any third-party dependencies. Unlike framework-dependent deployments, FDEs are platform-specific.

This new deployment mode has the distinct advantage of building an executable instead of a library, which means you can run your app directly without invoking `dotnet` first.

Core

Handling events in runtime services

You may often want to monitor your application's use of runtime services, such as the GC, JIT, and ThreadPool, to understand how they impact your application. On Windows systems, this is commonly done by monitoring the ETW events of the current process. While this continues to work well, it's not always possible to use ETW if you're running in a low-privilege environment or on Linux or macOS.

Starting with .NET Core 2.2, CoreCLR events can now be consumed using the [System.Diagnostics.Tracing.EventListener](#) class. These events describe the behavior of such runtime services as GC, JIT, ThreadPool, and interop. These are the same events that are exposed as part of the CoreCLR ETW provider. This allows for applications to consume these events or use a transport mechanism to send them to a telemetry aggregation service. You can see how to subscribe to events in the following code sample:

```

internal sealed class SimpleEventListener : EventListener
{
    // Called whenever an EventSource is created.
    protected override void OnEventSourceCreated(EventSource eventSource)
    {
        // Watch for the .NET runtime EventSource and enable all of its events.
        if (eventSource.Name.Equals("Microsoft-Windows-DotNETRuntime"))
        {
            EnableEvents(eventSource, EventLevel.Verbose, (EventKeywords)(-1));
        }
    }

    // Called whenever an event is written.
    protected override void OnEventWritten(EventWrittenEventArgs eventData)
    {
        // Write the contents of the event to the console.
        Console.WriteLine($"ThreadID = {eventData.OSThreadId} ID = {eventData.EventId} Name =
{eventData.EventName}");
        for (int i = 0; i < eventData.Payload.Count; i++)
        {
            string payloadString = eventData.Payload[i]?.ToString() ?? string.Empty;
            Console.WriteLine($" \tName = \"{eventData.PayloadNames[i]}\" Value = \"{payloadString}\"");
        }
        Console.WriteLine("\n");
    }
}

```

In addition, .NET Core 2.2 adds the following two properties to the [EventWrittenEventArgs](#) class to provide additional information about ETW events:

- [EventWrittenEventArgs.OSThreadId](#)
- [EventWrittenEventArgs.TimeStamp](#)

Data

AAD authentication to Azure SQL databases with the [SqlConnection.AccessToken](#) property

Starting with .NET Core 2.2, an access token issued by Azure Active Directory can be used to authenticate to an Azure SQL database. To support access tokens, the [AccessToken](#) property has been added to the [SqlConnection](#) class. To take advantage of AAD authentication, download version 4.6 of the System.Data.SqlClient NuGet package. In order to use the feature, you can obtain the access token value using the [Active Directory Authentication Library for .NET](#) contained in the [Microsoft.IdentityModel.Clients.ActiveDirectory](#) NuGet package.

JIT compiler improvements

Tiered compilation remains an opt-in feature

In .NET Core 2.1, the JIT compiler implemented a new compiler technology, *tiered compilation*, as an opt-in feature. The goal of tiered compilation is improved performance. One of the important tasks performed by the JIT compiler is optimizing code execution. For little-used code paths, however, the compiler may spend more time optimizing code than the runtime spends executing unoptimized code. Tiered compilation introduces two stages in JIT compilation:

- A **first tier**, which generates code as quickly as possible.
- A **second tier**, which generates optimized code for those methods that are executed frequently. The second tier of compilation is performed in parallel for enhanced performance.

For information on the performance improvement that can result from tiered compilation, see [Announcing .NET](#)

Core 2.2 Preview 2.

In .NET Core 2.2 Preview 2, tiered compilation was enabled by default. However, we've decided that we are still not ready to enable tiered compilation by default. So in .NET Core 2.2, tiered compilation continues to be an opt-in feature. For information on opting in to tiered compilation, see [Jit compiler improvements](#) in [What's new in .NET Core 2.1](#).

Runtime

Injecting code prior to executing the Main method

Starting with .NET Core 2.2, you can use a startup hook to inject code prior to running an application's Main method. Startup hooks make it possible for a host to customize the behavior of applications after they have been deployed without needing to recompile or change the application.

We expect hosting providers to define custom configuration and policy, including settings that potentially influence the load behavior of the main entry point, such as the [System.Runtime.Loader.AssemblyLoadContext](#) behavior. The hook can be used to set up tracing or telemetry injection, to set up callbacks for handling, or to define other environment-dependent behavior. The hook is separate from the entry point, so that user code doesn't need to be modified.

See [Host startup hook](#) for more information.

What's new in .NET Core 2.1

2/28/2019 • 9 minutes to read • [Edit Online](#)

.NET Core 2.1 includes enhancements and new features in the following areas:

- [Tooling](#)
- [Roll forward](#)
- [Deployment](#)
- [Windows Compatibility Pack](#)
- [JIT compilation improvements](#)
- [API changes](#)

Tooling

The .NET Core 2.1 SDK (v 2.1.300), the tooling included with .NET Core 2.1, includes the following changes and enhancements:

Build performance improvements

A major focus of .NET Core 2.1 is improving build-time performance, particularly for incremental builds. These performance improvements apply to both command-line builds using `dotnet build` and to builds in Visual Studio. Some individual areas of improvement include:

- For package asset resolution, resolving only assets used by a build rather than all assets.
- Caching of assembly references.
- Use of long-running SDK build servers, which are processes that span across individual `dotnet build` invocations. They eliminate the need to JIT-compile large blocks of code every time `dotnet build` is run. Build server processes can be automatically terminated with the following command:

```
dotnet buildserver shutdown
```

New CLI commands

A number of tools that were available only on a per project basis using [DotnetCliToolReference](#) are now available as part of the .NET Core SDK. These tools include:

- `dotnet watch` provides a file system watcher that waits for a file to change before executing a designated set of commands. For example, the following command automatically rebuilds the current project and generates verbose output whenever a file in it changes:

```
dotnet watch -- --verbose build
```

Note the `--` option that precedes the `--verbose` option. It delimits the options passed directly to the `dotnet watch` command from the arguments that are passed to the child `dotnet` process. Without it, the `--verbose` option applies to the `dotnet watch` command, not the `dotnet build` command.

For more information, see [Develop ASP.NET Core apps using dotnet watch](#)

- `dotnet dev-certs` generates and manages certificates used during development in ASP.NET Core applications.

- `dotnet user-secrets` manages the secrets in a user secret store in ASP.NET Core applications.
- `dotnet sql-cache` creates a table and indexes in a Microsoft SQL Server database to be used for distributed caching.
- `dotnet ef` is a tool for managing databases, `DbContext` objects, and migrations in Entity Framework Core applications. For more information, see [EF Core .NET Command-line Tools](#).

Global Tools

.NET Core 2.1 supports *Global Tools* -- that is, custom tools that are available globally from the command line. The extensibility model in previous versions of .NET Core made custom tools available on a per project basis only by using [DotnetCliToolReference](#).

To install a Global Tool, you use the `dotnet tool install` command. For example:

```
dotnet tool install -g dotnetsay
```

Once installed, the tool can be run from the command line by specifying the tool name. For more information, see [.NET Core Global Tools overview](#).

Tool management with the `dotnet tool` command

In .NET Core 2.1 SDK, all tools operations use the `dotnet tool` command. The following options are available:

- `dotnet tool install` to install a tool.
- `dotnet tool update` to uninstall and reinstall a tool, which effectively updates it.
- `dotnet tool list` to list currently installed tools.
- `dotnet tool uninstall` to uninstall currently installed tools.

Roll forward

All .NET Core applications starting with .NET Core 2.0 automatically roll forward to the latest *minor version* installed on a system.

Starting with .NET Core 2.0, if the version of .NET Core that an application was built with is not present at runtime, the application automatically runs against the latest installed *minor version* of .NET Core. In other words, if an application is built with .NET Core 2.0, and .NET Core 2.0 is not present on the host system but .NET Core 2.1 is, the application runs with .NET Core 2.1.

IMPORTANT

This roll-forward behavior doesn't apply to preview releases. By default, it also doesn't apply to major releases, but this can be changed with the settings below.

You can modify this behavior by changing the setting for the roll-forward on no candidate shared framework. The available settings are:

- `0` - disable minor version roll-forward behavior. With this setting, an application built for .NET Core 2.0.0 will roll forward to .NET Core 2.0.1, but not to .NET Core 2.2.0 or .NET Core 3.0.0.
- `1` - enable minor version roll-forward behavior. This is the default value for the setting. With this setting, an application built for .NET Core 2.0.0 will roll forward to either .NET Core 2.0.1 or .NET Core 2.2.0, depending on which one is installed, but it will not roll forward to .NET Core 3.0.0.
- `2` - enable minor and major version roll-forward behavior. If set, even different major versions are considered,

so an application built for .NET Core 2.0.0 will roll forward to .NET Core 3.0.0.

You can modify this setting in any of three ways:

- Set the `DOTNET_ROLL_FORWARD_ON_NO_CANDIDATE_FX` environment variable to the desired value.
- Add the following line with the desired value to the `runtimeconfig.json` file:

```
"rollForwardOnNoCandidateFx" : 0
```

- When using [.NET Core CLI tools](#), add the following option with the desired value to a .NET Core command such as `run`:

```
dotnet run --rollForwardOnNoCandidateFx=0
```

Patch version roll forward is independent of this setting and is done after any potential minor or major version roll forward is applied.

Deployment

Self-contained application servicing

`dotnet publish` now publishes self-contained applications with a serviced runtime version. When you publish a self-contained application with the .NET Core 2.1 SDK (v 2.1.300), your application includes the latest serviced runtime version known by that SDK. When you upgrade to the latest SDK, you'll publish with the latest .NET Core runtime version. This applies for .NET Core 1.0 runtimes and later.

Self-contained publishing relies on runtime versions on NuGet.org. You do not need to have the serviced runtime on your machine.

Using the .NET Core 2.0 SDK, self-contained applications are published with the .NET Core 2.0.0 runtime unless a different version is specified via the `RuntimeFrameworkVersion` property. With this new behavior, you'll no longer need to set this property to select a higher runtime version for a self-contained application. The easiest approach going forward is to always publish with .NET Core 2.1 SDK (v 2.1.300).

For more information, see [Self-contained deployment runtime roll forward](#).

Windows Compatibility Pack

When you port existing code from the .NET Framework to .NET Core, you can use the [Windows Compatibility Pack](#). It provides access to 20,000 more APIs than are available in .NET Core. These APIs include types in the `System.Drawing` namespace, the `EventLog` class, WMI, Performance Counters, Windows Services, and the Windows registry types and members.

JIT compiler improvements

.NET Core incorporates a new JIT compiler technology called *tiered compilation* (also known as *adaptive optimization*) that can significantly improve performance. Tiered compilation is an opt-in setting.

One of the important tasks performed by the JIT compiler is optimizing code execution. For little-used code paths, however, the compiler may spend more time optimizing code than the runtime spends running unoptimized code. Tiered compilation introduces two stages in JIT compilation:

- A **first tier**, which generates code as quickly as possible.
- A **second tier**, which generates optimized code for those methods that are executed frequently. The second

tier of compilation is performed in parallel for enhanced performance.

You can opt into tiered compilation in either of two ways.

- To use tiered compilation in all projects that use the .NET Core 2.1 SDK, set the following environment variable:

```
COMPlus_TieredCompilation="1"
```

- To use tiered compilation on a per-project basis, add the `<TieredCompilation>` property to the `<PropertyGroup>` section of the MSBuild project file, as the following example shows:

```
<PropertyGroup>
    <!-- other property definitions -->

    <TieredCompilation>true</TieredCompilation>
</PropertyGroup>
```

API changes

`Span<T>` and `Memory<T>`

.NET Core 2.1 includes some new types that make working with arrays and other types of memory much more efficient. The new types include:

- `System.Span<T>` and `System.ReadOnlySpan<T>`.
- `System.Memory<T>` and `System.ReadOnlyMemory<T>`.

Without these types, when passing such items as a portion of an array or a section of a memory buffer, you have to make a copy of some portion of the data before passing it to a method. These types provide a virtual view of that data that eliminates the need for the additional memory allocation and copy operations.

The following example uses a `Span<T>` and `Memory<T>` instance to provide a virtual view of 10 elements of an array.

```
using System;

class Program
{
    static void Main()
    {
        int[] numbers = new int[100];
        for (int i = 0; i < 100; i++)
        {
            numbers[i] = i * 2;
        }

        var part = new Span<int>(numbers, start: 10, length: 10);
        foreach (var value in part)
            Console.Write($"{value} ");
    }
}

// The example displays the following output:
//      20 22 24 26 28 30 32 34 36 38
```

```

Module Program
Sub Main()
    Dim numbers As Integer() = New Integer(99) {}

    For i As Integer = 0 To 99
        numbers(i) = i * 2
    Next

    Dim part = New Memory(Of Integer)(numbers, start:=10, length:=10)

    For Each value In part.Span
        Console.WriteLine($"{value} ")
    Next
End Sub
End Module
' The example displays the following output:
'      20  22  24  26  28  30  32  34  36  38

```

Brotli compression

.NET Core 2.1 adds support for Brotli compression and decompression. Brotli is a general-purpose lossless compression algorithm that is defined in [RFC 7932](#) and is supported by most web browsers and major web servers. You can use the stream-based [System.IO.Compression.BrotliStream](#) class or the high-performance span-based [System.IO.Compression.BrotliEncoder](#) and [System.IO.Compression.BrotliDecoder](#) classes. The following example illustrates compression with the [BrotliStream](#) class:

```

public static Stream DecompressWithBrotli(Stream toDecompress)
{
    MemoryStream decompressedStream = new MemoryStream();
    using (BrotliStream decompressionStream = new BrotliStream(toDecompress, CompressionMode.Decompress))
    {
        decompressionStream.CopyTo(decompressedStream);
    }
    decompressedStream.Position = 0;
    return decompressedStream;
}

```

The [BrotliStream](#) behavior is the same as [DeflateStream](#) and [GZipStream](#), which makes it easy to convert code that calls these APIs to [BrotliStream](#).

New cryptography APIs and cryptography improvements

.NET Core 2.1 includes numerous enhancements to the cryptography APIs:

- [System.Security.Cryptography.Pkcs.SignedCms](#) is available in the [System.Security.Cryptography.Pkcs](#) package. The implementation is the same as the [SignedCms](#) class in the .NET Framework.
- New overloads of the [X509Certificate.GetCertHash](#) and [X509Certificate.GetCertHashString](#) methods accept a hash algorithm identifier to enable callers to get certificate thumbprint values using algorithms other than SHA-1.
- New [Span<T>](#)-based cryptography APIs are available for hashing, HMAC, cryptographic random number generation, asymmetric signature generation, asymmetric signature processing, and RSA encryption.
- The performance of [System.Security.Cryptography.Rfc2898DeriveBytes](#) has improved by about 15% by using a [Span<T>](#)-based implementation.
- The new [System.Security.Cryptography.CryptographicOperations](#) class includes two new methods:
 - [FixedTimeEquals](#) takes a fixed amount of time to return for any two inputs of the same length, which makes it suitable for use in cryptographic verification to avoid contributing to timing side-channel

information.

- [ZeroMemory](#) is a memory-clearing routine that cannot be optimized.
- The static [RandomNumberGenerator.Fill](#) method fills a [Span<T>](#) with random values.
- The [System.Security.Cryptography.Pkcs.EnvelopedCms](#) is now supported on Linux and macOS.
- Elliptic-Curve Diffie-Hellman (ECDH) is now available in the [System.Security.Cryptography.ECDiffieHellman](#) class family. The surface area is the same as in the .NET Framework.
- The instance returned by [RSA.Create](#) can encrypt or decrypt with OAEP using a SHA-2 digest, as well as generate or validate signatures using RSA-PSS.

Sockets improvements

.NET Core includes a new type, [System.Net.Http.SocketsHttpHandler](#), and a rewritten [System.Net.Http.HttpMessageHandler](#), that form the basis of higher-level networking APIs. [System.Net.Http.SocketsHttpHandler](#), for example, is the basis of the [HttpClient](#) implementation. In previous versions of .NET Core, higher-level APIs were based on native networking implementations.

The sockets implementation introduced in .NET Core 2.1 has a number of advantages:

- A significant performance improvement when compared with the previous implementation.
- Elimination of platform dependencies, which simplifies deployment and servicing.
- Consistent behavior across all .NET Core platforms.

[SocketsHttpHandler](#) is the default implementation in .NET Core 2.1. However, you can configure your application to use the older [HttpClientHandler](#) class by calling the [AppContext.SetSwitch](#) method:

```
AppContext.SetSwitch("System.Net.Http.UseSocketsHttpHandler", false);
```

```
AppContext.SetSwitch("System.Net.Http.UseSocketsHttpHandler", False)
```

You can also use an environment variable to opt out of using sockets implementations based on [SocketsHttpHandler](#). To do this, set the `DOTNET_SYSTEM_NET_HTTP_USESOCKETSHTTPHANDLER` to either `false` or 0.

On Windows, you can also choose to use [System.Net.Http.WinHttpHandler](#), which relies on a native implementation, or the [SocketsHttpHandler](#) class by passing an instance of the class to the [HttpClient](#) constructor.

On Linux and macOS, you can only configure [HttpClient](#) on a per-process basis. On Linux, you need to deploy [libcurl](#) if you want to use the old [HttpClient](#) implementation. (It is installed with .NET Core 2.0.)

What's new in .NET Core 2.0

3/26/2019 • 6 minutes to read • [Edit Online](#)

.NET Core 2.0 includes enhancements and new features in the following areas:

- [Tooling](#)
- [Language support](#)
- [Platform improvements](#)
- [API changes](#)
- [Visual Studio integration](#)
- [Documentation improvements](#)

Tooling

dotnet restore runs implicitly

In previous versions of .NET Core, you had to run the `dotnet restore` command to download dependencies immediately after you created a new project with the `dotnet new` command, as well as whenever you added a new dependency to your project.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

You can also disable the automatic invocation of `dotnet restore` by passing the `--no-restore` switch to the `new`, `run`, `build`, `publish`, `pack`, and `test` commands.

Retargeting to .NET Core 2.0

If the .NET Core 2.0 SDK is installed, projects that target .NET Core 1.x can be retargeted to .NET Core 2.0.

To retarget to .NET Core 2.0, edit your project file by changing the value of the `<TargetFramework>` element (or the `<TargetFrameworks>` element if you have more than one target in your project file) from 1.x to 2.0:

```
<PropertyGroup>
  <TargetFramework>netcoreapp2.0</TargetFramework>
</PropertyGroup>
```

You can also retarget .NET Standard libraries to .NET Standard 2.0 the same way:

```
<PropertyGroup>
  <TargetFramework>netstandard2.0</TargetFramework>
</PropertyGroup>
```

For more information about migrating your project to .NET Core 2.0, see [Migrating from ASP.NET Core 1.x to ASP.NET Core 2.0](#).

Language support

In addition to supporting C# and F#, .NET Core 2.0 also supports Visual Basic.

Visual Basic

With version 2.0, .NET Core now supports Visual Basic 2017. You can use Visual Basic to create the following project types:

- .NET Core console apps
- .NET Core class libraries
- .NET Standard class libraries
- .NET Core unit test projects
- .NET Core xUnit test projects

For example, to create a Visual Basic "Hello World" application, do the following steps from the command line:

1. Open a console window, create a directory for your project, and make it the current directory.
2. Enter the command `dotnet new console -lang vb`.

The command creates a project file with a `.vbproj` file extension, along with a Visual Basic source code file named *Program.vb*. This file contains the source code to write the string "Hello World!" to the console window.

3. Enter the command `dotnet run`. The [.NET Core CLI](#) automatically compiles and executes the application, which displays the message "Hello World!" in the console window.

Support for C# 7.1

.NET Core 2.0 supports C# 7.1, which adds a number of new features, including:

- The `Main` method, the application entry point, can be marked with the `async` keyword.
- Inferred tuple names.
- Default expressions.

Platform improvements

.NET Core 2.0 includes a number of features that make it easier to install .NET Core and to use it on supported operating systems.

.NET Core for Linux is a single implementation

.NET Core 2.0 offers a single Linux implementation that works on multiple Linux distributions. .NET Core 1.x required that you download a distribution-specific Linux implementation.

You can also develop apps that target Linux as a single operating system. .NET Core 1.x required that you target each Linux distribution separately.

Support for the Apple cryptographic libraries

.NET Core 1.x on macOS required the OpenSSL toolkit's cryptographic library. .NET Core 2.0 uses the Apple cryptographic libraries and doesn't require OpenSSL, so you no longer need to install it.

API changes and library support

Support for .NET Standard 2.0

The .NET Standard defines a versioned set of APIs that must be available on .NET implementations that comply with that version of the standard. The .NET Standard is targeted at library developers. It aims to guarantee the functionality that is available to a library that targets a version of the .NET Standard on each .NET implementation.

.NET Core 1.x supports the .NET Standard version 1.6; .NET Core 2.0 supports the latest version, .NET Standard 2.0. For more information, see [.NET Standard](#).

.NET Standard 2.0 includes over 20,000 more APIs than were available in the .NET Standard 1.6. Much of this expanded surface area results from incorporating APIs that are common to the .NET Framework and Xamarin into .NET Standard.

.NET Standard 2.0 class libraries can also reference .NET Framework class libraries, provided that they call APIs that are present in the .NET Standard 2.0. No recompilation of the .NET Framework libraries is required.

For a list of the APIs that have been added to the .NET Standard since its last version, the .NET Standard 1.6, see [.NET Standard 2.0 vs. 1.6](#).

Expanded surface area

The total number of APIs available on .NET Core 2.0 has more than doubled in comparison with .NET Core 1.1.

And with the [Windows Compatibility Pack](#) porting from .NET Framework has also become much simpler.

Support for .NET Framework libraries

.NET Core code can reference existing .NET Framework libraries, including existing NuGet packages. Note that the libraries must use APIs that are found in .NET Standard.

Visual Studio integration

Visual Studio 2017 version 15.3 and in some cases Visual Studio for Mac offer a number of significant enhancements for .NET Core developers.

Retargeting .NET Core apps and .NET Standard libraries

If the .NET Core 2.0 SDK is installed, you can retarget .NET Core 1.x projects to .NET Core 2.0 and .NET Standard 1.x libraries to .NET Standard 2.0.

To retarget your project in Visual Studio, you open the **Application** tab of the project's properties dialog and change the **Target framework** value to **.NET Core 2.0** or **.NET Standard 2.0**. You can also change it by right-clicking on the project and selecting the **Edit *.csproj file** option. For more information, see the [Tooling](#) section earlier in this topic.

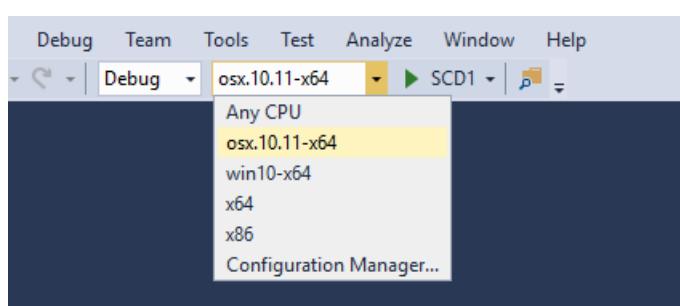

Live Unit Testing support for .NET Core

Whenever you modify your code, Live Unit Testing automatically runs any affected unit tests in the background and displays the results and code coverage live in the Visual Studio environment. .NET Core 2.0 now supports Live Unit Testing. Previously, Live Unit Testing was available only for .NET Framework applications.

For more information, see [Live Unit Testing with Visual Studio 2017](#) and the [Live Unit Testing FAQ](#).

Better support for multiple target frameworks

If you're building a project for multiple target frameworks, you can now select the target platform from the top-level menu. In the following figure, a project named SCD1 targets 64-bit macOS X 10.11 (`osx.10.11-x64`) and 64-bit Windows 10/Windows Server 2016 (`win10-x64`). You can select the target framework before selecting the project button, in this case to run a debug build.

Side-by-side support for .NET Core SDKs

You can now install the .NET Core SDK independently of Visual Studio. This makes it possible for a single version of Visual Studio to build projects that target different versions of .NET Core. Previously, Visual Studio and the .NET Core SDK were tightly coupled; a particular version of the SDK accompanied a particular version of Visual Studio.

Documentation improvements

.NET Application Architecture

[.NET Application Architecture](#) gives you access to a set of e-books that provide guidance, best practices, and sample applications when using .NET to build:

- [Microservices and Docker containers](#)
- [Web applications with ASP.NET](#)
- [Mobile applications with Xamarin](#)
- [Applications that are deployed to the Cloud with Azure](#)

Get started with .NET Core on macOS

3/25/2019 • 6 minutes to read • [Edit Online](#)

This document provides the steps and workflow to create a .NET Core solution for macOS. Learn how to create projects, unit tests, use the debugging tools, and incorporate third-party libraries via [NuGet](#).

NOTE

This article uses [Visual Studio Code](#) on macOS.

Prerequisites

Install the [.NET Core SDK](#). The .NET Core SDK includes the latest release of the .NET Core framework and runtime.

Install [Visual Studio Code](#). During the course of this article, you also install Visual Studio Code extensions that improve the .NET Core development experience.

Install the Visual Studio Code C# extension by opening Visual Studio Code and pressing F1 to open the Visual Studio Code palette. Type **ext install** to see the list of extensions. Select the C# extension. Restart Visual Studio Code to activate the extension. For more information, see the [Visual Studio Code C# Extension documentation](#).

Get started

In this tutorial, you create three projects: a library project, tests for that library project, and a console application that makes use of the library. You can [view or download the source](#) for this topic at the dotnet/samples repository on GitHub. For download instructions, see [Samples and Tutorials](#).

Start Visual Studio Code. Press **Ctrl+`** (the backquote or backtick character) or select **View > Integrated Terminal** from the menu to open an embedded terminal in Visual Studio Code. You can still open an external shell with the Explorer **Open in Command Prompt** command (**Open in Terminal** on Mac or Linux) if you prefer to work outside of Visual Studio Code.

Begin by creating a solution file, which serves as a container for one or more .NET Core projects. In the terminal, create a *golden* folder and open the folder. This folder is the root of your solution. Run the `dotnet new` command to create a new solution, *golden.sln*:

```
dotnet new sln
```

From the *golden* folder, execute the following command to create a library project, which produces two files, *library.csproj* and *Class1.cs*, in the *library* folder:

```
dotnet new classlib -o library
```

Execute the `dotnet sln` command to add the newly created *library.csproj* project to the solution:

```
dotnet sln add library/library.csproj
```

The *library.csproj* file contains the following information:

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>
<TargetFramework>netstandard1.4</TargetFramework>
</PropertyGroup>

</Project>
```

Our library methods serialize and deserialize objects in JSON format. To support JSON serialization and deserialization, add a reference to the `Newtonsoft.Json` NuGet package. The `dotnet add` command adds new items to a project. To add a reference to a NuGet package, use the `dotnet add package` command and specify the name of the package:

```
dotnet add library package Newtonsoft.Json
```

This adds `Newtonsoft.Json` and its dependencies to the library project. Alternatively, manually edit the `library.csproj` file and add the following node:

```
<ItemGroup>
<PackageReference Include="Newtonsoft.Json" Version="10.0.1" />
</ItemGroup>
```

Execute `dotnet restore`, (see note) which restores dependencies and creates an `obj` folder inside `library` with three files in it, including a `project.assets.json` file:

```
dotnet restore
```

In the `library` folder, rename the file `Class1.cs` to `Thing.cs`. Replace the code with the following:

```
using static Newtonsoft.Json.JsonConvert;

namespace Library
{
    public class Thing
    {
        public int Get(int left, int right) =>
            DeserializeObject<int>($"{left + right}");
    }
}
```

The `Thing` class contains one public method, `Get`, which returns the sum of two numbers but does so by converting the sum into a string and then deserializing it into an integer. This makes use of a number of modern C# features, such as `using static` directives, expression-bodied members, and string interpolation.

Build the library with the `dotnet build` command. This produces a `library.dll` file under `golden/library/bin/Debug/netstandard1.4`:

```
dotnet build
```

Create the test project

Build a test project for the library. From the `golden` folder, create a new test project:

```
dotnet new xunit -o test-library
```

Add the test project to the solution:

```
dotnet sln add test-library/test-library.csproj
```

Add a project reference to the library you created in the previous section so that the compiler can find and use the library project. Use the [dotnet add reference](#) command:

```
dotnet add test-library/test-library.csproj reference library/library.csproj
```

Alternatively, manually edit the *test-library.csproj* file and add the following node:

```
<ItemGroup>
  <ProjectReference Include="..\library\library.csproj" />
</ItemGroup>
```

Now that the dependencies have been properly configured, create the tests for your library. Open *UnitTest1.cs* and replace its contents with the following code:

```
using Library;
using Xunit;

namespace TestApp
{
    public class LibraryTests
    {
        [Fact]
        public void TestThing()
        {
            Assert.NotEqual(42, new Thing().Get(19, 23));
        }
    }
}
```

Note that you assert the value 42 is not equal to 19+23 (or 42) when you first create the unit test (`Assert.NotEqual`), which will fail. An important step in building unit tests is to create the test to fail once first to confirm its logic.

From the *golden* folder, execute the following commands:

```
dotnet restore
dotnet test test-library/test-library.csproj
```

These commands will recursively find all projects to restore dependencies, build them, and activate the xUnit test runner to run the tests. The single test fails, as you expect.

Edit the *UnitTest1.cs* file and change the assertion from `Assert.NotEqual` to `Assert.Equal`. Execute the following command from the *golden* folder to re-run the test, which passes this time:

```
dotnet test test-library/test-library.csproj
```

Create the console app

The console app you create over the following steps takes a dependency on the library project you created earlier and calls its library method when it runs. Using this pattern of development, you see how to create reusable libraries for multiple projects.

Create a new console application from the *golden* folder:

```
dotnet new console -o app
```

Add the console app project to the solution:

```
dotnet sln add app/app.csproj
```

Create the dependency on the library by running the `dotnet add reference` command:

```
dotnet add app/app.csproj reference library/library.csproj
```

Run `dotnet restore` ([see note](#)) to restore the dependencies of the three projects in the solution. Open *Program.cs* and replace the contents of the `Main` method with the following line:

```
WriteLine($"The answer is {new Thing().Get(19, 23)}");
```

Add two `using` directives to the top of the *Program.cs* file:

```
using static System.Console;
using Library;
```

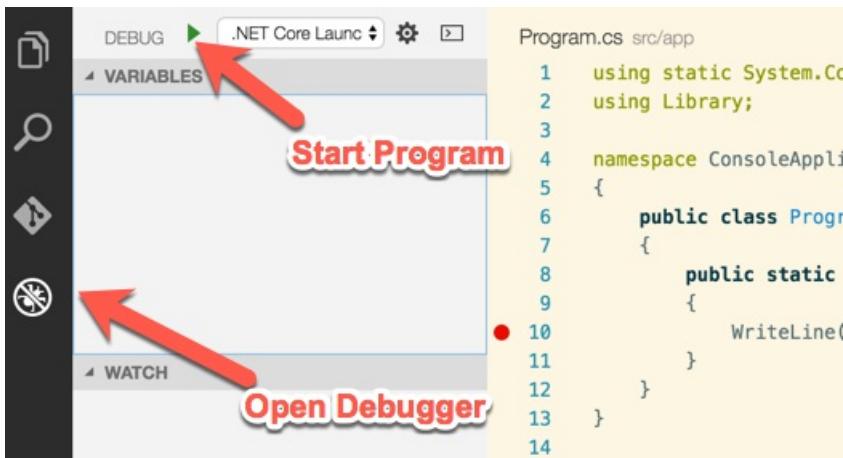

Execute the following `dotnet run` command to run the executable, where the `-p` option to `dotnet run` specifies the project for the main application. The app produces the string "The answer is 42".

```
dotnet run -p app/app.csproj
```

Debug the application

Set a breakpoint at the `WriteLine` statement in the `Main` method. Do this by either pressing the F9 key when the cursor is over the `WriteLine` line or by clicking the mouse in the left margin on the line where you want to set the breakpoint. A red circle will appear in the margin next to the line of code. When the breakpoint is reached, code execution will stop *before* the breakpoint line is executed.

Open the debugger tab by selecting the Debug icon in the Visual Studio Code toolbar, selecting **View > Debug** from the menu bar, or using the keyboard shortcut CTRL+SHIFT+D:

Press the Play button to start the application under the debugger. The app begins execution and runs to the breakpoint, where it stops. Step into the `Get` method and make sure that you have passed in the correct arguments. Confirm that the answer is 42.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

Get started with .NET Core on macOS using Visual Studio for Mac

3/12/2019 • 2 minutes to read • [Edit Online](#)

Visual Studio for Mac provides a full-featured Integrated Development Environment (IDE) for developing .NET Core applications. This topic walks you through building a simple console application using Visual Studio for Mac and .NET Core.

NOTE

Your feedback is highly valued. There are two ways you can provide feedback to the development team on Visual Studio for Mac:

- In Visual Studio for Mac, select **Help > Report a Problem** from the menu or **Report a Problem** from the Welcome screen, which will open a window for filing a bug report. You can track your feedback in the [Developer Community](#) portal.
- To make a suggestion, select **Help > Provide a Suggestion** from the menu or **Provide a Suggestion** from the Welcome screen, which will take you to the [Visual Studio for Mac Developer Community webpage](#).

Prerequisites

See the [Prerequisites for .NET Core on Mac](#) topic.

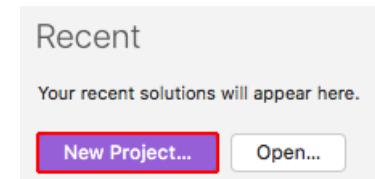

Get started

If you've already installed the prerequisites and Visual Studio for Mac, skip this section and proceed to [Creating a project](#). Follow these steps to install the prerequisites and Visual Studio for Mac:

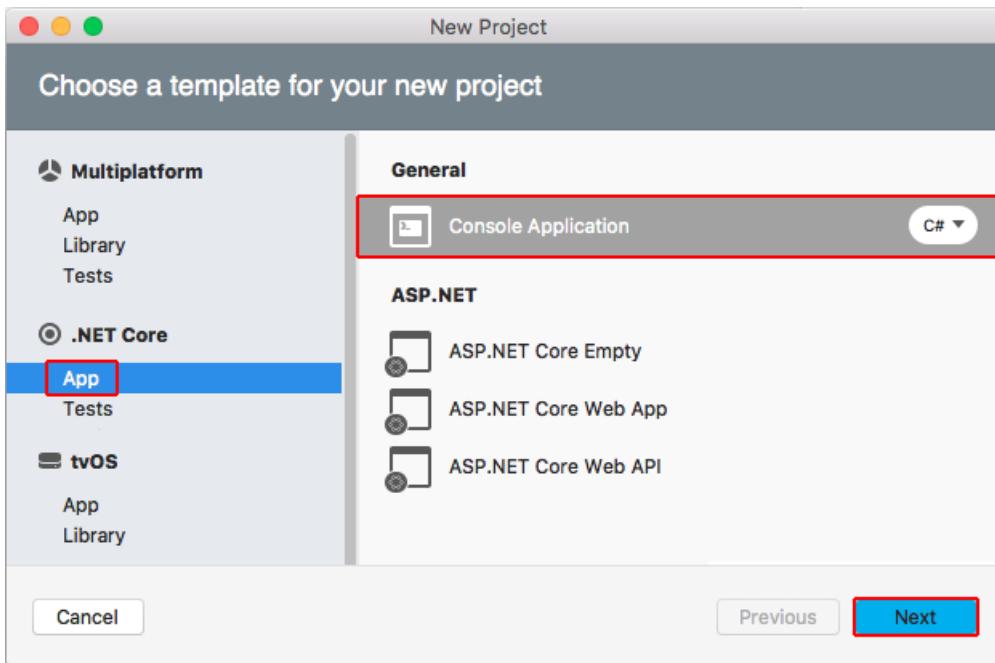

Download the [Visual Studio for Mac installer](#). Run the installer. Read and accept the license agreement. During the install, you're provided the opportunity to install Xamarin, a cross-platform mobile app development technology. Installing Xamarin and its related components is optional for .NET Core development. For a walk-through of the Visual Studio for Mac install process, see [Introducing Visual Studio for Mac](#). When the install is complete, start the Visual Studio for Mac IDE.

Creating a project

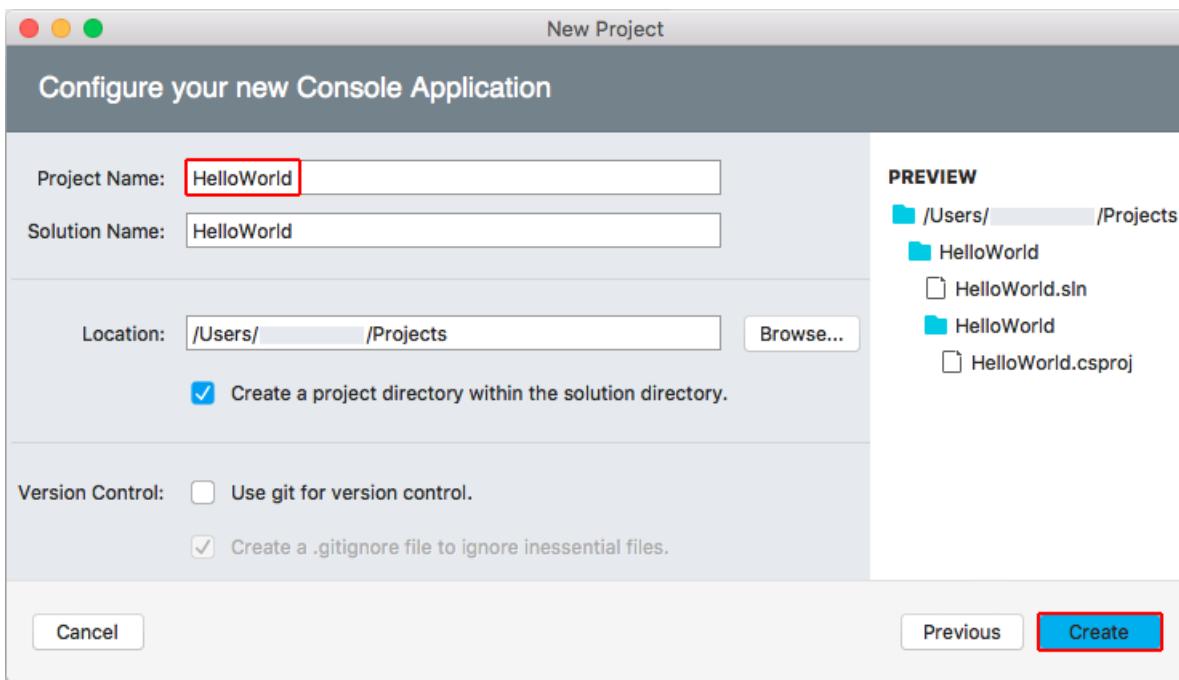

1. Select **New Project** on the Welcome screen.

2. In the **New Project** dialog, select **App** under the **.NET Core** node. Select the **Console Application** template followed by **Next**.

3. Type "HelloWorld" for the **Project Name**. Select **Create**.

4. Wait while the project's dependencies are restored. The project has a single C# file, `Program.cs`, containing a `Program` class with a `Main` method. The `Console.WriteLine` statement will output "Hello World!" to the console when the app is run.

A screenshot of the Visual Studio for Mac interface. The title bar says "Visual Studio for Mac Preview". The left sidebar shows a "Solution" tree with a "HelloWorld" project containing "Program.cs". The main editor window displays the following C# code:

```
1 using System;
2
3 namespace HelloWorld
4 {
5     class Program
6     {
7         static void Main(string[] args)
8         {
9             Console.WriteLine("Hello World!");
10        }
11    }
12 }
13
```

The "Program.cs" tab is selected and highlighted with a red box. The code block from "Main" to the closing brace of the class definition is also highlighted with a red box. The status bar at the bottom shows "Errors", "Tasks", and "Package Console".

Run the application

Run the app in Debug mode using F5 or in Release mode using CTRL+F5.

A screenshot of the "Application Output" window. It contains the text "Hello World!" which is highlighted with a red box. The window has standard OS X window controls (close, minimize, maximize) and a toolbar at the bottom with "Errors", "Tasks", and "Package Console" buttons.

Next step

The [Building a complete .NET Core solution on macOS using Visual Studio for Mac](#) topic shows you how to build a complete .NET Core solution that includes a reusable library and unit testing.

Building a complete .NET Core solution on macOS using Visual Studio for Mac

3/1/2019 • 9 minutes to read • [Edit Online](#)

Visual Studio for Mac provides a full-featured Integrated Development Environment (IDE) for developing .NET Core applications. This topic walks you through building a .NET Core solution that includes a reusable library and unit testing.

This tutorial shows you how to create an application that accepts a search word and a string of text from the user, counts the number of times the search word appears in the string using a method in a class library, and returns the result to the user. The solution also includes unit testing for the class library as an introduction to unit testing concepts. If you prefer to proceed through the tutorial with a complete sample, download the [sample solution](#). For download instructions, see [Samples and Tutorials](#).

NOTE

Your feedback is highly valued. There are two ways you can provide feedback to the development team on Visual Studio for Mac:

- In Visual Studio for Mac, select **Help > Report a Problem** from the menu or **Report a Problem** from the Welcome screen, which opens a window for filing a bug report. You can track your feedback in the [Developer Community](#) portal.
- To make a suggestion, select **Help > Provide a Suggestion** from the menu or **Provide a Suggestion** from the Welcome screen, which takes you to the [Visual Studio for Mac Developer Community webpage](#).

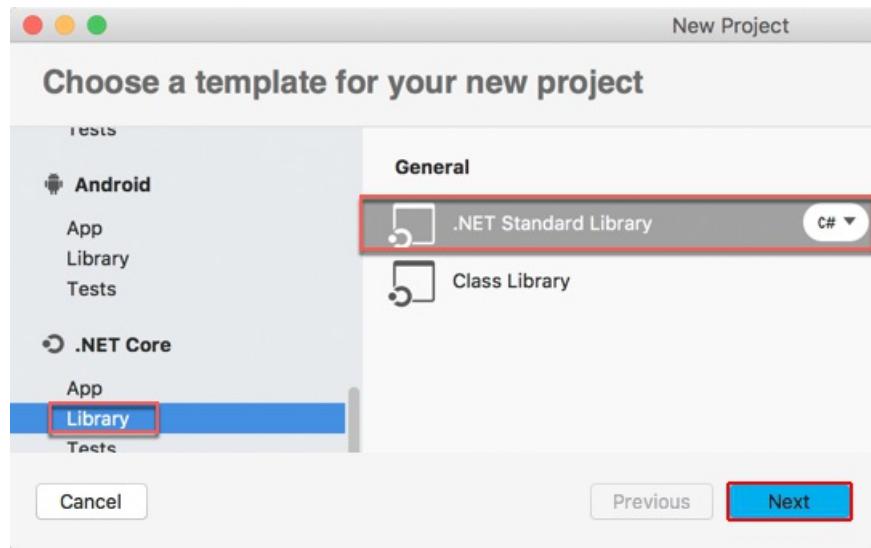

Prerequisites

- OpenSSL (if running .NET Core 1.1): See the [Prerequisites for .NET Core on Mac](#) topic.
- [.NET Core SDK 1.1 or later](#)
- [Visual Studio 2017 for Mac](#)

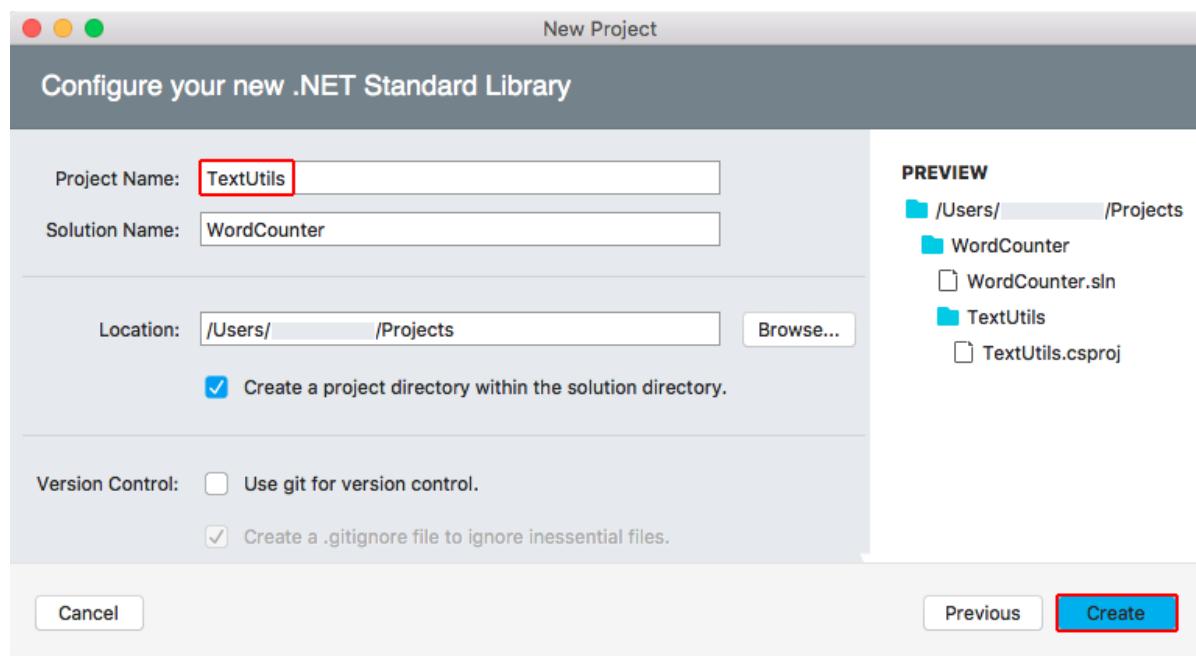

For more information on prerequisites, see the [Prerequisites for .NET Core on Mac](#). For the full system requirements of Visual Studio 2017 for Mac, see [Visual Studio 2017 for Mac Product Family System Requirements](#).

Building a library

1. On the Welcome screen, select **New Project**. In the **New Project** dialog under the **.NET Core** node, select the **.NET Standard Library** template. This creates a .NET Standard library that targets .NET Core as well as any other .NET implementation that supports version 2.0 of the **.NET Standard**. Select **Next**.

2. Name the project "TextUtils" (a short name for "Text Utilities") and the solution "WordCounter". Leave **Create a project directory within the solution directory** checked. Select **Create**.

3. In the **Solution** sidebar, expand the `TextUtils` node to reveal the class file provided by the template, `Class1.cs`. Right-click the file, select **Rename** from the context menu, and rename the file to `WordCount.cs`. Open the file and replace the contents with the following code:

```

using System;
using System.Linq;

namespace TextUtils
{
    public static class WordCount
    {
        public static int GetWordCount(string searchWord, string inputString)
        {
            // Null check these variables and determine if they have values.
            if (string.IsNullOrEmpty(searchWord) || string.IsNullOrEmpty(inputString))
            {
                return 0;
            }

            // Convert the string into an array of words.
            var source = inputString.Split(new char[] { '.', '?', '!', ' ', ';', ':', ',' },
                StringSplitOptions.RemoveEmptyEntries);

            // Create the query. Use ToLowerInvariant to match uppercase/lowercase strings.
            var matchQuery = from word in source
                            where word.ToLowerInvariant() == searchWord.ToLowerInvariant()
                            select word;

            // Count the matches, which executes the query. Return the result.
            return matchQuery.Count();
        }
    }
}

```

4. Save the file by using any of three different methods: use the keyboard shortcut ⌘+s, select **File > Save** from the menu, or right-click on the file's tab and select **Save** from the contextual menu. The following image shows the IDE window:

5. Select **Errors** in the margin at the bottom of the IDE window to open the **Errors** panel. Select the **Build Output** button.

6. Select **Build > Build All** from the menu.

The solution builds. The build output panel shows that the build is successful.

```

Build succeeded.
  0 Warning(s)
  0 Error(s)

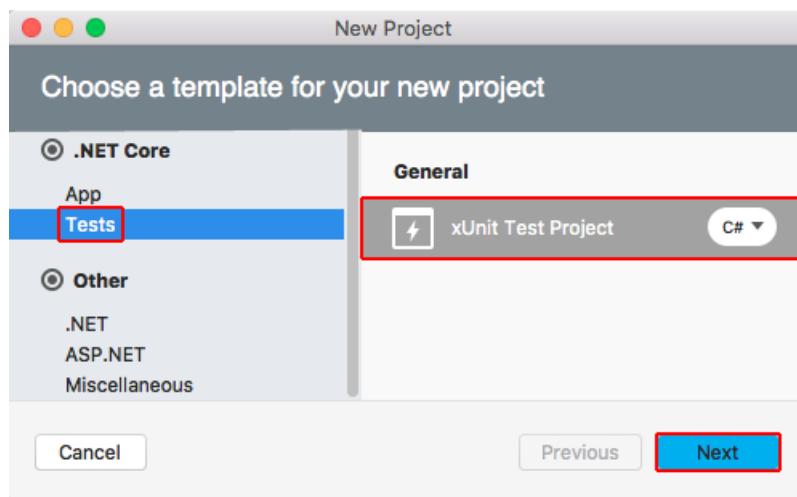

Time Elapsed 00:00:05.13
----- Done -----
Build successful.

```

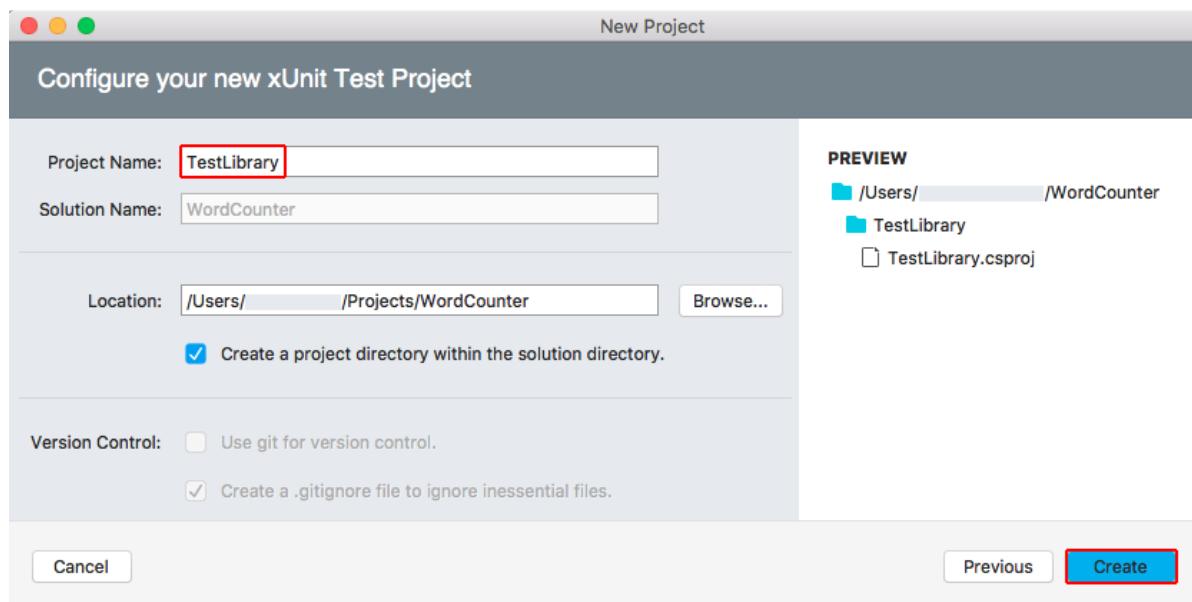

Creating a test project

Unit tests provide automated software testing during your development and publishing. The testing framework that you use in this tutorial is [xUnit \(version 2.2.0 or later\)](#), which is installed automatically when the xUnit test project is added to the solution in the following steps:

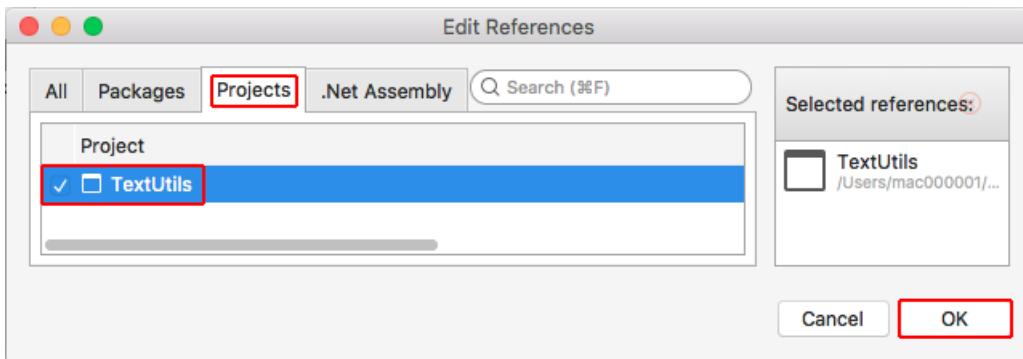

1. In the **Solution** sidebar, right-click the `WordCounter` solution and select **Add > Add New Project**.
2. In the **New Project** dialog, select **Tests** from the **.NET Core** node. Select the **xUnit Test Project** followed by **Next**.

3. Name the new project "TestLibrary" and select **Create**.

4. In order for the test library to work with the `WordCount` class, add a reference to the `TextUtils` project. In the **Solution** sidebar, right-click **Dependencies** under **TestLibrary**. Select **Edit References** from the context menu.
5. In the **Edit References** dialog, select the **TextUtils** project on the **Projects** tab. Select **OK**.

6. In the **TestLibrary** project, rename the *UnitTest1.cs* file to *TextUtilsTests.cs*.

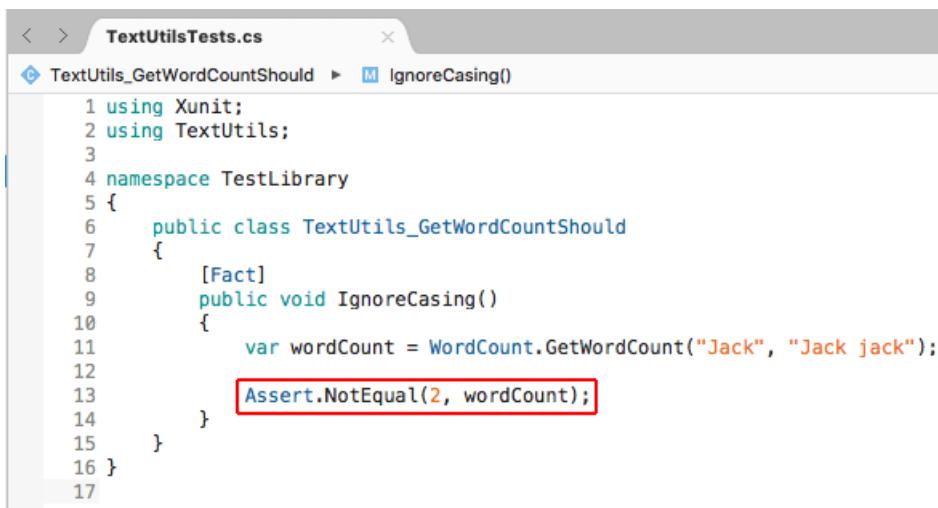

7. Open the file and replace the code with the following:

```
using Xunit;
using TextUtils;
using System.Diagnostics;

namespace TestLibrary
{
    public class TextUtils_GetWordCountShould
    {
        [Fact]
        public void IgnoreCasing()
        {
            var wordCount = WordCount.GetWordCount("Jack", "Jack jack");

            Assert.NotEqual(2, wordCount);
        }
    }
}
```

The following image shows the IDE with the unit test code in place. Pay attention to the `Assert.NotEqual` statement.

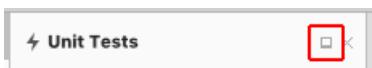

It's important to make a new test fail once to confirm its testing logic is correct. The method passes in the name "Jack" (uppercase) and a string with "Jack" and "jack" (uppercase and lowercase). If the `GetWordCount` method is working properly, it returns a count of two instances of the search word. In order to fail this test on purpose, you first implement the test asserting that two instances of the search word "Jack" aren't returned by the `GetWordCount` method. Continue to the next step to fail the test on purpose.

8. Open the **Unit Tests** panel on the right side of the screen.

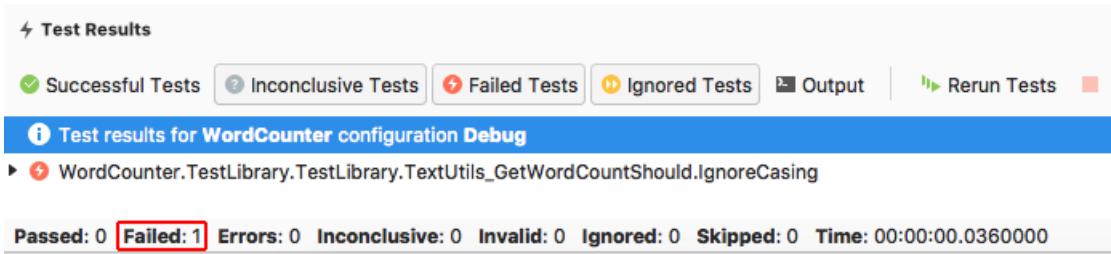

9. Click the **Dock** icon to keep the panel open.

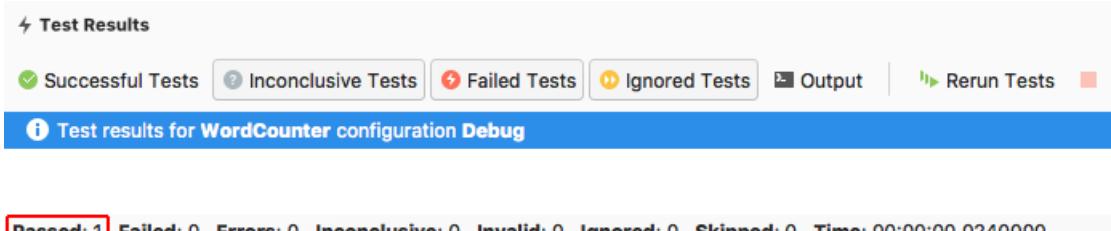

10. Click the **Run All** button.

The test fails, which is the correct result. The test method asserts that two instances of the `inputString`, "Jack," aren't returned from the string "Jack jack" provided to the `GetWordCount` method. Since word casing was factored out in the `GetWordCount` method, two instances are returned. The assertion that `2 is not equal to 2` fails. This is the correct outcome, and the logic of our test is good.

11. Modify the `IgnoreCasing` test method by changing `Assert.NotEqual` to `Assert.Equal`. Save the file by using the keyboard shortcut **⌘+s**, **File > Save** from the menu, or right-clicking on the file's tab and selecting **Save** from the context menu.

You expect that the `searchWord` "Jack" returns two instances with `inputString` "Jack jack" passed into `GetWordCount`. Run the test again by clicking the **Run Tests** button in the **Unit Tests** panel or the **Rerun Tests** button in the **Test Results** panel at the bottom of the screen. The test passes. There are two instances of "Jack" in the string "Jack jack" (ignoring casing), and the test assertion is `true`.

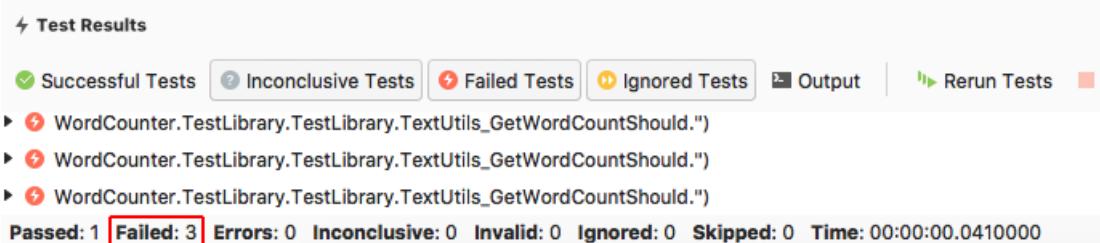

12. Testing individual return values with a `Fact` is only the beginning of what you can do with unit testing. Another powerful technique allows you to test several values at once using a `Theory`. Add the following

method to your `TextUtils_GetWordCountShould` class. You have two methods in the class after you add this method:

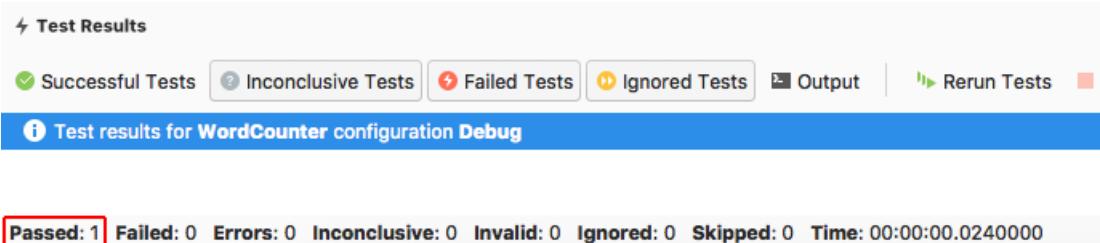

```
[Theory]
[InlineData(0, "Ting", "Does not appear in the string.")]
[InlineData(1, "Ting", "Ting appears once.")]
[InlineData(2, "Ting", "Ting appears twice with Ting.")]
public void CountInstancesCorrectly(int count,
                                    string searchWord,
                                    string inputString)
{
    Assert.NotEqual(count, WordCount.GetWordCount(searchWord,
                                                    inputString));
}
```

The `CountInstancesCorrectly` checks that the `GetWordCount` method counts correctly. The `InlineData` provides a count, a search word, and an input string to check. The test method runs once for each line of data. Note once again that you're asserting a failure first by using `Assert.NotEqual`, even when you know that the counts in the data are correct and that the values match the counts returned by the `GetWordCount` method. Performing the step of failing the test on purpose might seem like a waste of time at first, but checking the logic of the test by failing it first is an important check on the logic of your tests. When you come across a test method that passes when you expect it to fail, you've found a bug in the logic of the test. It's worth the effort to take this step every time you create a test method.

13. Save the file and run the tests again. The casing test passes but the three count tests fail. This is exactly what you expect to happen.

14. Modify the `CountInstancesCorrectly` test method by changing `Assert.NotEqual` to `Assert.Equal`. Save the file. Run the tests again. All tests pass.

Adding a console app

1. In the **Solution** sidebar, right-click the `WordCounter` solution. Add a new **Console Application** project by selecting the template from the **.NET Core > App** templates. Select **Next**. Name the project `WordCounterApp`. Select **Create** to create the project in the solution.
2. In the **Solutions** sidebar, right-click the **Dependencies** node of the new `WordCounterApp` project. In the **Edit References** dialog, check `TextUtils` and select **OK**.
3. Open the `Program.cs` file. Replace the code with the following:

```
using System;
using TextUtils;

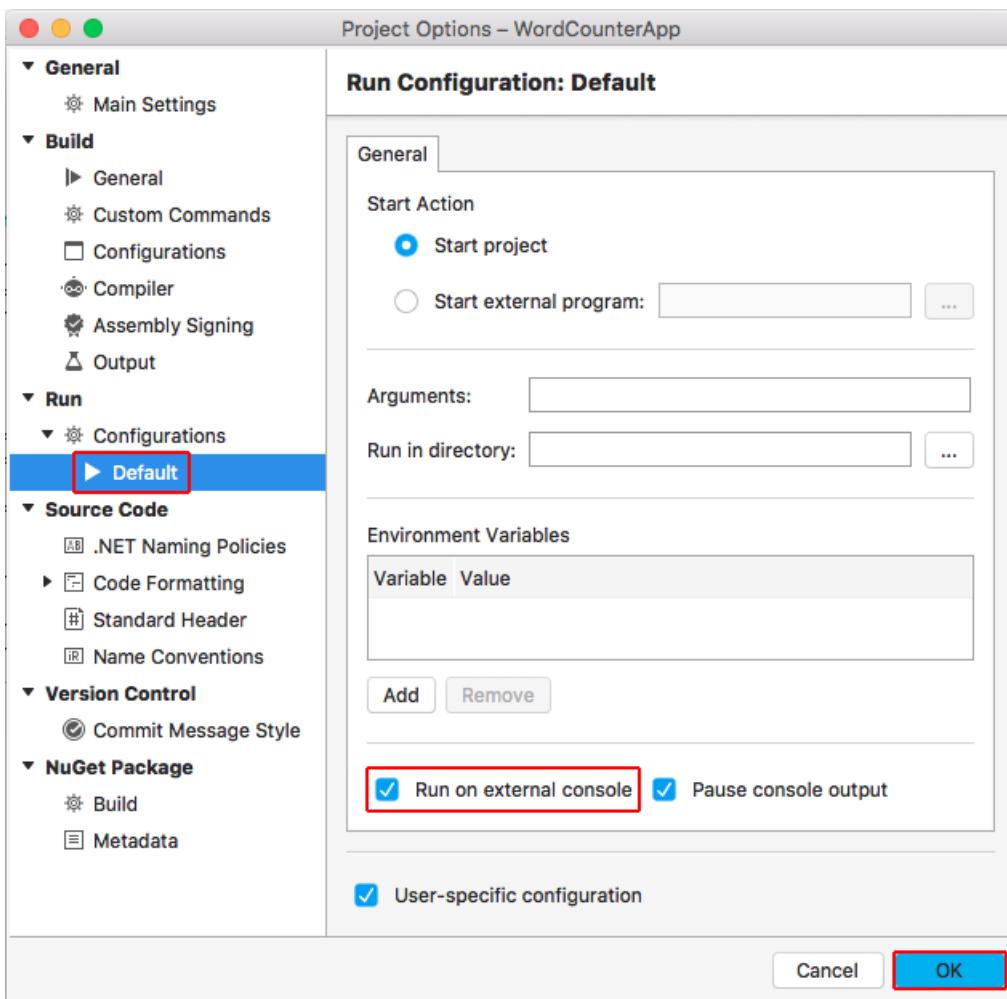

namespace WordCounterApp
{
    class Program
    {
        static void Main(string[] args)
        {
            Console.WriteLine("Enter a search word:");
            var searchWord = Console.ReadLine();
            Console.WriteLine("Provide a string to search:");
            var inputString = Console.ReadLine();

            var wordCount = WordCount.GetWordCount(searchWord, inputString);

            var pluralChar = "s";
            if (wordCount == 1)
            {
                pluralChar = string.Empty;
            }

            Console.WriteLine($"The search word {searchWord} appears " +
                $"{wordCount} time{pluralChar}.");
        }
    }
}
```

4. To run the app in a console window instead of the IDE, right-click the `WordCounterApp` project, select **Options**, and open the **Default** node under **Configurations**. Check the box for **Run on external console**. Leave the **Pause console output** option checked. This setting causes the app to spawn in a console window so that you can type input for the `Console.ReadLine` statements. If you leave the app to run in the IDE, you can only see the output of `Console.WriteLine` statements. `Console.ReadLine` statements do not work in the IDE's **Application Output** panel.

5. Because the current version of Visual Studio for Mac cannot run the tests when the solution is run, you run the console app directly. Right-click on the `WordCounterApp` project and select **Run item** from the context menu. If you attempt to run the app with the Play button, the test runner and app fail to run. For more information on the status of the work on this issue, see [xunit/xamarinstudio.xunit \(#60\)](#). When you run the app, provide values for the search word and input string at the prompts in the console window. The app indicates the number of times the search word appears in the string.

```
— Visual Studio External Console —
Enter a search word:
olives
Provide a string to search:
I ate olives by the lake, and the olives were wonderful.
The search word olives appears 2 times.

Press any key to continue...[
```

6. The last feature to explore is debugging with Visual Studio for Mac. Set a breakpoint on the `Console.WriteLine` statement: Select in the left margin of line 23, and you see a red circle appear next to the line of code. Alternatively, select anywhere on the line of code and select **Run > Toggle Breakpoint** from the menu.

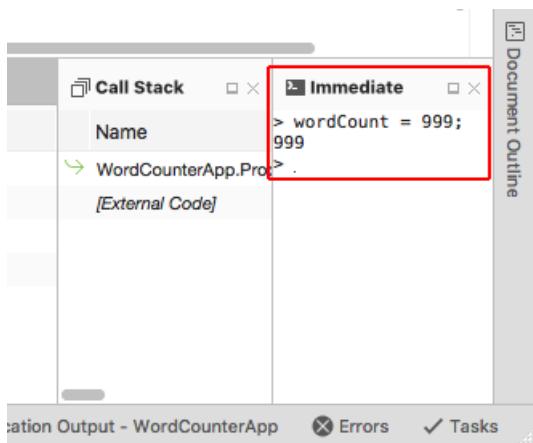

```
22
23     Console.WriteLine($"The search word {searchWord} appears " +
24                     $"{wordCount} time{pluralChar}.");
25
```

7. Right-click the `WordCounterApp` project. Select **Start Debugging item** from the context menu. When the app runs, enter the search word "cat" and "The dog chased the cat, but the cat escaped." for the string to search. When the `Console.WriteLine` statement is reached, program execution halts before the statement is executed. In the **Locals** tab, you can see the `searchWord`, `inputString`, `wordCount`, and `pluralChar` values.

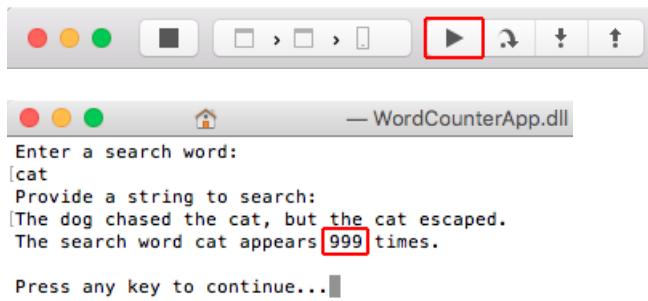

Console.WriteLine(\$"The search word {searchWord} appears " +
\$"{wordCount} time{pluralChar}.");

Name	Type	Value
args	string[]	{string[0]}
searchWord	string	"cat"
inputString	string	"The dog chased the cat, but the cat escaped."
wordCount	int	2
pluralChar	string	"s"

8. In the **Immediate** pane, type "wordCount = 999;" and press Enter. This assigns a nonsense value of 999 to the `wordCount` variable showing that you can replace variable values while debugging.

9. In the toolbar, click the *continue* arrow. Look at the output in the console window. It reports the incorrect value of 999 that you set when you were debugging the app.

- [Visual Studio 2017 for Mac Release Notes](#)

Get started with .NET Core on Windows/Linux/macOS using the command line

3/28/2019 • 5 minutes to read • [Edit Online](#)

This topic will show you how to start developing cross-platforms apps in your machine using the .NET Core CLI tools.

If you're unfamiliar with the .NET Core CLI toolset, read the [.NET Core SDK overview](#).

Prerequisites

- [.NET Core SDK 2.1](#).
- A text editor or code editor of your choice.

Hello, Console App!

You can [view or download the sample code](#) from the dotnet/samples GitHub repository. For download instructions, see [Samples and Tutorials](#).

Open a command prompt and create a folder named *Hello*. Navigate to the folder you created and type the following:

```
dotnet new console  
dotnet run
```

Let's do a quick walkthrough:

1. `dotnet new console`

`dotnet new` creates an up-to-date `Hello.csproj` project file with the dependencies necessary to build a console app. It also creates a `Program.cs`, a basic file containing the entry point for the application.

`Hello.csproj`:

```
<Project Sdk="Microsoft.NET.Sdk">  
  
<PropertyGroup>  
    <OutputType>Exe</OutputType>  
    <TargetFramework>netcoreapp2.2</TargetFramework>  
</PropertyGroup>  
  
</Project>
```

The project file specifies everything that's needed to restore dependencies and build the program.

- The `OutputType` tag specifies that we're building an executable, in other words a console application.
- The `TargetFramework` tag specifies what .NET implementation we're targeting. In an advanced scenario, you can specify multiple target frameworks and build to all those in a single operation. In this tutorial, we'll stick to building only for .NET Core 2.1.

`Program.cs`:

```
using System;

namespace Hello
{
    class Program
    {
        static void Main(string[] args)
        {
            Console.WriteLine("Hello World!");
        }
    }
}
```

The program starts by `using System`, which means "bring everything in the `System` namespace into scope for this file". The `System` namespace includes basic constructs such as `string`, or numeric types.

We then define a namespace called `Hello`. You can change this to anything you want. A class named `Program` is defined within that namespace, with a `Main` method that takes an array of strings as its argument. This array contains the list of arguments passed in when the compiled program is called. As it is, this array is not used: all the program is doing is to write "Hello World!" to the console. Later, we'll make changes to the code that will make use of this argument.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

`dotnet new` calls `dotnet restore` implicitly. `dotnet restore` calls into [NuGet](#) (.NET package manager) to restore the tree of dependencies. NuGet analyzes the `Hello.csproj` file, downloads the dependencies defined in the file (or grabs them from a cache on your machine), and writes the `obj/project.assets.json` file, which is necessary to compile and run the sample.

IMPORTANT

If you're using a .NET Core 1.x version of the SDK, you'll have to call `dotnet restore` yourself after calling `dotnet new`.

2. `dotnet run`

`dotnet run` calls `dotnet build` to ensure that the build targets have been built, and then calls `dotnet <assembly.dll>` to run the target application.

```
$ dotnet run
Hello World!
```

Alternatively, you can also execute `dotnet build` to compile the code without running the build console applications. This results in a compiled application as a DLL file that can be run with `dotnet bin\Debug\netcoreapp2.1\Hello.dll` on Windows (use `/` for non-Windows systems). You may also specify arguments to the application as you'll see later on the topic.

```
$ dotnet bin\Debug\netcoreapp2.1\Hello.dll
Hello World!
```

As an advanced scenario, it's possible to build the application as a self-contained set of platform-specific files that can be deployed and run to a machine that doesn't necessarily have .NET Core installed. See [.NET Core Application Deployment](#) for details.

Augmenting the program

Let's change the program a bit. Fibonacci numbers are fun, so let's add that in addition to use the argument to greet the person running the app.

1. Replace the contents of your *Program.cs* file with the following code:

```
using System;

namespace Hello
{
    class Program
    {
        static void Main(string[] args)
        {
            if (args.Length > 0)
            {
                Console.WriteLine($"Hello {args[0]}!");
            }
            else
            {
                Console.WriteLine("Hello!");
            }

            Console.WriteLine("Fibonacci Numbers 1-15:");

            for (int i = 0; i < 15; i++)
            {
                Console.WriteLine($"{i + 1}: {FibonacciNumber(i)}");
            }
        }

        static int FibonacciNumber(int n)
        {
            int a = 0;
            int b = 1;
            int tmp;

            for (int i = 0; i < n; i++)
            {
                tmp = a;
                a = b;
                b += tmp;
            }

            return a;
        }
    }
}
```

2. Execute `dotnet build` to compile the changes.
3. Run the program passing a parameter to the app:

```
$ dotnet run -- John
Hello John!
Fibonacci Numbers 1-15:
1: 0
2: 1
3: 1
4: 2
5: 3
6: 5
7: 8
8: 13
9: 21
10: 34
11: 55
12: 89
13: 144
14: 233
15: 377
```

And that's it! You can augment `Program.cs` any way you like.

Working with multiple files

Single files are fine for simple one-off programs, but if you're building a more complex app, you're probably going to have multiple source files on your project. Let's build off of the previous Fibonacci example by caching some Fibonacci values and add some recursive features.

1. Add a new file inside the `Hello` directory named `FibonacciGenerator.cs` with the following code:

```
using System;
using System.Collections.Generic;

namespace Hello
{
    public class FibonacciGenerator
    {
        private Dictionary<int, int> _cache = new Dictionary<int, int>();

        private int Fib(int n) => n < 2 ? n : FibValue(n - 1) + FibValue(n - 2);

        private int FibValue(int n)
        {
            if (!_cache.ContainsKey(n))
            {
                _cache.Add(n, Fib(n));
            }

            return _cache[n];
        }

        public IEnumerable<int> Generate(int n)
        {
            for (int i = 0; i < n; i++)
            {
                yield return FibValue(i);
            }
        }
    }
}
```

2. Change the `Main` method in your `Program.cs` file to instantiate the new class and call its method as in the following example:

```
using System;

namespace Hello
{
    class Program
    {
        static void Main(string[] args)
        {
            var generator = new FibonacciGenerator();
            foreach (var digit in generator.Generate(15))
            {
                Console.WriteLine(digit);
            }
        }
    }
}
```

3. Execute `dotnet build` to compile the changes.

4. Run your app by executing `dotnet run`. The following shows the program output:

```
$ dotnet run
0
1
1
2
3
5
8
13
21
34
55
89
144
233
377
```

And that's it! Now, you can start using the basic concepts learned here to create your own programs.

Note that the commands and steps shown in this tutorial to run your application are used during development time only. Once you're ready to deploy your app, you'll want to take a look at the different [deployment strategies](#) for .NET Core apps and the `dotnet publish` command.

Organizing and testing projects with the .NET Core command line

3/14/2019 • 6 minutes to read • [Edit Online](#)

This tutorial follows [Get started with .NET Core on Windows/Linux/macOS using the command line](#), taking you beyond the creation of a simple console app to develop advanced and well-organized applications. After showing you how to use folders to organize your code, this tutorial shows you how to extend a console application with the [xUnit](#) testing framework.

Using folders to organize code

If you want to introduce new types into a console app, you can do so by adding files containing the types to the app. For example if you add files containing `AccountInformation` and `MonthlyReportRecords` types to your project, the project file structure is flat and easy to navigate:

```
/MyProject
|__AccountInformation.cs
|__MonthlyReportRecords.cs
|__MyProject.csproj
|__Program.cs
```

However, this only works well when the size of your project is relatively small. Can you imagine what will happen if you add 20 types to the project? The project definitely wouldn't be easy to navigate and maintain with that many files littering the project's root directory.

To organize the project, create a new folder and name it *Models* to hold the type files. Place the type files into the *Models* folder:

```
/MyProject
|__/Models
    |__AccountInformation.cs
    |__MonthlyReportRecords.cs
|__MyProject.csproj
|__Program.cs
```

Projects that logically group files into folders are easy to navigate and maintain. In the next section, you create a more complex sample with folders and unit testing.

Organizing and testing using the *NewTypes* Pets Sample

Building the sample

For the following steps, you can either follow along using the [NewTypes Pets Sample](#) or create your own files and folders. The types are logically organized into a folder structure that permits the addition of more types later, and tests are also logically placed in folders permitting the addition of more tests later.

The sample contains two types, `Dog` and `Cat`, and has them implement a common interface, `IPet`. For the `NewTypes` project, your goal is to organize the pet-related types into a *Pets* folder. If another set of types is added later, *WildAnimals* for example, they're placed in the *NewTypes* folder alongside the *Pets* folder. The *WildAnimals* folder may contain types for animals that aren't pets, such as `Squirrel` and `Rabbit` types. In this way as types are added, the project remains well organized.

Create the following folder structure with file content indicated:

```
/NewTypes
|__src
  |__NewTypes
    |__Pets
      |__Dog.cs
      |__Cat.cs
      |__IPet.cs
    |__Program.cs
  |__NewTypes.csproj
```

IPet.cs:

```
using System;

namespace Pets
{
    public interface IPet
    {
        string TalkToOwner();
    }
}
```

Dog.cs:

```
using System;

namespace Pets
{
    public class Dog : IPet
    {
        public string TalkToOwner() => "Woof!";
    }
}
```

Cat.cs:

```
using System;

namespace Pets
{
    public class Cat : IPet
    {
        public string TalkToOwner() => "Meow!";
    }
}
```

Program.cs:

```
using System;
using Pets;
using System.Collections.Generic;

namespace ConsoleApplication
{
    public class Program
    {
        public static void Main(string[] args)
        {
            List<IPet> pets = new List<IPet>
            {
                new Dog(),
                new Cat()
            };

            foreach (var pet in pets)
            {
                Console.WriteLine(pet.TalkToOwner());
            }
        }
    }
}
```

NewTypes.csproj:

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>netcoreapp2.2</TargetFramework>
</PropertyGroup>

</Project>
```

Execute the following command:

```
dotnet run
```

Obtain the following output:

```
Woof!
Meow!
```

Optional exercise: You can add a new pet type, such as a `Bird`, by extending this project. Make the bird's `TalkToOwner` method give a `Tweet!` to the owner. Run the app again. The output will include `Tweet!`

Testing the sample

The `NewTypes` project is in place, and you've organized it by keeping the pets-related types in a folder. Next, create your test project and start writing tests with the `xUnit` test framework. Unit testing allows you to automatically check the behavior of your pet types to confirm that they're operating properly.

Navigate back to the `src` folder and create a `test` folder with a `NewTypesTests` folder within it. At a command prompt from the `NewTypesTests` folder, execute `dotnet new xunit`. This produces two files: `NewTypesTests.csproj` and `UnitTest1.cs`.

The test project cannot currently test the types in `NewTypes` and requires a project reference to the `NewTypes` project. To add a project reference, use the `dotnet add reference` command:

```
dotnet add reference ../../NewTypes/NewTypes.csproj
```

Or, you also have the option of manually adding the project reference by adding an `<ItemGroup>` node to the `NewTypesTests.csproj` file:

```
<ItemGroup>
  <ProjectReference Include="../../NewTypes/NewTypes.csproj" />
</ItemGroup>
```

`NewTypesTests.csproj`:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.2</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.9.0" />
    <PackageReference Include="xunit" Version="2.4.0" />
    <PackageReference Include="xunit.runner.visualstudio" Version="2.4.0" />
  </ItemGroup>

  <ItemGroup>
    <ProjectReference Include="../../src/NewTypes/NewTypes.csproj"/>
  </ItemGroup>

</Project>
```

The `NewTypesTests.csproj` file contains the following:

- Package reference to `Microsoft.NET.Test.Sdk`, the .NET testing infrastructure
- Package reference to `xunit`, the xUnit testing framework
- Package reference to `xunit.runner.visualstudio`, the test runner
- Project reference to `NewTypes`, the code to test

Change the name of `UnitTest1.cs` to `PetTests.cs` and replace the code in the file with the following:

```

using System;
using Xunit;
using Pets;

public class PetTests
{
    [Fact]
    public void DogTalkToOwnerReturnsWoof()
    {
        string expected = "Woof!";
        string actual = new Dog().TalkToOwner();

        Assert.NotEqual(expected, actual);
    }

    [Fact]
    public void CatTalkToOwnerReturnsMeow()
    {
        string expected = "Meow!";
        string actual = new Cat().TalkToOwner();

        Assert.NotEqual(expected, actual);
    }
}

```

Optional exercise: If you added a `Bird` type earlier that yields a `Tweet!` to the owner, add a test method to the `PetTests.cs` file, `BirdTalkToOwnerReturnsTweet`, to check that the `TalkToOwner` method works correctly for the `Bird` type.

NOTE

Although you expect that the `expected` and `actual` values are equal, an initial assertion with the `Assert.NotEqual` check specifies that these values are *not equal*. Always initially create a test to fail in order to check the logic of the test. After you confirm that the test fails, adjust the assertion to allow the test to pass.

The following shows the complete project structure:

```

/NewTypes
|__/src
|__/NewTypes
|__/Pets
|__Dog.cs
|__Cat.cs
|__IPet.cs
|__Program.cs
|__NewTypes.csproj
|__/test
|__NewTypesTests
|__PetTests.cs
|__NewTypesTests.csproj

```

Start in the `test/NewTypesTests` directory. Restore the test project with the `dotnet restore` command. Run the tests with the `dotnet test` command. This command starts the test runner specified in the project file.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

As expected, testing fails, and the console displays the following output:

```
Test run for c:\Users\ronpet\repos\samples\core\Console-
apps\NewTypesMsBuild\test\NewTypesTests\bin\Debug\netcoreapp2.1\NewTypesTests.dll(.NETCoreApp,Version=v2.1)
Microsoft (R) Test Execution Command Line Tool Version 15.8.0
Copyright (c) Microsoft Corporation. All rights reserved.

Starting test execution, please wait...
[xUnit.net 00:00:00.77]      PetTests.DogTalkToOwnerReturnsWoof [FAIL]
[xUnit.net 00:00:00.78]      PetTests.CatTalkToOwnerReturnsMeow [FAIL]
Failed   PetTests.DogTalkToOwnerReturnsWoof
Error Message:
  Assert.NotEqual() Failure
Expected: Not "Woof!"
Actual:   "Woof!"
Stack Trace:
  at PetTests.DogTalkToOwnerReturnsWoof() in c:\Users\ronpet\repos\samples\core\Console-
apps\NewTypesMsBuild\test\NewTypesTests\PetTests.cs:line 13
Failed   PetTests.CatTalkToOwnerReturnsMeow
Error Message:
  Assert.NotEqual() Failure
Expected: Not "Meow!"
Actual:   "Meow!"
Stack Trace:
  at PetTests.CatTalkToOwnerReturnsMeow() in c:\Users\ronpet\repos\samples\core\Console-
apps\NewTypesMsBuild\test\NewTypesTests\PetTests.cs:line 22

Total tests: 2. Passed: 0. Failed: 2. Skipped: 0.
Test Run Failed.
Test execution time: 1.7000 Seconds
```

Change the assertions of your tests from `Assert.NotEqual` to `Assert.Equal`:

```
using System;
using Xunit;
using Pets;

public class PetTests
{
    [Fact]
    public void DogTalkToOwnerReturnsWoof()
    {
        string expected = "Woof!";
        string actual = new Dog().TalkToOwner();

        Assert.Equal(expected, actual);
    }

    [Fact]
    public void CatTalkToOwnerReturnsMeow()
    {
        string expected = "Meow!";
        string actual = new Cat().TalkToOwner();

        Assert.Equal(expected, actual);
    }
}
```

Re-run the tests with the `dotnet test` command and obtain the following output:

```
Test run for c:\Users\ronpet\repos\samples\core\Console-
apps\NewTypesMsBuild\test\NewTypesTests\bin\Debug\netcoreapp2.1\NewTypesTests.dll(.NETCoreApp,Version=v2.1)
Microsoft (R) Test Execution Command Line Tool Version 15.8.0
Copyright (c) Microsoft Corporation. All rights reserved.

Starting test execution, please wait...

Total tests: 2. Passed: 2. Failed: 0. Skipped: 0.
Test Run Successful.
Test execution time: 1.6029 Seconds
```

Testing passes. The pet types' methods return the correct values when talking to the owner.

You've learned techniques for organizing and testing projects using xUnit. Go forward with these techniques applying them in your own projects. *Happy coding!*

Developing Libraries with Cross Platform Tools

3/1/2019 • 11 minutes to read • [Edit Online](#)

This article covers how to write libraries for .NET using cross-platform CLI tools. The CLI provides an efficient and low-level experience that works across any supported OS. You can still build libraries with Visual Studio, and if that is your preferred experience [refer to the Visual Studio guide](#).

Prerequisites

You need [the .NET Core SDK and CLI](#) installed on your machine.

For the sections of this document dealing with .NET Framework versions, you need the [.NET Framework](#) installed on a Windows machine.

Additionally, if you wish to support older .NET Framework targets, you need to install targeting/developer packs for older framework versions from the [.NET download archives page](#). Refer to this table:

.NET FRAMEWORK VERSION	WHAT TO DOWNLOAD
4.6.1	.NET Framework 4.6.1 Targeting Pack
4.6	.NET Framework 4.6 Targeting Pack
4.5.2	.NET Framework 4.5.2 Developer Pack
4.5.1	.NET Framework 4.5.1 Developer Pack
4.5	Windows Software Development Kit for Windows 8
4.0	Windows SDK for Windows 7 and .NET Framework 4
2.0, 3.0, and 3.5	.NET Framework 3.5 SP1 Runtime (or Windows 8+ version)

How to target the .NET Standard

If you're not quite familiar with the .NET Standard, refer to the [.NET Standard](#) to learn more.

In that article, there is a table which maps .NET Standard versions to various implementations:

.NET STANDARD	1.0	1.1	1.2	1.3	1.4	1.5	1.6	2.0
Xamarin.iOS	10.0	10.0	10.0	10.0	10.0	10.0	10.0	10.14
Xamarin.Mac	3.0	3.0	3.0	3.0	3.0	3.0	3.0	3.8
Xamarin.Android	7.0	7.0	7.0	7.0	7.0	7.0	7.0	8.0
Universal Windows Platform	10.0	10.0	10.0	10.0	10.0	10.0.16299	10.0.16299	10.0.16299
Unity	2018.1	2018.1	2018.1	2018.1	2018.1	2018.1	2018.1	2018.1

1 The versions listed for .NET Framework apply to .NET Core 2.0 SDK and later versions of the tooling. Older versions used a different mapping for .NET Standard 1.5 and higher. You can [download tooling for .NET Core tools for Visual Studio 2015](#) if you cannot upgrade to Visual Studio 2017.

2 The versions listed here represent the rules that NuGet uses to determine whether a given .NET Standard library is applicable. While NuGet considers .NET Framework 4.6.1 as supporting .NET Standard 1.5 through 2.0, there are several issues with consuming .NET Standard libraries that were built for those versions from .NET Framework 4.6.1 projects. For .NET Framework projects that need to use such libraries, we recommend that you upgrade the project to target .NET Framework 4.7.2 or higher.

- The columns represent .NET Standard versions. Each header cell is a link to a document that shows which APIs got added in that version of .NET Standard.
- The rows represent the different .NET implementations.
- The version number in each cell indicates the *minimum* version of the implementation you'll need in order to target that .NET Standard version.
- For an interactive table, see [.NET Standard versions](#).

Here's what this table means for the purposes of creating a library:

The version of the .NET Standard you pick will be a tradeoff between access to the newest APIs and the ability to target more .NET implementations and .NET Standard versions. You control the range of targetable platforms and versions by picking a version of `netstandardX.X` (Where `X.X` is a version number) and adding it to your project file (`.csproj` or `.fsproj`).

You have three primary options when targeting the .NET Standard, depending on your needs.

1. You can use the default version of the .NET Standard supplied by templates - `netstandard1.4` - which gives you access to most APIs on .NET Standard while still being compatible with UWP, .NET Framework 4.6.1, and the forthcoming .NET Standard 2.0.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>netstandard1.4</TargetFramework>
  </PropertyGroup>
</Project>
```

2. You can use a lower or higher version of the .NET Standard by modifying the value in the `TargetFramework` node of your project file.

.NET Standard versions are backward compatible. That means that `netstandard1.0` libraries run on

`netstandard1.1` platforms and higher. However, there is no forward compatibility - lower .NET Standard platforms cannot reference higher ones. This means that `netstandard1.0` libraries cannot reference libraries targeting `netstandard1.1` or higher. Select the Standard version that has the right mix of APIs and platform support for your needs. We recommend `netstandard1.4` for now.

3. If you want to target the .NET Framework versions 4.0 or below, or you wish to use an API available in the .NET Framework but not in the .NET Standard (for example, `System.Drawing`), read the following sections and learn how to multitarget.

How to target the .NET Framework

NOTE

These instructions assume you have the .NET Framework installed on your machine. Refer to the [Prerequisites](#) to get dependencies installed.

Keep in mind that some of the .NET Framework versions used here are no longer in support. Refer to the [.NET Framework Support Lifecycle Policy FAQ](#) about unsupported versions.

If you want to reach the maximum number of developers and projects, use the .NET Framework 4.0 as your baseline target. To target the .NET Framework, you will need to begin by using the correct Target Framework Moniker (TFM) that corresponds to the .NET Framework version you wish to support.

```
.NET Framework 2.0    --> net20
.NET Framework 3.0    --> net30
.NET Framework 3.5    --> net35
.NET Framework 4.0    --> net40
.NET Framework 4.5    --> net45
.NET Framework 4.5.1  --> net451
.NET Framework 4.5.2  --> net452
.NET Framework 4.6    --> net46
.NET Framework 4.6.1  --> net461
.NET Framework 4.6.2  --> net462
.NET Framework 4.7    --> net47
```

You then insert this TFM into the `TargetFramework` section of your project file. For example, here's how you would write a library which targets the .NET Framework 4.0:

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>net40</TargetFramework>
  </PropertyGroup>
</Project>
```

And that's it! Although this compiled only for the .NET Framework 4, you can use the library on newer versions of the .NET Framework.

How to Multitarget

NOTE

The following instructions assume you have the .NET Framework installed on your machine. Refer to the [Prerequisites](#) section to learn which dependencies you need to install and where to download them from.

You may need to target older versions of the .NET Framework when your project supports both the .NET Framework and .NET Core. In this scenario, if you want to use newer APIs and language constructs for the newer targets, use `#if` directives in your code. You also might need to add different packages and dependencies for each platform you're targeting to include the different APIs needed for each case.

For example, let's say you have a library that performs networking operations over HTTP. For .NET Standard and the .NET Framework versions 4.5 or higher, you can use the `HttpClient` class from the `System.Net.Http` namespace. However, earlier versions of the .NET Framework don't have the `HttpClient` class, so you could use the `WebClient` class from the `System.Net` namespace for those instead.

Your project file could look like this:

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFrameworks>netstandard1.4;net40;net45</TargetFrameworks>
  </PropertyGroup>

  <!-- Need to conditionally bring in references for the .NET Framework 4.0 target -->
  <ItemGroup Condition="$(TargetFramework) == 'net40'">
    <Reference Include="System.Net" />
  </ItemGroup>

  <!-- Need to conditionally bring in references for the .NET Framework 4.5 target -->
  <ItemGroup Condition="$(TargetFramework) == 'net45'">
    <Reference Include="System.Net.Http" />
    <Reference Include="System.Threading.Tasks" />
  </ItemGroup>
</Project>
```

You'll notice three major changes here:

1. The `TargetFramework` node has been replaced by `TargetFrameworks`, and three TFMs are expressed inside.
2. There is an `<ItemGroup>` node for the `net40` target pulling in one .NET Framework reference.
3. There is an `<ItemGroup>` node for the `net45` target pulling in two .NET Framework references.

The build system is aware of the following preprocessor symbols used in `#if` directives:

TARGET FRAMEWORKS	SYMBOLS
.NET Framework	NET20, NET35, NET40, NET45, NET451, NET452, NET46, NET461, NET462, NET47, NET471, NET472
.NET Standard	NETSTANDARD1_0, NETSTANDARD1_1, NETSTANDARD1_2, NETSTANDARD1_3, NETSTANDARD1_4, NETSTANDARD1_5, NETSTANDARD1_6, NETSTANDARD2_0
.NET Core	NETCOREAPP1_0, NETCOREAPP1_1, NETCOREAPP2_0, NETCOREAPP2_1, NETCOREAPP2_2

Here is an example making use of conditional compilation per-target:

```

using System;
using System.Text.RegularExpressions;
#if NET40
// This only compiles for the .NET Framework 4 targets
using System.Net;
#else
// This compiles for all other targets
using System.Net.Http;
using System.Threading.Tasks;
#endif

namespace MultitargetLib
{
    public class Library
    {
#if NET40
        private readonly WebClient _client = new WebClient();
        private readonly object _locker = new object();
#else
        private readonly HttpClient _client = new HttpClient();
#endif

#if NET40
        // .NET Framework 4.0 does not have async/await
        public string GetDotNetCount()
        {
            string url = "https://www.dotnetfoundation.org/";

            var uri = new Uri(url);

            string result = "";

            // Lock here to provide thread-safety.
            lock(_locker)
            {
                result = _client.DownloadString(uri);
            }

            int dotNetCount = Regex.Matches(result, ".NET").Count;

            return $"Dotnet Foundation mentions .NET {dotNetCount} times!";
        }
#else
        // .NET 4.5+ can use async/await!
        public async Task<string> GetDotNetCountAsync()
        {
            string url = "https://www.dotnetfoundation.org/";

            // HttpClient is thread-safe, so no need to explicitly lock here
            var result = await _client.GetStringAsync(url);

            int dotNetCount = Regex.Matches(result, ".NET").Count;

            return $"dotnetfoundation.org mentions .NET {dotNetCount} times in its HTML!";
        }
#endif
    }
}

```

If you build this project with `dotnet build`, you'll notice three directories under the `bin/` folder:

```

net40/
net45/
netstandard1.4/

```

Each of these contain the `.dll` files for each target.

How to test libraries on .NET Core

It's important to be able to test across platforms. You can use either [xUnit](#) or MSTest out of the box. Both are perfectly suitable for unit testing your library on .NET Core. How you set up your solution with test projects will depend on the [structure of your solution](#). The following example assumes that the test and source directories live in the same top-level directory.

NOTE

This uses some [.NET Core CLI commands](#). See [dotnet new](#) and [dotnet sln](#) for more information.

1. Set up your solution. You can do so with the following commands:

```
mkdir SolutionWithSrcAndTest
cd SolutionWithSrcAndTest
dotnet new sln
dotnet new classlib -o MyProject
dotnet new xunit -o MyProject.Test
dotnet sln add MyProject/MyProject.csproj
dotnet sln add MyProject.Test/MyProject.Test.csproj
```

This will create projects and link them together in a solution. Your directory for `SolutionWithSrcAndTest` should look like this:

```
/SolutionWithSrcAndTest
|__SolutionWithSrcAndTest.sln
|__MyProject/
|__MyProject.Test/
```

2. Navigate to the test project's directory and add a reference to `MyProject.Test` from `MyProject`.

```
cd MyProject.Test
dotnet add reference ../MyProject/MyProject.csproj
```

3. Restore packages and build projects:

```
dotnet restore
dotnet build
```

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

4. Verify that xUnit runs by executing the `dotnet test` command. If you chose to use MSTest, then the MSTest console runner should run instead.

And that's it! You can now test your library across all platforms using command line tools. To continue testing now that you have everything set up, testing your library is very simple:

1. Make changes to your library.
2. Run tests from the command line, in your test directory, with `dotnet test` command.

Your code will be automatically rebuilt when you invoke `dotnet test` command.

How to use multiple projects

A common need for larger libraries is to place functionality in different projects.

Imagine you wished to build a library which could be consumed in idiomatic C# and F#. That would mean that consumers of your library consume them in ways which are natural to C# or F#. For example, in C# you might consume the library like this:

```
using AwesomeLibrary.CSharp;

public Task DoThings(Data data)
{
    var convertResult = await AwesomeLibrary.ConvertAsync(data);
    var result = AwesomeLibrary.Process(convertResult);
    // do something with result
}
```

In F#, it might look like this:

```
open AwesomeLibrary.FSharp

let doWork data = async {
    let! result = AwesomeLibrary.AsyncConvert data // Uses an F# async function rather than C# async method
    // do something with result
}
```

Consumption scenarios like this mean that the APIs being accessed have to have a different structure for C# and F#. A common approach to accomplishing this is to factor all of the logic of a library into a core project, with C# and F# projects defining the API layers that call into that core project. The rest of the section will use the following names:

- **AwesomeLibrary.Core** - A core project which contains all logic for the library
- **AwesomeLibrary.CSharp** - A project with public APIs intended for consumption in C#
- **AwesomeLibrary.FSharp** - A project with public APIs intended for consumption in F#

You can run the following commands in your terminal to produce the same structure as this guide:

```
mkdir AwesomeLibrary && cd AwesomeLibrary
dotnet new sln
mkdir AwesomeLibrary.Core && cd AwesomeLibrary.Core && dotnet new classlib
cd ..
mkdir AwesomeLibrary.CSharp && cd AwesomeLibrary.CSharp && dotnet new classlib
cd ..
mkdir AwesomeLibrary.FSharp && cd AwesomeLibrary.FSharp && dotnet new classlib -lang F#
cd ..
dotnet sln add AwesomeLibrary.Core/AwesomeLibrary.Core.csproj
dotnet sln add AwesomeLibrary.CSharp/AwesomeLibrary.CSharp.csproj
dotnet sln add AwesomeLibrary.FSharp/AwesomeLibrary.FSharp.fsproj
```

This will add the three projects above and a solution file which links them together. Creating the solution file and linking projects will allow you to restore and build projects from a top-level.

Project-to-project referencing

The best way to reference a project is to use the .NET Core CLI to add a project reference. From the **AwesomeLibrary.CSharp** and **AwesomeLibrary.FSharp** project directories, you can run the following command:

```
dotnet add reference ../AwesomeLibrary.Core/AwesomeLibrary.Core.csproj
```

The project files for both **AwesomeLibrary.CSharp** and **AwesomeLibrary.FSharp** will now reference **AwesomeLibrary.Core** as a `ProjectReference` target. You can verify this by inspecting the project files and seeing the following in them:

```
<ItemGroup>
  <ProjectReference Include="..\AwesomeLibrary.Core\AwesomeLibrary.Core.csproj" />
</ItemGroup>
```

You can add this section to each project file manually if you prefer not to use the .NET Core CLI.

Structuring a solution

Another important aspect of multi-project solutions is establishing a good overall project structure. You can organize code however you like, and as long as you link each project to your solution file with `dotnet sln add`, you will be able to run `dotnet restore` and `dotnet build` at the solution level.

Get started with ASP.NET Core

3/12/2019 • 2 minutes to read • [Edit Online](#)

For tutorials about developing ASP.NET Core web applications, see [ASP.NET Core Tutorials](#).

Write a custom .NET Core host to control the .NET runtime from your native code

2/28/2019 • 18 minutes to read • [Edit Online](#)

Like all managed code, .NET Core applications are executed by a host. The host is responsible for starting the runtime (including components like the JIT and garbage collector) and invoking managed entry points.

Hosting the .NET Core runtime is an advanced scenario and, in most cases, .NET Core developers don't need to worry about hosting because .NET Core build processes provide a default host to run .NET Core applications. In some specialized circumstances, though, it can be useful to explicitly host the .NET Core runtime, either as a means of invoking managed code in a native process or in order to gain more control over how the runtime works.

This article gives an overview of the steps necessary to start the .NET Core runtime from native code and execute managed code in it.

Prerequisites

Because hosts are native applications, this tutorial will cover constructing a C++ application to host .NET Core. You will need a C++ development environment (such as that provided by [Visual Studio](#)).

You will also want a simple .NET Core application to test the host with, so you should install the [.NET Core SDK](#) and [build a small .NET Core test app](#) (such as a 'Hello World' app). The 'Hello World' app created by the new .NET Core console project template is sufficient.

Hosting APIs

There are two different APIs that can be used to host .NET Core. This document (and its associated [samples](#)) cover both options.

- The preferred method of hosting the .NET Core runtime is with the [CoreClrHost.h](#) API. This API exposes functions for easily starting and stopping the runtime and invoking managed code (either by launching a managed exe or by calling static managed methods).
- .NET Core can also be hosted with the `ICLRRuntimeHost4` interface in [mscoree.h](#). This API has been around longer than CoreClrHost.h, so you may have seen older hosts using it. It still works and allows a bit more control over the hosting process than CoreClrHost. For most scenarios, though, CoreClrHost.h is preferred now because of its simpler APIs.

Sample Hosts

[Sample hosts](#) demonstrating the steps outlined in the tutorials below are available in the `dotnet/samples` GitHub repository. Comments in the samples clearly associate the numbered steps from these tutorials with where they're performed in the sample. For download instructions, see [Samples and Tutorials](#).

Keep in mind that the sample hosts are meant to be used for learning purposes, so they are light on error checking and are designed to emphasize readability over efficiency. More real-world host samples are available in the `dotnet/coreclr` repository. The [CoreRun host](#) and [Unix CoreRun host](#), in particular, are good general-purpose hosts to study after reading through these simpler samples.

Create a host using CoreClrHost.h

The following steps detail how to use the CoreClrHost.h API to start the .NET Core runtime in a native application and call into a managed static method. The code snippets in this document use some Windows-specific APIs, but the [full sample host](#) shows both Windows and Linux code paths.

Step 1 - Find and load CoreCLR

The .NET Core runtime APIs are in `coreclr.dll` (on Windows), in `libcoreclr.so` (on Linux), or in `libcoreclr.dylib` (on macOS). The first step to hosting .NET Core is to load the CoreCLR library. Some hosts probe different paths or use input parameters to find the library while others know to load it from a certain path (next to the host, for example, or from a machine-wide location).

Once found, the library is loaded with `LoadLibraryEx` (on Windows) or `dlopen` (on Linux/Mac).

```
HMODULE coreClr = LoadLibraryExA(coreClrPath.c_str(), NULL, 0);
```

Step 2 - Get .NET Core hosting functions

CoreClrHost has several important methods useful for hosting .NET Core:

- `coreclr_initialize` : Starts the .NET Core runtime and sets up the default (and only) AppDomain.
- `coreclr_execute_assembly` : Executes a managed assembly.
- `coreclr_create_delegate` : Creates a function pointer to a managed method.
- `coreclr_shutdown` : Shuts down the .NET Core runtime.
- `coreclr_shutdown_2` : Like `coreclr_shutdown`, but also retrieves the managed code's exit code.

After loading the CoreCLR library, the next step is to get references to these functions using `GetProcAddress` (on Windows) or `dlsym` (on Linux/Mac).

```
coreclr_initialize_ptr initializeCoreClr = (coreclr_initialize_ptr)GetProcAddress(coreClr,
"coreclr_initialize");
coreclr_create_delegate_ptr createManagedDelegate = (coreclr_create_delegate_ptr)GetProcAddress(coreClr,
"coreclr_create_delegate");
coreclr_shutdown_ptr shutdownCoreClr = (coreclr_shutdown_ptr)GetProcAddress(coreClr, "coreclr_shutdown");
```

Step 3 - Prepare runtime properties

Before starting the runtime, it is necessary to prepare some properties to specify behavior (especially concerning the assembly loader).

Common properties include:

- `TRUSTED_PLATFORM_ASSEMBLIES` This is a list of assembly paths (delimited by ';' on Windows and ':' on Linux) which the runtime will be able to resolve by default. Some hosts have hard-coded manifests listing assemblies they can load. Others will put any library in certain locations (next to `coreclr.dll`, for example) on this list.
- `APP_PATHS` This is a list of paths to probe in for an assembly if it can't be found in the trusted platform assemblies (TPA) list. Because the host has more control over which assemblies are loaded using the TPA list, it is a best practice for hosts to determine which assemblies they expect to load and list them explicitly. If probing at runtime is needed, however, this property can enable that scenario.
- `APP_NI_PATHS` This list is similar to APP_PATHS except that it's meant to be paths that will be probed for native images.
- `NATIVE_DLL_SEARCH_DIRECTORIES` This property is a list of paths the loader should probe when looking for native libraries called via p/invoke.
- `PLATFORM_RESOURCE_ROOTS` This list includes paths to probe in for resource satellite assemblies (in culture-specific sub-directories).

In this sample host, the TPA list is constructed by simply listing all libraries in the current directory:

```

void BuildTpaList(const char* directory, const char* extension, std::string& tpaList)
{
    // This will add all files with a .dll extension to the TPA list.
    // This will include unmanaged assemblies (coreclr.dll, for example) that don't
    // belong on the TPA list. In a real host, only managed assemblies that the host
    // expects to load should be included. Having extra unmanaged assemblies doesn't
    // cause anything to fail, though, so this function just enumerates all dll's in
    // order to keep this sample concise.
    std::string searchPath(directory);
    searchPath.append(FS_SEPARATOR);
    searchPath.append("*");
    searchPath.append(extension);

    WIN32_FIND_DATAA findData;
    HANDLE fileHandle = FindFirstFileA(searchPath.c_str(), &findData);

    if (fileHandle != INVALID_HANDLE_VALUE)
    {
        do
        {
            // Append the assembly to the list
            tpaList.append(directory);
            tpaList.append(FS_SEPARATOR);
            tpaList.append(findData.cFileName);
            tpaList.append(PATH_DELIMITER);

            // Note that the CLR does not guarantee which assembly will be loaded if an assembly
            // is in the TPA list multiple times (perhaps from different paths or perhaps with different
NI/NI.dll
            // extensions. Therefore, a real host should probably add items to the list in priority order and
only
            // add a file if it's not already present on the list.
            //
            // For this simple sample, though, and because we're only loading TPA assemblies from a single
path,
            // and have no native images, we can ignore that complication.
        }
        while (FindNextFileA(fileHandle, &findData));
        FindClose(fileHandle);
    }
}

```

Because the sample is simple, it only needs the `TRUSTED_PLATFORM_ASSEMBLIES` property:

```

// Define CoreCLR properties
// Other properties related to assembly loading are common here,
// but for this simple sample, TRUSTED_PLATFORM_ASSEMBLIES is all
// that is needed. Check hosting documentation for other common properties.
const char* propertyKeys[] = {
    "TRUSTED_PLATFORM_ASSEMBLIES"      // Trusted assemblies
};

const char* propertyValues[] = {
    tpaList.c_str()
};

```

Step 4 - Start the runtime

Unlike the mscoree.h hosting API (described below), CoreCLRHost.h APIs start the runtime and create the default AppDomain all with a single call. The `coreclr_initialize` function takes a base path, name, and the properties described earlier and returns back a handle to the host via the `hostHandle` parameter.

```

void* hostHandle;
unsigned int domainId;

// This function both starts the .NET Core runtime and creates
// the default (and only) AppDomain
int hr = initializeCoreClr(
    runtimePath,           // App base path
    "SampleHost",          // AppDomain friendly name
    sizeof(propertyKeys) / sizeof(char*), // Property count
    propertyKeys,          // Property names
    propertyValues,         // Property values
    &hostHandle,            // Host handle
    &domainId);            // AppDomain ID

```

Step 5 - Run managed code!

With the runtime started, the host can call managed code. This can be done in a couple of different ways. The sample code linked to this tutorial uses the `coreclr_create_delegate` function to create a delegate to a static managed method. This API takes the [assembly name](#), namespace-qualified type name, and method name as inputs and returns a delegate that can be used to invoke the method.

```

doWork_ptr managedDelegate;

// The assembly name passed in the third parameter is a managed assembly name
// as described at https://docs.microsoft.com/dotnet/framework/app-domains/assembly-names
hr = createManagedDelegate(
    hostHandle,
    domainId,
    "ManagedLibrary, Version=1.0.0.0",
    "ManagedLibrary.ManagedWorker",
    "DoWork",
    (void**)&managedDelegate);

```

In this sample, the host can now call `managedDelegate` to run the `ManagedWorker.DoWork` method.

Alternatively, the `coreclr_execute_assembly` function can be used to launch a managed executable. This API takes an assembly path and array of arguments as input parameters. It loads the assembly at that path and invokes its main method.

```

int hr = executeAssembly(
    hostHandle,
    domainId,
    argumentCount,
    arguments,
    "HelloWorld.exe",
    (unsigned int*)&exitCode);

```

Step 6 - Shutdown and clean up

Finally, when the host is done running managed code, the .NET Core runtime is shut down with `coreclr_shutdown` or `coreclr_shutdown_2`.

```
hr = shutdownCoreClr(hostHandle, domainId);
```

Remember to unload the CoreCLR library using `FreeLibrary` (on Windows) or `dlopen` (on Linux/Mac).

Create a host using Mscoree.h

As mentioned previously, CoreClrHost.h is now the preferred method of hosting the .NET Core runtime. The `ICLRRuntimeHost4` interface can still be used, though, if the CoreClrHost.h interfaces aren't sufficient (if non-standard startup flags are needed, for example, or if an AppDomainManager is needed on the default domain). These instructions will guide you through hosting .NET Core using mscoree.h.

A note about mscoree.h

The `ICLRRuntimeHost4` .NET Core hosting interface is defined in [MSCOREE.IDL](#). A header version of this file (mscoree.h), which your host will need to reference, is produced via MIDL when the [.NET Core runtime](#) is built. If you do not want to build the .NET Core runtime, mscoree.h is also available as a [pre-built header](#) in the dotnet/coreclr repository. [Instructions on building the .NET Core runtime](#) can be found in its GitHub repository.

Step 1 - Identify the managed entry point

After referencing necessary headers (`mscoree.h` and `stdio.h`, for example), one of the first things a .NET Core host must do is locate the managed entry point it will be using. In our sample host, this is done by just taking the first command line argument to our host as the path to a managed binary whose `main` method will be executed.

```
// The managed application to run should be the first command-line parameter.  
// Subsequent command line parameters will be passed to the managed app later in this host.  
wchar_t targetApp[MAX_PATH];  
GetFullPathNameW(argv[1], MAX_PATH, targetApp, NULL);
```

Step 2 - Find and load CoreCLR

The .NET Core runtime APIs are in `CoreCLR.dll` (on Windows). To get our hosting interface (`ICLRRuntimeHost4`), it's necessary to find and load `CoreCLR.dll`. It is up to the host to define a convention for how it will locate `CoreCLR.dll`. Some hosts expect the file to be present in a well-known machine-wide location (such as `%programfiles%\dotnet\shared\Microsoft.NETCore.App\2.1.6`). Others expect that `CoreCLR.dll` will be loaded from a location next to either the host itself or the app to be hosted. Still others might consult an environment variable to find the library.

On Linux or Mac, the core runtime library is `libcoreclr.so` or `libcoreclr.dylib`, respectively.

Our sample host probes a few common locations for `CoreCLR.dll`. Once found, it must be loaded via `LoadLibrary` (or `dlopen` on Linux/Mac).

```
HMODULE ret = LoadLibraryExW(coreDllPath, NULL, 0);
```

Step 3 - Get an ICLRRuntimeHost4 Instance

The `ICLRRuntimeHost4` hosting interface is retrieved by calling `GetProcAddress` (or `dlsym` on Linux/Mac) on `GetCLRRuntimeHost`, and then invoking that function.

```
ICLRRuntimeHost4* runtimeHost;  
  
FnGetCLRRuntimeHost pfnGetCLRRuntimeHost =  
    (FnGetCLRRuntimeHost)::GetProcAddress(coreCLRModule, "GetCLRRuntimeHost");  
  
if (!pfnGetCLRRuntimeHost)  
{  
    printf("ERROR - GetCLRRuntimeHost not found");  
    return -1;  
}  
  
// Get the hosting interface  
HRESULT hr = pfnGetCLRRuntimeHost(IID_ICLRRuntimeHost4, (IUnknown**)&runtimeHost);
```

Step 4 - Set startup flags and start the runtime

With an `ICLRRuntimeHost4` in-hand, we can now specify runtime-wide startup flags and start the runtime. Startup flags determine which garbage collector (GC) to use (concurrent or server), whether we will use a single AppDomain or multiple AppDomains, and what loader optimization policy to use (for domain-neutral loading of assemblies).

```
hr = runtimeHost->SetStartupFlags(
    // These startup flags control runtime-wide behaviors.
    // A complete list of STARTUP_FLAGS can be found in mscoree.h,
    // but some of the more common ones are listed below.
    static_cast<STARTUP_FLAGS>(
        // STARTUP_FLAGS::STARTUP_SERVER_GC |           // Use server GC
        // STARTUP_FLAGS::STARTUP_LOADER_OPTIMIZATION_MULTI_DOMAIN | // Maximize domain-neutral loading
        // STARTUP_FLAGS::STARTUP_LOADER_OPTIMIZATION_MULTI_DOMAIN_HOST | // Domain-neutral loading for
        // strongly-named assemblies
        STARTUP_FLAGS::STARTUP_CONCURRENT_GC |           // Use concurrent GC
        STARTUP_FLAGS::STARTUP_SINGLE_APPDOMAIN |         // All code executes in the default AppDomain
                                                        // (required to use the runtimeHost-
        >ExecuteAssembly helper function)
        STARTUP_FLAGS::STARTUP_LOADER_OPTIMIZATION_SINGLE_DOMAIN // Prevents domain-neutral loading
    )
);
```

The runtime is started with a call to the `Start` function.

```
hr = runtimeHost->Start();
```

Step 5 - Preparing AppDomain settings

Once the runtime is started, we will want to set up an AppDomain. There are a number of options that must be specified when creating a .NET AppDomain, however, so it's necessary to prepare those first.

AppDomain flags specify AppDomain behaviors related to security and interop. Older Silverlight hosts used these settings to sandbox user code, but most modern .NET Core hosts run user code as full trust and enable interop.

```
int appDomainFlags =
    // APPDOMAIN_FORCE_TRIVIAL_WAIT_OPERATIONS | // Do not pump messages during wait
    // APPDOMAIN_SECURITY_SANDBOXED |           // Causes assemblies not from the TPA list to be loaded as partially
    // trusted
    APPDOMAIN_ENABLE_PLATFORM_SPECIFIC_APPS |   // Enable platform-specific assemblies to run
    APPDOMAIN_ENABLE_PINVOKE_AND_CLASSIC_COMINTEROP | // Allow PInvoking from non-TPA assemblies
    APPDOMAIN_DISABLE_TRANSPARENCY_ENFORCEMENT; // Entirely disables transparency checks
```

After deciding which AppDomain flags to use, AppDomain properties must be defined. The properties are key/value pairs of strings. Many of the properties relate to how the AppDomain will load assemblies.

Common AppDomain properties include:

- `TRUSTED_PLATFORM_ASSEMBLIES` This is a list of assembly paths (delimited by `;` on Windows and `:` on Linux/Mac) which the AppDomain should prioritize loading and give full trust to (even in partially-trusted domains). This list is meant to contain 'Framework' assemblies and other trusted modules, similar to the GAC in .NET Framework scenarios. Some hosts will put any library next to `coreclr.dll` on this list, others have hard-coded manifests listing trusted assemblies for their purposes.
- `APP_PATHS` This is a list of paths to probe in for an assembly if it can't be found in the trusted platform assemblies (TPA) list. Because the host has more control over which assemblies are loaded using the TPA list, it is a best practice for hosts to determine which assemblies they expect to load and list them explicitly. If probing at runtime is needed, however, this property can enable that scenario.
- `APP_NI_PATHS` This list is very similar to `APP_PATHS` except that it's meant to be paths that will be probed for

native images.

- **NATIVE_DLL_SEARCH_DIRECTORIES** This property is a list of paths the loader should probe when looking for native DLLs called via p/invoke.
- **PLATFORM_RESOURCE_ROOTS** This list includes paths to probe in for resource satellite assemblies (in culture-specific sub-directories).

In our [simple sample host](#), these properties are set up as follows:

```
// TRUSTED_PLATFORM_ASSEMBLIES
// "Trusted Platform Assemblies" are prioritized by the loader and always loaded with full trust.
// A common pattern is to include any assemblies next to CoreCLR.dll as platform assemblies.
// More sophisticated hosts may also include their own Framework extensions (such as AppDomain managers)
// in this list.
size_t tpaSize = 100 * MAX_PATH; // Starting size for our TPA (Trusted Platform Assemblies) list
wchar_t* trustedPlatformAssemblies = new wchar_t[tpaSize];
trustedPlatformAssemblies[0] = L'\0';

// Extensions to probe for when finding TPA list files
const wchar_t *tpaExtensions[] = {
    L"*.dll",
    L"*.exe",
    L"*.winmd"
};

// Probe next to CoreCLR.dll for any files matching the extensions from tpaExtensions and
// add them to the TPA list. In a real host, this would likely be extracted into a separate function
// and perhaps also run on other directories of interest.
for (int i = 0; i < _countof(tpaExtensions); i++)
{
    // Construct the file name search pattern
    wchar_t searchPath[MAX_PATH];
    wcscpy_s(searchPath, MAX_PATH, coreRoot);
    wcscat_s(searchPath, MAX_PATH, L"\\");
    wcscat_s(searchPath, MAX_PATH, tpaExtensions[i]);

    // Find files matching the search pattern
    WIN32_FIND_DATAW findData;
    HANDLE fileHandle = FindFirstFileW(searchPath, &findData);

    if (fileHandle != INVALID_HANDLE_VALUE)
    {
        do
        {
            // Construct the full path of the trusted assembly
            wchar_t pathToAdd[MAX_PATH];
            wcscpy_s(pathToAdd, MAX_PATH, coreRoot);
            wcscat_s(pathToAdd, MAX_PATH, L"\\");
            wcscat_s(pathToAdd, MAX_PATH, findData.cFileName);

            // Check to see if TPA list needs expanded
            if (wcsnlen(pathToAdd, MAX_PATH) + (3) + wcsnlen(trustedPlatformAssemblies, tpaSize) >= tpaSize)
            {
                // Expand, if needed
                tpaSize *= 2;
                wchar_t* newTPAList = new wchar_t[tpaSize];
                wcscpy_s(newTPAList, tpaSize, trustedPlatformAssemblies);
                trustedPlatformAssemblies = newTPAList;
            }

            // Add the assembly to the list and delimited with a semi-colon
            wcscat_s(trustedPlatformAssemblies, tpaSize, pathToAdd);
            wcscat_s(trustedPlatformAssemblies, tpaSize, L";");

            // Note that the CLR does not guarantee which assembly will be loaded if an assembly
            // is in the TPA list multiple times (perhaps from different paths or perhaps with different
            NI/NI.dll
```

```

        // extensions. Therefore, a real host should probably add items to the list in priority order and
only
        // add a file if it's not already present on the list.
        //
        // For this simple sample, though, and because we're only loading TPA assemblies from a single
path,
        // we can ignore that complication.
    }
    while (FindNextFileW(fileHandle, &findData));
    FindClose(fileHandle);
}
}

// APP_PATHS
// App paths are directories to probe in for assemblies which are not one of the well-known Framework
assemblies
// included in the TPA list.
//
// For this simple sample, we just include the directory the target application is in.
// More complex hosts may want to also check the current working directory or other
// locations known to contain application assets.
wchar_t appPaths[MAX_PATH * 50];

// Just use the targetApp provided by the user and remove the file name
wcscpy_s(appPaths, targetAppPath);

// APP_NI_PATHS
// App (NI) paths are the paths that will be probed for native images not found on the TPA list.
// It will typically be similar to the app paths.
// For this sample, we probe next to the app and in a hypothetical directory of the same name with 'NI'
suffixed to the end.
wchar_t appNiPaths[MAX_PATH * 50];
wcscpy_s(appNiPaths, targetAppPath);
wcscat_s(appNiPaths, MAX_PATH * 50, L";");
wcscat_s(appNiPaths, MAX_PATH * 50, targetAppPath);
wcscat_s(appNiPaths, MAX_PATH * 50, L"NI");

// NATIVE_DLL_SEARCH_DIRECTORIES
// Native dll search directories are paths that the runtime will probe for native DLLs called via PInvoke
wchar_t nativeDllSearchDirectories[MAX_PATH * 50];
wcscpy_s(nativeDllSearchDirectories, appPaths);
wcscat_s(nativeDllSearchDirectories, MAX_PATH * 50, L";");
wcscat_s(nativeDllSearchDirectories, MAX_PATH * 50, coreRoot);

// PLATFORM_RESOURCE_ROOTS
// Platform resource roots are paths to probe in for resource assemblies (in culture-specific sub-directories)
wchar_t platformResourceRoots[MAX_PATH * 50];
wcscpy_s(platformResourceRoots, appPaths);

```

Step 6 - Create the AppDomain

Once all AppDomain flags and properties are prepared, `ICLRRuntimeHost4::CreateAppDomainWithManager` can be used to set up the AppDomain. This function optionally takes a fully qualified assembly name and type name to use as the domain's AppDomain manager. An AppDomain manager can allow a host to control some aspects of AppDomain behavior and may provide entry points for launching managed code if the host doesn't intend to invoke user code directly.

```

DWORD domainId;

// Setup key/value pairs for AppDomain properties
const wchar_t* propertyKeys[] = {
    L"TRUSTED_PLATFORM_ASSEMBLIES",
    L"APP_PATHS",
    L"APP_NI_PATHS",
    L"NATIVE_DLL_SEARCH_DIRECTORIES",
    L"PLATFORM_RESOURCE_ROOTS"
};

// Property values which were constructed in step 5
const wchar_t* propertyValues[] = {
    trustedPlatformAssemblies,
    appPaths,
    appNiPaths,
    nativeDllSearchDirectories,
    platformResourceRoots
};

// Create the AppDomain
hr = runtimeHost->CreateAppDomainWithManager(
    L"Sample Host AppDomain", // Friendly AD name
    appDomainFlags,
    NULL, // Optional AppDomain manager assembly name
    NULL, // Optional AppDomain manager type (including namespace)
    sizeof(propertyKeys) / sizeof(wchar_t*),
    propertyKeys,
    propertyValues,
    &domainId);

```

Step 7 - Run managed code!

With an AppDomain up and running, the host can now start executing managed code. The easiest way to do this is to use `ICLRRuntimeHost4::ExecuteAssembly` to invoke a managed assembly's entry point method. Note that this function only works in single-domain scenarios.

```

DWORD exitCode = -1;
hr = runtimeHost->ExecuteAssembly(domainId, targetApp, argc - 1, (LPCWSTR*)(argc > 1 ? &argv[1] : NULL),
&exitCode);

```

Another option, if `ExecuteAssembly` doesn't meet your host's needs, is to use `CreateDelegate` to create a function pointer to a static managed method. This requires the host to know the signature of the method it is calling into (in order to create the function pointer type) but allows hosts the flexibility to invoke code other than an assembly's entry point. The assembly name provided in the second parameter is the [full managed assembly name](#) of the library to load.

```

void *pfnDelegate = NULL;
hr = runtimeHost->CreateDelegate(
    domainId,
    L"HW, Version=1.0.0.0, Culture=neutral", // Target managed assembly
    L"ConsoleApplication.Program", // Target managed type
    L"Main", // Target entry point (static method)
    (INT_PTR*)&pfnDelegate);

((MainMethodFp*)pfnDelegate)(NULL);

```

Step 8 - Clean up

Finally, the host should clean up after itself by unloading AppDomains, stopping the runtime, and releasing the `ICLRRuntimeHost4` reference.

```
runtimeHost->UnloadAppDomain(domainId, true /* Wait until unload complete */);
runtimeHost->Stop();
runtimeHost->Release();
```

Conclusion

Once your host is built, it can be tested by running it from the command line and passing any arguments the host expects (like the managed app to run for the mscoree example host). When specifying the .NET Core app for the host to run, be sure to use the .dll that is produced by `dotnet build`. Executables (.exe files) produced by `dotnet publish` for self-contained applications are actually the default .NET Core host (so that the app can be launched directly from the command line in mainline scenarios); user code is compiled into a dll of the same name.

If things don't work initially, double-check that `coreclr.dll` is available in the location expected by the host, that all necessary Framework libraries are in the TPA list, and that CoreCLR's bitness (32- or 64-bit) matches how the host was built.

Hosting the .NET Core runtime is an advanced scenario that many developers won't require, but for those who need to launch managed code from a native process, or who need more control over the .NET Core runtime's behavior, it can be very useful. Because .NET Core is able to run side-by-side with itself, it's even possible to create hosts which initialize and start multiple versions of the .NET Core runtime and execute apps on all of them in the same process.

Create a custom template for dotnet new

3/8/2019 • 7 minutes to read • [Edit Online](#)

This tutorial shows you how to:

- Create a basic template from an existing project or a new console app project.
- Pack the template for distribution at nuget.org or from a local *nupkg* file.
- Install the template from nuget.org, a local *nupkg* file, or the local file system.
- Uninstall the template.

If you prefer to proceed through the tutorial with a complete sample, download the [sample project template](#). The sample template is configured for NuGet distribution.

If you wish to use the downloaded sample with file system distribution, do the following:

- Move the contents of the *content* folder of the sample up one level into the *GarciaSoftware.ConsoleTemplate.CSharp* folder.
- Delete the empty *content* folder.
- Delete the *nuspec* file.

Prerequisites

- Install the [.NET Core 2.0 SDK](#) or later versions.
- Read the reference topic [Custom templates for dotnet new](#).

Create a template from a project

Use an existing project that you've confirmed compiles and runs, or create a new console app project in a folder on your hard drive. This tutorial assumes that the name of the project folder is

GarciaSoftware.ConsoleTemplate.CSharp stored at *Documents\Templates* in the user's profile. The tutorial project template name is in the format <Company Name>. <Template Type>. <Programming Language>, but you're free to name your project and template anything you wish.

1. Add a folder to the root of the project named *.template.config*.
2. Inside the *.template.config* folder, create a *template.json* file to configure your template. For more information and member definitions for the *template.json* file, see the [Custom templates for dotnet new](#) topic and the [template.json schema at the JSON Schema Store](#).

```
{  
  "$schema": "http://json.schemastore.org/template",  
  "author": "Catalina Garcia",  
  "classifications": [ "Common", "Console" ],  
  "identity": "GarciaSoftware.ConsoleTemplate.CSharp",  
  "name": "Garcia Software Console Application",  
  "shortName": "garciaconsole"  
}
```

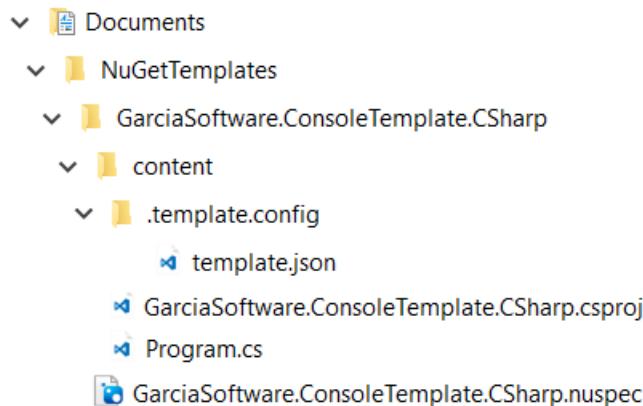

The template is finished. At this point, you have two options for template distribution. To continue this tutorial, choose one path or the other:

1. [NuGet distribution](#): install the template from NuGet or from the local *nupkg* file, and use the installed template.
2. [File system distribution](#).

Use NuGet Distribution

Pack the template into a NuGet package

1. Create a folder for the NuGet package. For the tutorial, the folder name `GarciaSoftware.ConsoleTemplate.CSharp` is used, and the folder is created inside a `Documents\NuGetTemplates` folder in the user's profile. Create a folder named `content` inside of the new template folder to hold the project files.
2. Copy the contents of your project folder, together with its `.template.config/template.json` file, into the `content` folder you created.
3. Next to the `content` folder, add a [nuspec file](#). The nuspec file is an XML manifest file that describes a package's contents and drives the process of creating the NuGet package.

4. Inside of a `<packageTypes>` element in the `nuspec` file, include a `<packageType>` element with a `name` attribute value of `Template`. Both the `content` folder and the `nuspec` file should reside in the same directory. The table shows the minimum `nuspec` file elements required to produce a template as a NuGet package.

ELEMENT	TYPE	DESCRIPTION
<code><authors></code>	string	A comma-separated list of packages authors, matching the profile names on nuget.org. Authors are displayed in the NuGet Gallery on nuget.org and are used to cross-reference packages by the same authors.
<code><description></code>	string	A long description of the package for UI display.
<code><id></code>	string	The case-insensitive package identifier, which must be unique across nuget.org or whatever gallery the package will reside in. IDs may not contain spaces or characters that are not valid for a URL and generally follow .NET namespace rules. See Choosing a unique package identifier and setting the version number for guidance.

ELEMENT	TYPE	DESCRIPTION
<code><packageType></code>	string	Place this element inside a <code><packageTypes></code> element among the <code><metadata></code> elements. Set the <code>name</code> attribute of the <code><packageType></code> element to <code>Template</code> .
<code><version></code>	string	The version of the package, following the major.minor.patch pattern. Version numbers may include a pre-release suffix as described in Pre-release versions .

See the [.nuspec reference](#) for the complete *nuspec* file schema.

The *nuspec* file for the tutorial is named *GarciaSoftware.ConsoleTemplate.CSharp.nuspec* and contains the following content:

```

<?xml version="1.0" encoding="utf-8"?>
<package xmlns="http://schemas.microsoft.com/packaging/2012/06/nuspec.xsd">
  <metadata>
    <id>GarciaSoftware.ConsoleTemplate.CSharp</id>
    <version>1.0.0</version>
    <description>
      Creates the Garcia Software console app.
    </description>
    <authors>Catalina Garcia</authors>
    <packageTypes>
      <packageType name="Template" />
    </packageTypes>
  </metadata>
</package>

```

5. Create the package using the `nuget pack <PATH_TO_NUSPEC_FILE>` command. The following command assumes that the folder that holds the NuGet assets is at `C:\Users\<USER>\Documents\Templates\GarciaSoftware.ConsoleTemplate.CSharp`. But wherever you place the folder on your system, the `nuget pack` command accepts the path to the *nuspec* file:

```

nuget pack C:\Users\<USER>\Documents\NuGetTemplates\GarciaSoftware.ConsoleTemplate.CSharp\GarciaSoftware.ConsoleTemplate.CSharp.nuspec

```

Publishing the package to nuget.org

To publish a NuGet package, follow the instructions in the [Create and publish a package](#) topic. However, we recommend that you don't publish the tutorial template to NuGet as it can never be deleted once published, only delisted. Now that you have the NuGet package in the form of a *nupkg* file, we suggest that you follow the instructions below to install the template directly from the local *nupkg* file.

Install the template from a NuGet package

Install the template from the local *nupkg* file

To install the template from the *nupkg* file that you produced, use the `dotnet new` command with the `-i|--install` option and provide the path to the *nupkg* file:

```

dotnet new -i C:\Users\<USER>\GarciaSoftware.ConsoleTemplate.CSharp.1.0.0.nupkg

```

Install the template from a NuGet package stored at nuget.org

If you wish to install a template from a NuGet package stored at nuget.org, use the `dotnet new` command with the `-i|--install` option and supply the name of the NuGet package:

```
dotnet new -i GarciaSoftware.ConsoleTemplate.CSharp
```

NOTE

The example is for demonstration purposes only. There isn't a `GarciaSoftware.ConsoleTemplate.CSharp` NuGet package at nuget.org, and we don't recommend that you publish and consume test templates from NuGet. If you run the command, no template is installed. However, you can install a template that hasn't been published to nuget.org by referencing the `nupkg` file directly on your local file system as shown in the previous section [Install the template from the local nupkg file](#).

If you'd like a live example of how to install a template from a package at nuget.org, you can use the [NUnit 3 template for dotnet-new](#). This template sets up a project to use NUnit unit testing. Use the following command to install it:

```
dotnet new -i NUnit3.DotNetNew.Template
```

When you list the templates with `dotnet new -l`, you see the *NUnit 3 Test Project* with a short name of `nunit` in the template list. You're ready to use the template in the next section.

Templates	Short Name
Console Application	console
Class library	classlib
Unit Test Project	mstest
NUnit 3 Test Project	nunit
xUnit Test Project	xunit
ASP.NET Core Empty	web
ASP.NET Core Web App (Model-View-Controller)	mvc

Create a project from the template

After the template is installed from NuGet, use the template by executing the `dotnet new <TEMPLATE>` command from the directory where you want to the template engine's output placed (unless you're using the `-o|--output` option to specify a specific directory). For more information, see [dotnet new Options](#). Supply the template's short name directly to the `dotnet new` command. To create a project from the NUnit template, run the following command:

```
dotnet new nunit
```

The console shows that the project is created and that the project's packages are restored. After the command is run, the project is ready for use.

```
C:\NUnitTemplateTest>dotnet new nunit
The template "NUnit 3 Test Project" was created successfully.

Processing post-creation actions...
Running 'dotnet restore' on C:\NUnitTemplateTest\NUnitTemplateTest.csproj...
Restoring packages for C:\NUnitTemplateTest\NUnitTemplateTest.csproj...
  Installing System.Private.DataContractSerialization 4.3.0
  Installing System.Runtime.InteropServices
  Installing NUnit 3.7.1
Generating MSBuild file C:\NUnitTemplateTest\obj\NUnitTemplateTest.csproj.nuget.g.props.
Generating MSBuild file C:\NUnitTemplateTest\obj\NUnitTemplateTest.csproj.nuget.g.targets.
Restore completed in 3.76 sec for C:\NUnitTemplateTest\NUnitTemplateTest.csproj.

Restore succeeded.
```

To uninstall a template from a NuGet package stored at nuget.org

```
dotnet new -u GarciaSoftware.ConsoleTemplate.CSharp
```

NOTE

The example is for demonstration purposes only. There isn't a `GarciaSoftware.ConsoleTemplate.CSharp` NuGet package at nuget.org or installed with the .NET Core SDK. If you run the command, no package/template is uninstalled and you receive the following exception:

```
Could not find something to uninstall called 'GarciaSoftware.ConsoleTemplate.CSharp'.
```

If you installed the [NUnit 3 template for dotnet-new](#) and wish to uninstall it, use the following command:

```
dotnet new -u NUnit3.DotNetNew.Template
```

Uninstall the template from a local nupkg file

When you wish to uninstall the template, don't attempt to use the path to the *nupkg* file. *Attempting to uninstall a template using `dotnet new -u <PATH_TO_NUPKG_FILE>` fails.* Reference the package by its `id`:

```
dotnet new -u GarciaSoftware.ConsoleTemplate.CSharp.1.0.0
```

Use file system distribution

To distribute the template, place the project template folder in a location accessible to users on your network. Use the `dotnet new` command with the `-i|--install` option and specify the path to the template folder (the project folder containing the project and the `.template.config` folder).

The tutorial assumes the project template is stored in the *Documents/Templates* folder of the user's profile. From that location, install the template with the following command replacing `<USER>` with the user's profile name:

```
dotnet new -i C:\Users\<USER>\Documents\Templates\GarciaSoftware.ConsoleTemplate.CSharp
```

Create a project from the template

After the template is installed from the file system, use the template by executing the `dotnet new <TEMPLATE>` command from the directory where you want to the template engine's output placed (unless you're using the `-o|--output` option to specify a specific directory). For more information, see [dotnet new Options](#). Supply the template's short name directly to the `dotnet new` command.

From a new project folder created at `C:\Users\<USER>\Documents\Projects\MyConsoleApp`, create a project

from the `garciaconsole` template:

```
dotnet new garciaconsole
```

Uninstall the template

If you created the template on your local file system at `C:\Users\<USER>\Documents\Templates\GarciaSoftware.ConsoleTemplate.CSharp`, uninstall it with the `-u|--uninstall` switch and the path to the template folder:

```
dotnet new -u C:\Users\<USER>\Documents\Templates\GarciaSoftware.ConsoleTemplate.CSharp
```

NOTE

To uninstall the template from your local file system, you need to fully qualify the path. For example, `C:\Users\<USER>\Documents\Templates\GarciaSoftware.ConsoleTemplate.CSharp` will work, but `./GarciaSoftware.ConsoleTemplate.CSharp` from the containing folder will not. Additionally, do not include a final terminating directory slash on your template path.

Packages, metapackages and frameworks

12/10/2018 • 7 minutes to read • [Edit Online](#)

.NET Core is a platform made of NuGet packages. Some product experiences benefit from fine-grained definition of packages while others from coarse-grained. To accommodate this duality, the product is distributed as a fine-grained set of packages and in coarser chunks with a package type informally called a [metapackage](#).

Each of the .NET Core packages support being run on multiple .NET implementations, represented as frameworks. Some of those frameworks are traditional frameworks, like `net46`, representing the .NET Framework. Another set is new frameworks that can be thought of as "package-based frameworks", which establish a new model for defining frameworks. These package-based frameworks are entirely formed and defined as packages, forming a strong relationship between packages and frameworks.

Packages

.NET Core is split into a set of packages, which provide primitives, higher-level data types, app composition types and common utilities. Each of these packages represent a single assembly of the same name. For example, [System.Runtime](#) contains `System.Runtime.dll`.

There are advantages to defining packages in a fine-grained manner:

- Fine-grained packages can ship on their own schedule with relatively limited testing of other packages.
- Fine-grained packages can provide differing OS and CPU support.
- Fine-grained packages can have dependencies specific to only one library.
- Apps are smaller because unreferenced packages don't become part of the app distribution.

Some of these benefits are only used in certain circumstances. For example, .NET Core packages will typically ship on the same schedule with the same platform support. In the case of servicing, fixes can be distributed and installed as small single package updates. Due to the narrow scope of change, the validation and time to make a fix available is limited to what is needed for a single library.

The following is a list of the key NuGet packages for .NET Core:

- [System.Runtime](#) - The most fundamental .NET Core package, including [Object](#), [String](#), [Array](#), [Action](#), and [IList<T>](#).
- [System.Collections](#) - A set of (primarily) generic collections, including [List<T>](#) and [Dictionary< TKey, TValue >](#).
- [System.Net.Http](#) - A set of types for HTTP network communication, including [HttpClient](#) and [HttpResponseMessage](#).
- [System.IO.FileSystem](#) - A set of types for reading and writing to local or networked disk-based storage, including [File](#) and [Directory](#).
- [System.Linq](#) - A set of types for querying objects, including [Enumerable](#) and [ILookup< TKey, TElement >](#).
- [System.Reflection](#) - A set of types for loading, inspecting, and activating types, including [Assembly](#), [TypeInfo](#) and [MethodInfo](#).

Typically, rather than including each package, it's easier and more robust to include a [metapackage](#). However, when you need a single package, you can include it as in the following example, which references the [System.Runtime](#) package.

```

<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>netstandard1.6</TargetFramework>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="System.Runtime" Version="4.3.0" />
  </ItemGroup>
</Project>

```

Metapackages

Metapackages are a NuGet package convention for describing a set of packages that are meaningful together. They represent this set of packages by making them dependencies. They can optionally establish a framework for this set of packages by specifying a framework.

Previous versions of the .NET Core tools (both project.json and csproj-based tools) by default specified both a framework and a metapackage. Currently, however, the metapackage is implicitly referenced by the target framework, so that each metapackage is tied to a target framework. For example, the `netstandard1.6` framework references the `NetStandard.Library` version 1.6.0 metapackage. Similarly, the `netcoreapp2.1` framework references the `Microsoft.NETCore.App` Version 2.1.0 metapackage. For more information, see [Implicit metapackage package reference in the .NET Core SDK](#).

Targeting a framework and implicitly referencing a metapackage means that you in effect are adding a reference to each of its dependent packages as a single gesture. That makes all of the libraries in those packages available for IntelliSense (or similar experience) and for publishing your app.

There are advantages to using metapackages:

- Provides a convenient user experience to reference a large set of fine-grained packages.
- Defines a set of packages (including specific versions) that are tested and work well together.

The .NET Standard metapackage is:

- [NETStandard.Library](#) - Describes the libraries that are part of the ".NET Standard". Applies to all .NET implementations (for example, .NET Framework, .NET Core and Mono) that support .NET Standard. Establishes the 'netstandard' framework.

The key .NET Core metapackages are:

- [Microsoft.NETCore.App](#) - Describes the libraries that are part of the .NET Core distribution. Establishes the `.NETCoreApp` framework. Depends on the smaller `NETStandard.Library`.
- [Microsoft.AspNetCore.App](#) - Includes all the supported packages from ASP.NET Core and Entity Framework Core except those that contain third-party dependencies. See [Microsoft.AspNetCore.App metapackage for ASP.NET Core](#) for more information.
- [Microsoft.AspNetCore.All](#) - Includes all the supported packages from ASP.NET Core, Entity Framework Core, and internal and third-party dependencies used by ASP.NET Core and Entity Framework Core. See [Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.x](#) for more information.
- [Microsoft.NETCore.Portable.Compatibility](#) - A set of compatibility facades that enable msclr-based Portable Class Libraries (PCLs) to run on .NET Core.

Frameworks

.NET Core packages each support a set of runtime frameworks. Frameworks describe an available API set (and potentially other characteristics) that you can rely on when you target a given framework. They are versioned as new APIs are added.

For example, [System.IO.FileSystem](#) supports the following frameworks:

- .NETFramework,Version=4.6
- .NETStandard,Version=1.3
- 6 Xamarin platforms (for example, xamarinios10)

It is useful to contrast the first two of these frameworks, since they are examples of the two different ways that frameworks are defined.

The `.NETFramework,Version=4.6` framework represents the available APIs in the .NET Framework 4.6. You can produce libraries compiled with the .NET Framework 4.6 reference assemblies and then distribute those libraries in NuGet packages in a `net46 lib` folder. It will be used for apps that target the .NET Framework 4.6 or that are compatible with it. This is how all frameworks have traditionally worked.

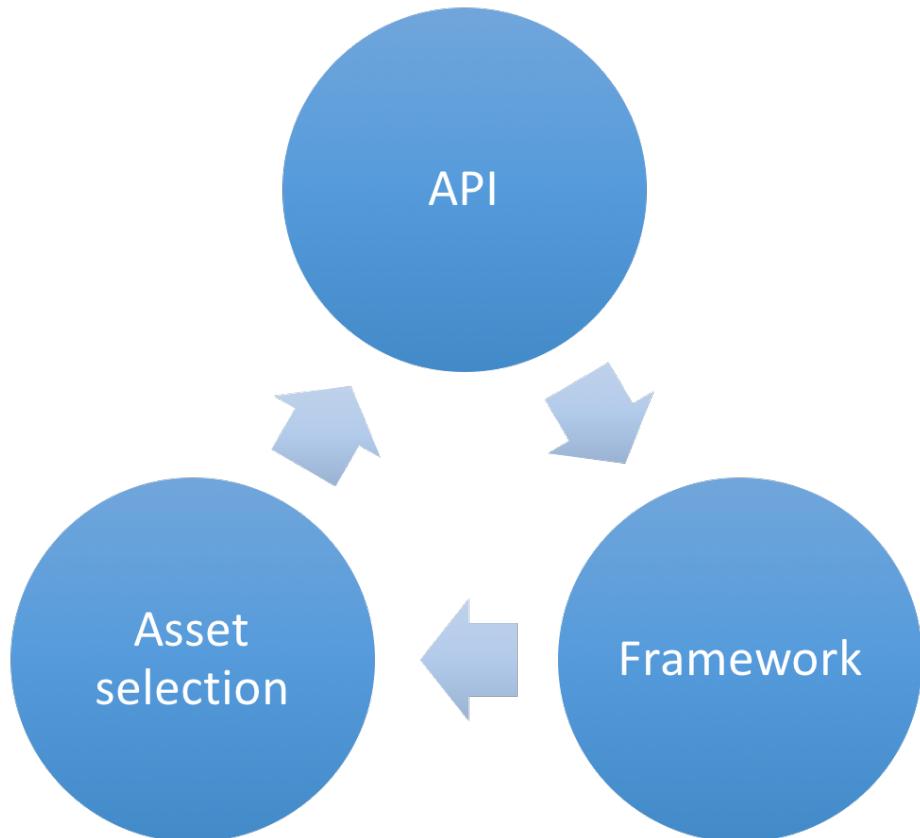

The `.NETStandard,Version=1.3` framework is a package-based framework. It relies on packages that target the framework to define and expose APIs in terms of the framework.

Package-based frameworks

There is a two-way relationship between frameworks and packages. The first part is defining the APIs available for a given framework, for example `netstandard1.3`. Packages that target `netstandard1.3` (or compatible frameworks, like `netstandard1.0`) define the APIs available for `netstandard1.3`. That may sound like a circular definition, but it isn't. By virtue of being "package-based", the API definition for the framework comes from packages. The framework itself doesn't define any APIs.

The second part of the relationship is asset selection. Packages can contain assets for multiple frameworks. Given a reference to a set of packages and/or metapackages, the framework is needed to determine which asset should be selected, for example `net46` or `netstandard1.3`. It is important to select the correct asset. For example, a `net46` asset is not likely to be compatible with .NET Framework 4.0 or .NET Core 1.0.

You can see this relationship in the following image. The *API* targets and defines the *framework*. The *framework* is used for *asset selection*. The *asset* gives you the API.

The two primary package-based frameworks used with .NET Core are:

- `netstandard`
- `netcoreapp`

.NET Standard

The .NET Standard ([Target Framework Moniker](#): `netstandard`) framework represents the APIs defined by and built on top of the [.NET Standard](#). Libraries that are intended to run on multiple runtimes should target this framework. They will be supported on any .NET Standard compliant runtime, such as .NET Core, .NET Framework and Mono/Xamarin. Each of these runtimes supports a set of .NET Standard versions, depending on which APIs they implement.

The `netstandard` framework implicitly references the `NETStandard.Library` metapackage. For example, the following MSBuild project file indicates that the project targets `netstandard1.6`, which references the `NETStandard.Library` version 1.6 metapackage.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>netstandard1.6</TargetFramework>
  </PropertyGroup>
</Project>
```

However, the framework and metapackage references in the project file do not need to match, and you can use the `<NetStandardImplicitPackageVersion>` element in your project file to specify a framework version that is lower than the metapackage version. For example, the following project file is valid.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>netstandard1.3</TargetFramework>
    <NetStandardImplicitPackageVersion>1.6.0</NetStandardImplicitPackageVersion>
  </PropertyGroup>
</Project>
```

It may seem strange to target `netstandard1.3` but use the 1.6.0 version of `NETStandard.Library`. It is a valid use-case, since the metapackage maintains support for older `netstandard` versions. It could be the case you've standardized on the 1.6.0 version of the metapackage and use it for all your libraries, which target a variety of `netstandard` versions. With this approach, you only need to restore `NETStandard.Library` 1.6.0 and not earlier versions.

The reverse would not be valid: targeting `netstandard1.6` with the 1.3.0 version of `NETStandard.Library`. You cannot target a higher framework with a lower metapackage, since the lower version metapackage will not expose any assets for that higher framework. The versioning scheme for metapackages asserts that metapackages match the highest version of the framework they describe. By virtue of the versioning scheme, the first version of `NETStandard.Library` is v1.6.0 given that it contains `netstandard1.6` assets. v1.3.0 is used in the example above, for symmetry with the example above, but does not actually exist.

.NET Core application

The .NET Core ([Target Framework Moniker](#): `netcoreapp`) framework represents the packages and associated APIs that come with the .NET Core distribution and the console application model that it provides. .NET Core apps must use this framework, due to targeting the console application model, as should libraries that intended to run only on .NET Core. Using this framework restricts apps and libraries to running only on .NET Core.

The `Microsoft.NETCore.App` metapackage targets the `netcoreapp` framework. It provides access to ~60 libraries, ~40 provided by the `NETStandard.Library` package and ~20 more in addition. You can reference additional libraries that target `netcoreapp` or compatible frameworks, such as `netstandard`, to get access to additional APIs.

Most of the additional libraries provided by `Microsoft.NETCore.App` also target `netstandard` given that their dependencies are satisfied by other `netstandard` libraries. That means that `netstandard` libraries can also reference those packages as dependencies.

High-level overview of changes in the .NET Core tools

3/8/2019 • 4 minutes to read • [Edit Online](#)

This document describes the changes associated with moving from *project.json* to MSBuild and the *csproj* project system with information on the changes to the layering of the .NET Core tooling and the implementation of the CLI commands. These changes occurred with the release of .NET Core SDK 1.0 and Visual Studio 2017 on March 7, 2017 (see the [announcement](#)) but were initially implemented with the release of the .NET Core SDK Preview 3.

Moving away from *project.json*

The biggest change in the tooling for .NET Core is certainly the [move away from *project.json* to *csproj*](#) as the project system. The latest versions of the command-line tools don't support *project.json* files. That means that it cannot be used to build, run or publish *project.json* based applications and libraries. In order to use this version of the tools, you will need to migrate your existing projects or start new ones.

As part of this move, the custom build engine that was developed to build *project.json* projects was replaced with a mature and fully capable build engine called [MSBuild](#). MSBuild is a well-known engine in the .NET community, since it has been a key technology since the platform's first release. Of course, because it needs to build .NET Core applications, MSBuild has been ported to .NET Core and can be used on any platform that .NET Core runs on. One of the main promises of .NET Core is that of a cross-platform development stack, and we have made sure that this move does not break that promise.

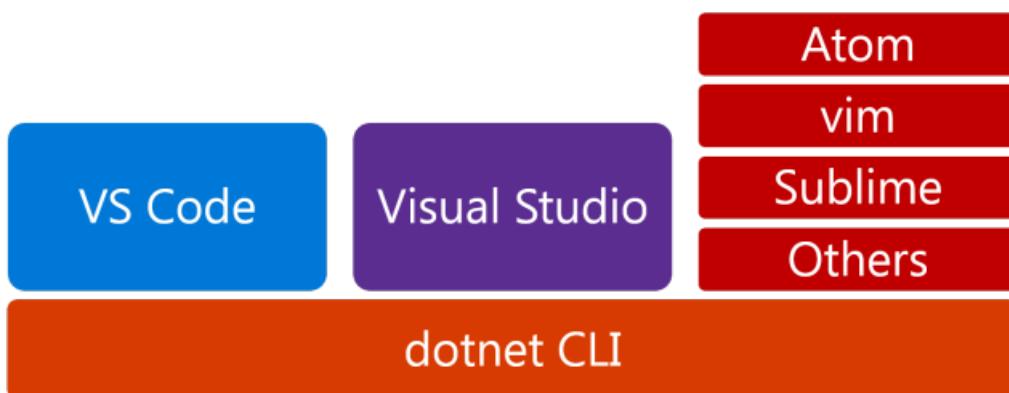

NOTE

If you are new to MSBuild and would like to learn more about it, you can start by reading the [MSBuild Concepts](#) article.

The tooling layers

With the move away from the existing project system as well as with building engine switches, the question that naturally follows is do any of these changes change the overall "layering" of the whole .NET Core tooling ecosystem? Are there new bits and components?

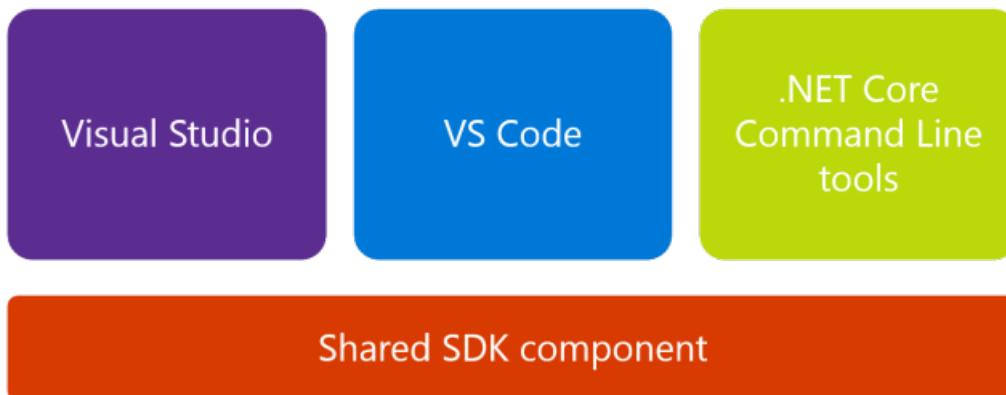

Let's start with a quick refresher on Preview 2 layering as shown in the following picture:

The layering of the tools is quite simple. At the bottom we have the .NET Core Command Line tools as a foundation. All other, higher-level tools such as Visual Studio or Visual Studio Code, depend and rely on the CLI to

build projects, restore dependencies and so on. This meant that, for example, if Visual Studio wanted to perform a restore operation, it would call into `dotnet restore` (see note) command in the CLI.

With the move to the new project system, the previous diagram changes:

The main difference is that the CLI is not the foundational layer anymore; this role is now filled by the "shared SDK component". This shared SDK component is a set of targets and associated tasks that are responsible for compiling your code, publishing it, packing NuGet packages etc. The SDK itself is open-source and is available on GitHub on the [SDK repo](#).

NOTE

A "target" is a MSBuild term that indicates a named operation that MSBuild can invoke. It is usually coupled with one or more tasks that execute some logic that the target is supposed to do. MSBuild supports many ready-made targets such as `Copy` or `Execute`; it also allows users to write their own tasks using managed code and define targets to execute those tasks. For more information, see [MSBuild tasks](#).

All the toolsets now consume the shared SDK component and its targets, CLI included. For example, the next version of Visual Studio will not call into `dotnet restore` (see note) command to restore dependencies for .NET Core projects, it will use the "Restore" target directly. Since these are MSBuild targets, you can also use raw MSBuild to execute them using the `dotnet msbuild` command.

CLI commands

The shared SDK component means that the majority of existing CLI commands have been re-implemented as MSBuild tasks and targets. What does this mean for the CLI commands and your usage of the toolset?

From an usage perspective, it doesn't change the way you use the CLI. The CLI still has the core commands that exist in Preview 2 release:

- `new`
- `restore`
- `run`
- `build`
- `publish`
- `test`
- `pack`

These commands still do what you expect them to do (new up a project, build it, publish it, pack it and so on).

Majority of the options are not changed, and are still there, and you can consult either the commands' help screens (using `dotnet <command> --help`) or documentation on this site to get familiar with any changes.

From an execution perspective, the CLI commands will take their parameters and construct a call to "raw" MSBuild that will set the needed properties and run the desired target. To better illustrate this, consider the following

command:

```
dotnet publish -o pub -c Release
```

This command is publishing an application into a `pub` folder using the "Release" configuration. Internally, this command gets translated into the following MSBuild invocation:

```
dotnet msbuild -t:Publish -p:OutputPath=pub -p:Configuration=Release
```

The notable exception to this rule are `new` and `run` commands, as they have not been implemented as MSBuild targets.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

Managing dependencies with .NET Core SDK 1.0

3/8/2019 • 2 minutes to read • [Edit Online](#)

With the move of .NET Core projects from project.json to csproj and MSBuild, a significant investment also happened that resulted in unification of the project file and assets that allow tracking of dependencies. For .NET Core projects this is similar to what project.json did. There is no separate JSON or XML file that tracks NuGet dependencies. With this change, we've also introduced another type of *reference* into the csproj syntax called the `<PackageReference>`.

This document describes the new reference type. It also shows how to add a package dependency using this new reference type to your project.

The new `<PackageReference>` element

The `<PackageReference>` has the following basic structure:

```
<PackageReference Include="PACKAGE_ID" Version="PACKAGE_VERSION" />
```

If you are familiar with MSBuild, it will look familiar to the other reference types that already exist. The key is the `Include` statement which specifies the package id that you wish to add to the project. The `<Version>` child element specifies the version to get. The versions are specified as per [NuGet version rules](#).

NOTE

If you are not familiar with the overall `csproj` syntax, see the [MSBuild project reference](#) documentation for more information.

Adding a dependency that is available only in a specific target is done using conditions like in the following example:

```
<PackageReference Include="PACKAGE_ID" Version="PACKAGE_VERSION" Condition="$(TargetFramework) == 'netcoreapp2.1'" />
```

The above means that the dependency will only be valid if the build is happening for that given target. The `$(TargetFramework)` in the condition is a MSBuild property that is being set in the project. For most common .NET Core applications, you will not need to do this.

Adding a dependency to your project

Adding a dependency to your project is straightforward. Here is an example of how to add Json.NET version `9.0.1` to your project. Of course, it is applicable to any other NuGet dependency.

When you open your project file, you will see two or more `<ItemGroup>` nodes. You will notice that one of the nodes already has `<PackageReference>` elements in it. You can add your new dependency to this node, or create a new one; it is completely up to you as the result will be the same.

In this example we will use the default template that is dropped by `dotnet new console`. This is a simple console application. When we open up the project, we first find the `<ItemGroup>` with already existing `<PackageReference>` in it. We then add the following to it:

```
<PackageReference Include="Newtonsoft.Json" Version="9.0.1" />
```

After this, we save the project and run the `dotnet restore` command to install the dependency.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

The full project looks like this:

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>netcoreapp2.1</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Newtonsoft.Json" Version="9.0.1" />
  </ItemGroup>
</Project>
```

Removing a dependency from the project

Removing a dependency from the project file involves simply removing the `<PackageReference>` from the project file.

Additions to the csproj format for .NET Core

3/14/2019 • 12 minutes to read • [Edit Online](#)

This document outlines the changes that were added to the project files as part of the move from *project.json* to *csproj* and [MSBuild](#). For more information about general project file syntax and reference, see [the MSBuild project file documentation](#).

Implicit package references

Metapackages are implicitly referenced based on the target framework(s) specified in the `<TargetFramework>` or `<TargetFrameworks>` property of your project file. `<TargetFrameworks>` is ignored if `<TargetFramework>` is specified, independent of order.

```
<PropertyGroup>
  <TargetFramework>netcoreapp2.1</TargetFramework>
</PropertyGroup>
```

```
<PropertyGroup>
  <TargetFrameworks>netcoreapp2.1;net462</TargetFrameworks>
</PropertyGroup>
```

Recommendations

Since `Microsoft.NETCore.App` or `NetStandard.Library` metapackages are implicitly referenced, the following are our recommended best practices:

- When targeting .NET Core or .NET Standard, never have an explicit reference to the `Microsoft.NETCore.App` or `NetStandard.Library` metapackages via a `<PackageReference>` item in your project file.
- If you need a specific version of the runtime when targeting .NET Core, you should use the `<RuntimeFrameworkVersion>` property in your project (for example, `1.0.4`) instead of referencing the metapackage.
 - This might happen if you are using [self-contained deployments](#) and you need a specific patch version of 1.0.0 LTS runtime, for example.
- If you need a specific version of the `NetStandard.Library` metapackage when targeting .NET Standard, you can use the `<NetStandardImplicitPackageVersion>` property and set the version you need.
- Don't explicitly add or update references to either the `Microsoft.NETCore.App` or `NetStandard.Library` metapackage in .NET Framework projects. If any version of `NetStandard.Library` is needed when using a .NET Standard-based NuGet package, NuGet automatically installs that version.

Default compilation includes in .NET Core projects

With the move to the *csproj* format in the latest SDK versions, we've moved the default includes and excludes for compile items and embedded resources to the SDK properties files. This means that you no longer need to specify these items in your project file.

The main reason for doing this is to reduce the clutter in your project file. The defaults that are present in the SDK should cover most common use cases, so there is no need to repeat them in every project that you create. This leads to smaller project files that are much easier to understand as well as edit by hand, if needed.

The following table shows which element and which [globs](#) are both included and excluded in the SDK:

ELEMENT	INCLUDE GLOB	EXCLUDE GLOB	REMOVE GLOB
Compile	**/*.cs (or other language extensions)	**/*.user; **/*.proj; **/*.sln; **/*.vsscc	N/A
EmbeddedResource	**/*.resx	**/*.user; **/*.proj; **/*.sln; **/*.vsscc	N/A
None	**/*	**/*.user; **/*.proj; **/*.sln; **/*.vsscc	**/*.cs; **/*.resx

NOTE

Exclude glob always excludes the `./bin` and `./obj` folders, which are represented by the `$(BaseOutputPath)` and `$(BaseIntermediateOutputPath)` MSBuild properties, respectively. As a whole, all excludes are represented by `$(DefaultItemExcludes)`.

If you have globs in your project and you try to build it using the newest SDK, you'll get the following error:

Duplicate Compile items were included. The .NET SDK includes Compile items from your project directory by default. You can either remove these items from your project file, or set the 'EnableDefaultCompileItems' property to 'false' if you want to explicitly include them in your project file.

In order to get around this error, you can either remove the explicit `Compile` items that match the ones listed on the previous table, or you can set the `<EnableDefaultCompileItems>` property to `false`, like this:

```
<PropertyGroup>
  <EnableDefaultCompileItems>false</EnableDefaultCompileItems>
</PropertyGroup>
```

Setting this property to `false` will disable implicit inclusion, reverting to the behavior of previous SDKs where you had to specify the default globs in your project.

This change does not modify the main mechanics of other includes. However, if you wish to specify, for example, some files to get published with your app, you can still use the known mechanisms in `csproj` for that (for example, the `<Content>` element).

`<EnableDefaultCompileItems>` only disables `Compile` globs but doesn't affect other globs, like the implicit `None` glob, which also applies to `*.cs` items. Because of that, **Solution Explorer** will continue show `*.cs` items as part of the project, included as `None` items. In a similar way, you can use `<EnableDefaultNoneItems>` to disable the implicit `None` glob.

To disable **all implicit globs**, you can set the `<EnableDefaultItems>` property to `false` as in the following example:

```
<PropertyGroup>
  <EnableDefaultItems>false</EnableDefaultItems>
</PropertyGroup>
```

How to see the whole project as MSBuild sees it

While those `csproj` changes greatly simplify project files, you might want to see the fully expanded project as MSBuild sees it once the SDK and its targets are included. Preprocess the project with the `/pp` switch of the `dotnet msbuild` command, which shows which files are imported, their sources, and their contributions to the build without actually building the project:

```
dotnet msbuild -pp:fullproject.xml
```

If the project has multiple target frameworks, the results of the command should be focused on only one of them by specifying it as an MSBuild property:

```
dotnet msbuild -p:TargetFramework=netcoreapp2.0 -pp:fullproject.xml
```

Additions

Sdk attribute

The root `<Project>` element of the `.csproj` file has a new attribute called `Sdk`. `Sdk` specifies which SDK will be used by the project. The SDK, as the [layering document](#) describes, is a set of MSBuild [tasks](#) and [targets](#) that can build .NET Core code. We ship three main SDKs with the .NET Core tools:

1. The .NET Core SDK with the ID of `Microsoft.NET.Sdk`
2. The .NET Core web SDK with the ID of `Microsoft.NET.Sdk.Web`
3. The .NET Core Razor Class Library SDK with the ID of `Microsoft.NET.Sdk.Razor`

You need to have the `Sdk` attribute set to one of those IDs on the `<Project>` element in order to use the .NET Core tools and build your code.

PackageReference

A `<PackageReference>` item element specifies a [NuGet dependency in the project](#). The `Include` attribute specifies the package ID.

```
<PackageReference Include="<package-id>" Version="" PrivateAssets="" IncludeAssets="" ExcludeAssets="" />
```

Version

The required `Version` attribute specifies the version of the package to restore. The attribute respects the rules of the [NuGet versioning](#) scheme. The default behavior is an exact version match. For example, specifying `Version="1.2.3"` is equivalent to NuGet notation `[1.2.3]` for the exact 1.2.3 version of the package.

IncludeAssets, ExcludeAssets and PrivateAssets

`IncludeAssets` attribute specifies which assets belonging to the package specified by `<PackageReference>` should be consumed. By default, all package assets are included.

`ExcludeAssets` attribute specifies which assets belonging to the package specified by `<PackageReference>` should not be consumed.

`PrivateAssets` attribute specifies which assets belonging to the package specified by `<PackageReference>` should be consumed but not flow to the next project. The `Analyzers`, `Build` and `ContentFiles` assets are private by default when this attribute is not present.

NOTE

`PrivateAssets` is equivalent to the `project.json/xproj` `SuppressParent` element.

These attributes can contain one or more of the following items, separated by the semicolon `;` character if more than one is listed:

- `Compile` – the contents of the lib folder are available to compile against.
- `Runtime` – the contents of the runtime folder are distributed.
- `ContentFiles` – the contents of the `contentfiles` folder are used.
- `Build` – the props/targets in the build folder are used.
- `Native` – the contents from native assets are copied to the output folder for runtime.

- `Analyzers` – the analyzers are used.

Alternatively, the attribute can contain:

- `None` – none of the assets are used.
- `All` – all assets are used.

DotNetCliToolReference

A `<DotNetCliToolReference>` item element specifies the CLI tool that the user wants to restore in the context of the project. It's a replacement for the `tools` node in *project.json*.

```
<DotNetCliToolReference Include=<package-id> Version="" />
```

Version

`Version` specifies the version of the package to restore. The attribute respects the rules of the [NuGet versioning](#) scheme. The default behavior is an exact version match. For example, specifying `Version="1.2.3"` is equivalent to NuGet notation `[1.2.3]` for the exact 1.2.3 version of the package.

RuntimeIdentifiers

The `<RuntimeIdentifiers>` property element lets you specify a semicolon-delimited list of [Runtime Identifiers \(RIDs\)](#) for the project. RIDs enable publishing self-contained deployments.

```
<RuntimeIdentifiers>win10-x64;osx.10.11-x64;ubuntu.16.04-x64</RuntimeIdentifiers>
```

RuntimeIdentifier

The `<RuntimeIdentifier>` property element allows you to specify only one [Runtime Identifier \(RID\)](#) for the project. The RID enables publishing a self-contained deployment.

```
<RuntimeIdentifier>ubuntu.16.04-x64</RuntimeIdentifier>
```

Use `<RuntimeIdentifiers>` (plural) instead if you need to publish for multiple runtimes. `<RuntimeIdentifier>` can provide faster builds when only a single runtime is required.

PackageTargetFallback

The `<PackageTargetFallback>` property element allows you to specify a set of compatible targets to be used when restoring packages. It's designed to allow packages that use the dotnet [TxM \(Target x Moniker\)](#) to operate with packages that don't declare a dotnet TxM. If your project uses the dotnet TxM, then all the packages it depends on must also have a dotnet TxM, unless you add the `<PackageTargetFallback>` to your project in order to allow non-dotnet platforms to be compatible with dotnet.

The following example provides the fallbacks for all targets in your project:

```
<PackageTargetFallback>
  $(PackageTargetFallback);portable-net45+win8+wpa81+wp8
</PackageTargetFallback >
```

The following example specifies the fallbacks only for the `netcoreapp2.1` target:

```
<PackageTargetFallback Condition="$(TargetFramework) == 'netcoreapp2.1'>
  $(PackageTargetFallback);portable-net45+win8+wpa81+wp8
</PackageTargetFallback >
```

NuGet metadata properties

With the move to MSBuild, we have moved the input metadata that is used when packing a NuGet package from `project.json` to `.csproj` files. The inputs are MSBuild properties so they have to go within a `<PropertyGroup>` group. The following is the list of properties that are used as inputs to the packing process when using the `dotnet pack` command or the `Pack` MSBuild target that is part of the SDK.

IsPackable

A Boolean value that specifies whether the project can be packed. The default value is `true`.

PackageVersion

Specifies the version that the resulting package will have. Accepts all forms of NuGet version string. Default is the value of `$(Version)`, that is, of the property `Version` in the project.

PackageId

Specifies the name for the resulting package. If not specified, the `pack` operation will default to using the `AssemblyName` or directory name as the name of the package.

Title

A human-friendly title of the package, typically used in UI displays as on nuget.org and the Package Manager in Visual Studio. If not specified, the package ID is used instead.

Authors

A semicolon-separated list of packages authors, matching the profile names on nuget.org. These are displayed in the NuGet Gallery on nuget.org and are used to cross-reference packages by the same authors.

PackageDescription

A long description of the package for UI display.

Description

A long description for the assembly. If `PackageDescription` is not specified then this property is also used as the description of the package.

Copyright

Copyright details for the package.

PackageRequireLicenseAcceptance

A Boolean value that specifies whether the client must prompt the consumer to accept the package license before installing the package. The default is `false`.

PackageLicenseExpression

An [SPDX license identifier](#) or expression. For example, `Apache-2.0`.

Here is the complete list of [SPDX license identifiers](#). NuGet.org accepts only OSI or FSF approved licenses when using license type expression.

The exact syntax of the license expressions is described below in [ABNF](#).

```

license-id          = <short form license identifier from https://spdx.org/spdx-specification-21-web-
version#h.luq9dgcle9mo>

license-exception-id = <short form license exception identifier from https://spdx.org/spdx-specification-21-web-
version#h.ruv3yl8g6czd>

simple-expression = license-id / license-id""

compound-expression = 1*1(simple-expression /
    simple-expression "WITH" license-exception-id /
    compound-expression "AND" compound-expression /
    compound-expression "OR" compound-expression ) /
    "(" compound-expression ")" )

license-expression = 1*1(simple-expression / compound-expression / UNLICENSED)

```

NOTE

Only one of `PackageLicenseExpression`, `PackageLicenseFile` and `PackageLicenseUrl` can be specified at a time.

PackageLicenseFile

Path to a license file within the package if you are using a license that hasn't been assigned an SPDX identifier, or it is a custom license (Otherwise `PackageLicenseExpression` is preferred)

Replaces `PackageLicenseUrl`, can't be combined with `PackageLicenseExpression` and requires Visual Studio 15.9.4, .NET SDK 2.1.502 or 2.2.101, or newer.

You will need to ensure the license file is packed by adding it explicitly to the project, example usage:

```

<PropertyGroup>
  <PackageLicenseFile>LICENSE.txt</PackageLicenseFile>
</PropertyGroup>
<ItemGroup>
  <None Include="licenses\LICENSE.txt" Pack="true" PackagePath="$(PackageLicenseFile)"/>
</ItemGroup>

```

PackageLicenseUrl

An URL to the license that is applicable to the package. (*deprecated since Visual Studio 15.9.4, .NET SDK 2.1.502 and 2.2.101*)

PackageIconUrl

A URL for a 64x64 image with transparent background to use as the icon for the package in UI display.

PackageReleaseNotes

Release notes for the package.

PackageTags

A semicolon-delimited list of tags that designates the package.

PackageOutputPath

Determines the output path in which the packed package will be dropped. Default is `$(OutputPath)`.

IncludeSymbols

This Boolean value indicates whether the package should create an additional symbols package when the project is packed. This package will have a `.symbols.nupkg` extension and will copy the PDB files along with the DLL and other output files.

IncludeSource

This Boolean value indicates whether the pack process should create a source package. The source package contains the library's source code as well as PDB files. Source files are put under the `src/ProjectName` directory in the resulting package file.

IsTool

Specifies whether all output files are copied to the *tools* folder instead of the *lib* folder. Note that this is different from a `DotNetCliTool` which is specified by setting the `PackageType` in the `.csproj` file.

RepositoryUrl

Specifies the URL for the repository where the source code for the package resides and/or from which it's being built.

RepositoryType

Specifies the type of the repository. Default is "git".

NoPackageAnalysis

Specifies that pack should not run package analysis after building the package.

MinClientVersion

Specifies the minimum version of the NuGet client that can install this package, enforced by nuget.exe and the Visual Studio Package Manager.

IncludeBuildOutput

This Boolean values specifies whether the build output assemblies should be packed into the `.nupkg` file or not.

IncludeContentInPack

This Boolean value specifies whether any items that have a type of `Content` will be included in the resulting package automatically. The default is `true`.

BuildOutputTargetFolder

Specifies the folder where to place the output assemblies. The output assemblies (and other output files) are copied into their respective framework folders.

ContentTargetFolders

This property specifies the default location of where all the content files should go if `PackagePath` is not specified for them. The default value is "content;contentFiles".

NuspecFile

Relative or absolute path to the `.nuspec` file being used for packing.

NOTE

If the `.nuspec` file is specified, it's used **exclusively** for packaging information and any information in the projects is not used.

NuspecBasePath

Base path for the `.nuspec` file.

NuspecProperties

Semicolon separated list of key=value pairs.

AssemblyInfo properties

[Assembly attributes](#) that were typically present in an `AssemblyInfo` file are now automatically generated from properties.

Properties per attribute

Each attribute has a property that control its content and another to disable its generation as shown in the following

table:

ATTRIBUTE	PROPERTY	PROPERTY TO DISABLE
AssemblyCompanyAttribute	Company	GenerateAssemblyCompanyAttribute
AssemblyConfigurationAttribute	Configuration	GenerateAssemblyConfigurationAttribute
AssemblyCopyrightAttribute	Copyright	GenerateAssemblyCopyrightAttribute
AssemblyDescriptionAttribute	Description	GenerateAssemblyDescriptionAttribute
AssemblyFileVersionAttribute	FileVersion	GenerateAssemblyFileVersionAttribute
AssemblyInformationalVersionAttribute	InformationalVersion	GenerateAssemblyInformationalVersionAttribute
AssemblyProductAttribute	Product	GenerateAssemblyProductAttribute
AssemblyTitleAttribute	AssemblyTitle	GenerateAssemblyTitleAttribute
AssemblyVersionAttribute	AssemblyVersion	GenerateAssemblyVersionAttribute
NeutralResourcesLanguageAttribute	NeutralLanguage	GenerateNeutralResourcesLanguageAttribute

Notes:

- `AssemblyVersion` and `FileVersion` default is to take the value of `$(Version)` without suffix. For example, if `$(Version)` is `1.2.3-beta.4`, then the value would be `1.2.3`.
- `InformationalVersion` defaults to the value of `$(Version)`.
- `InformationalVersion` has `$(SourceRevisionId)` appended if the property is present. It can be disabled using `IncludeSourceRevisionInInformationalVersion`.
- `Copyright` and `Description` properties are also used for NuGet metadata.
- `Configuration` is shared with all the build process and set via the `--configuration` parameter of `dotnet` commands.

GenerateAssemblyInfo

A Boolean that enable or disable all the AssemblyInfo generation. The default value is `true`.

GeneratedAssemblyInfoFile

The path of the generated assembly info file. Default to a file in the `$(IntermediateOutputPath)` (obj) directory.

Migrate from .NET Core 2.0 to 2.1

1/23/2019 • 2 minutes to read • [Edit Online](#)

This article shows you the basic steps for migrating your .NET Core 2.0 app to 2.1. If you're looking to migrate your ASP.NET Core app to 2.1, see [Migrate from ASP.NET Core 2.0 to 2.1](#).

For an overview of the new features in .NET Core 2.1, see [What's new in .NET Core 2.1](#).

Update the project file to use 2.1 versions

- Open the project file (the *.csproj, *.vbproj, or *.fsproj file).
- Change the `target framework` value from `netcoreapp2.0` to `netcoreapp2.1`. The target framework is defined by the `<TargetFramework>` or `<TargetFrameworks>` element.

For example, change `<TargetFramework>netcoreapp2.0</TargetFramework>` to `<TargetFramework>netcoreapp2.1</TargetFramework>`.

- Remove `<DotNetCliToolReference>` references for tools that are bundled in the .NET Core 2.1 SDK (v 2.1.300 or later). These references include:
 - `dotnet-watch` (`Microsoft.DotNet.Watcher.Tools`)
 - `dotnet-user-secrets` (`Microsoft.Extensions.SecretManager.Tools`)
 - `dotnet-sql-cache` (`Microsoft.Extensions.Caching.SqlConfig.Tools`)
 - `dotnet-eif` (`Microsoft.EntityFrameworkCore.Tools.DotNet`)

In previous .NET Core SDK versions, the reference to one of these tools in your project file looks similar to the following example:

```
<DotNetCliToolReference Include="Microsoft.EntityFrameworkCore.Tools.DotNet" Version="2.0.0" />
```

Since this entry isn't used by the .NET Core SDK any longer, you'll see a warning similar to the following if you still have references to one of these bundled tools in your project:

The tool 'Microsoft.EntityFrameworkCore.Tools.DotNet' is now included in the .NET Core SDK. Here is information on resolving this warning.

Removing the `<DotNetCliToolReference>` references for those tools from your project file fixes this issue.

Migrating .NET Core projects from project.json

3/8/2019 • 4 minutes to read • [Edit Online](#)

This document will cover migration scenarios for .NET Core projects and will go over the following three migration scenarios:

1. [Migration from a valid latest schema of *project.json* to *csproj*](#)
2. [Migration from DNX to csproj](#)
3. [Migration from RC3 and previous .NET Core csproj projects to the final format](#)

This document is only applicable to older .NET Core projects that still use *project.json*. It is not applicable for migrating from .NET Framework to .NET Core.

Migration from *project.json* to *csproj*

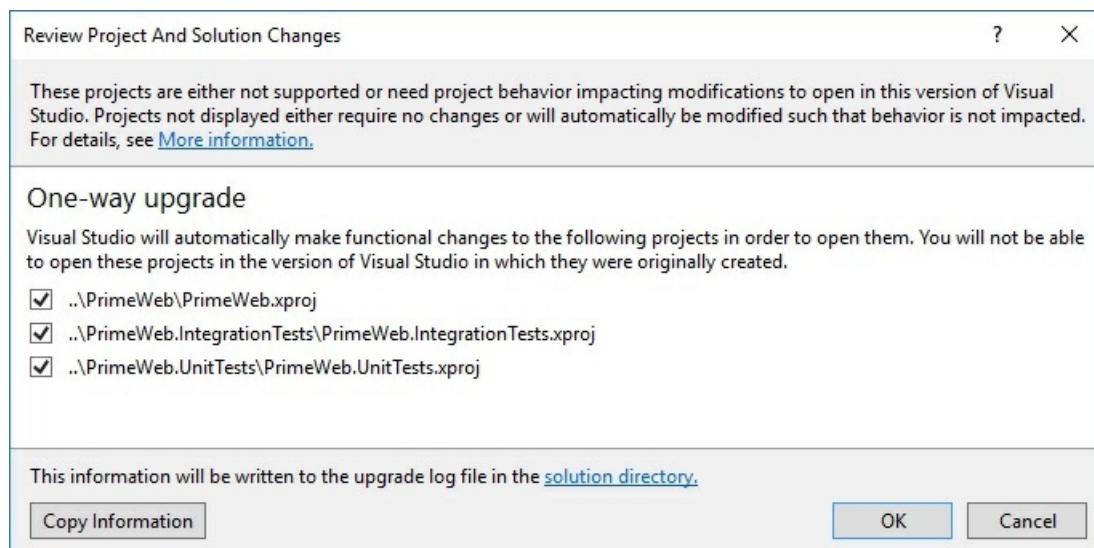

Migration from *project.json* to *.csproj* can be done using one of the following methods:

- [Visual Studio 2017](#)
- [dotnet migrate command-line tool](#)

Both methods use the same underlying engine to migrate the projects, so the results will be the same for both. In most cases, using one of these two ways to migrate the *project.json* to *csproj* is the only thing that is needed and no further manual editing of the project file is necessary. The resulting *.csproj* file will be named the same as the containing directory name.

Visual Studio 2017

When you open a *.xproj* file or a solution file which references *.xproj* files, the **One-way upgrade** dialog appears. The dialog displays the projects to be migrated. If you open a solution file, all the projects specified in the solution file will be listed. Review the list of projects to be migrated and select **OK**.

Visual Studio will migrate the projects chosen automatically. When migrating a solution, if you don't choose all projects, the same dialog will appear asking you to upgrade the remaining projects from that solution. After the project is migrated, you can see and modify its contents by right-clicking the project in the **Solution Explorer** window and selecting **Edit <project name>.csproj**.

Files that were migrated (*project.json*, *global.json*, *.xproj* and solution file) will be moved to a *Backup* folder. The

solution file that is migrated will be upgraded to Visual Studio 2017 and you won't be able to open that solution file in previous versions of Visual Studio. A file named *UpgradeLog.htm* is also saved and automatically opened that contains a migration report.

IMPORTANT

The new tooling is not available in Visual Studio 2015, so you cannot migrate your projects using that version of Visual Studio.

dotnet migrate

In the command-line scenario, you can use the `dotnet migrate` command. It will migrate a project, a solution or a set of folders in that order, depending on which ones were found. When you migrate a project, the project and all its dependencies are migrated.

Files that were migrated (*project.json*, *global.json* and *.xproj*) will be moved to a *backup* folder.

NOTE

If you are using Visual Studio Code, the `dotnet migrate` command will not modify Visual Studio Code-specific files such as `tasks.json`. These files need to be changed manually. This is also true if you are using Project Ryder or any editor or Integrated Development Environment (IDE) other than Visual Studio.

See [A mapping between project.json and csproj properties](#) for a comparison of project.json and csproj formats.

Common issues

- If you get an error: "No executable found matching command dotnet-migrate":

Run `dotnet --version` to see which version you are using. `dotnet migrate` requires .NET Core CLI RC3 or higher. You'll get this error if you have a *global.json* file in the current or parent directory and the `sdk` version is set to an older version.

Migration from DNX to csproj

If you are still using DNX for .NET Core development, your migration process should be done in two stages:

1. Use the [existing DNX migration guidance](#) to migrate from DNX to project-json enabled CLI.
2. Follow the steps from the previous section to migrate from *project.json* to *.csproj*.

NOTE

DNX has become officially deprecated during the Preview 1 release of the .NET Core CLI.

Migration from earlier .NET Core csproj formats to RTM csproj

The .NET Core csproj format has been changing and evolving with each new pre-release version of the tooling. There is no tool that will migrate your project file from earlier versions of csproj to the latest, so you need to manually edit the project file. The actual steps depend on the version of the project file you are migrating. The following is some guidance to consider based on the changes that happened between versions:

- Remove the tools version property from the `<Project>` element, if it exists.
- Remove the XML namespace (`xmlns`) from the `<Project>` element.
- If it doesn't exist, add the `Sdk` attribute to the `<Project>` element and set it to `Microsoft.NET.Sdk` or `Microsoft.NET.Sdk.Web`. This attribute specifies that the project uses the SDK to be used. `Microsoft.NET.Sdk.Web`

is used for web apps.

- Remove the `<Import Project="$(MSBuildExtensionsPath)\$(MSBuildToolsVersion)\Microsoft.Common.props" />` and `<Import Project="$(MSBuildToolsPath)\Microsoft.CSharp.targets" />` statements from the top and bottom of the project. These import statements are implied by the SDK, so there is no need for them to be in the project.
- If you have `Microsoft.NETCore.App` or `NETStandard.Library` `<PackageReference>` items in your project, you should remove them. These package references are [implied by the SDK](#).
- Remove the `Microsoft.NET.Sdk` `<PackageReference>` element, if it exists. The SDK reference comes through the `Sdk` attribute on the `<Project>` element.
- Remove the `globs` that are [implied by the SDK](#). Leaving these globs in your project will cause an error on build because compile items will be duplicated.

After these steps your project should be fully compatible with the RTM .NET Core csproj format.

For examples of before and after the migration from old csproj format to the new one, see the [Updating Visual Studio 2017 RC – .NET Core Tooling improvements](#) article on the .NET blog.

- [Port, Migrate, and Upgrade Visual Studio Projects](#)

A mapping between project.json and csproj properties

2/23/2019 • 6 minutes to read • [Edit Online](#)

By [Nate McMaster](#)

During the development of the .NET Core tooling, an important design change was made to no longer support *project.json* files and instead move the .NET Core projects to the MSBuild/csproj format.

This article shows how the settings in *project.json* are represented in the MSBuild/csproj format so you can learn how to use the new format and understand the changes made by the migration tools when you're upgrading your project to the latest version of the tooling.

The csproj format

The new format, *.csproj, is an XML-based format. The following example shows the root node of a .NET Core project using the `Microsoft.NET.Sdk`. For web projects, the SDK used is `Microsoft.NET.Sdk.Web`.

```
<Project Sdk="Microsoft.NET.Sdk">
...
</Project>
```

Common top-level properties

name

```
{
  "name": "MyProjectName"
}
```

No longer supported. In csproj, this is determined by the project filename, which usually matches the directory name. For example, `MyProjectName.csproj`.

By default, the project filename also specifies the value of the `<AssemblyName>` and `<PackageId>` properties.

```
<PropertyGroup>
  <AssemblyName>MyProjectName</AssemblyName>
  <PackageId>MyProjectName</PackageId>
</PropertyGroup>
```

The `<AssemblyName>` will have a different value than `<PackageId>` if `buildOptions\outputName` property was defined in *project.json*. For more information, see [Other common build options](#).

version

```
{
  "version": "1.0.0-alpha-*"
}
```

Use the `VersionPrefix` and `VersionSuffix` properties:

```
<PropertyGroup>
  <VersionPrefix>1.0.0</VersionPrefix>
  <VersionSuffix>alpha</VersionSuffix>
</PropertyGroup>
```

You can also use the `Version` property, but this may override version settings during packaging:

```
<PropertyGroup>
  <Version>1.0.0-alpha</Version>
</PropertyGroup>
```

Other common root-level options

```
{
  "authors": [ "Anne", "Bob" ],
  "company": "Contoso",
  "language": "en-US",
  "title": "My library",
  "description": "This is my library.\r\nAnd it's really great!",
  "copyright": "Nugetizer 3000",
  "userSecretsId": "xyz123"
}
```

```
<PropertyGroup>
  <Authors>Anne;Bob</Authors>
  <Company>Contoso</Company>
  <NeutralLanguage>en-US</NeutralLanguage>
  <AssemblyTitle>My library</AssemblyTitle>
  <Description>This is my library.
  And it's really great!</Description>
  <Copyright>Nugetizer 3000</Copyright>
  <UserSecretsId>xyz123</UserSecretsId>
</PropertyGroup>
```

frameworks

One target framework

```
{
  "frameworks": {
    "netcoreapp1.0": {}
  }
}
```

```
<PropertyGroup>
  <TargetFramework>netcoreapp1.0</TargetFramework>
</PropertyGroup>
```

Multiple target frameworks

```
{
  "frameworks": {
    "netcoreapp1.0": {},
    "net451": {}
  }
}
```

Use the `TargetFrameworks` property to define your list of target frameworks. Use semi-colon to separate multiple framework values.

```
<PropertyGroup>
  <TargetFrameworks>netcoreapp1.0;net451</TargetFrameworks>
</PropertyGroup>
```

dependencies

IMPORTANT

If the dependency is a **project** and not a package, the format is different. For more information, see the [dependency type](#) section.

NETStandard.Library metapackage

```
{
  "dependencies": {
    "NETStandard.Library": "1.6.0"
  }
}
```

```
<PropertyGroup>
  <NetStandardImplicitPackageVersion>1.6.0</NetStandardImplicitPackageVersion>
</PropertyGroup>
```

Microsoft.NETCore.App metapackage

```
{
  "dependencies": {
    "Microsoft.NETCore.App": "1.0.0"
  }
}
```

```
<PropertyGroup>
  <RuntimeFrameworkVersion>1.0.3</RuntimeFrameworkVersion>
</PropertyGroup>
```

Note that the `<RuntimeFrameworkVersion>` value in the migrated project is determined by the version of the SDK you have installed.

Top-level dependencies

```
{
  "dependencies": {
    "Microsoft.AspNetCore": "1.1.0"
  }
}
```

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore" Version="1.1.0" />
</ItemGroup>
```

Per-framework dependencies

```
{
  "framework": {
    "net451": {
      "dependencies": {
        "System.Collections.Immutable": "1.3.1"
      }
    },
    "netstandard1.5": {
      "dependencies": {
        "Newtonsoft.Json": "9.0.1"
      }
    }
  }
}
```

```
<ItemGroup Condition="$(TargetFramework)=='net451'">
  <PackageReference Include="System.Collections.Immutable" Version="1.3.1" />
</ItemGroup>

<ItemGroup Condition="$(TargetFramework)=='netstandard1.5'">
  <PackageReference Include="Newtonsoft.Json" Version="9.0.1" />
</ItemGroup>
```

imports

```
{
  "dependencies": {
    "YamlDotNet": "4.0.1-pre309"
  },
  "frameworks": {
    "netcoreapp1.0": {
      "imports": [
        "dnxcore50",
        "dotnet"
      ]
    }
  }
}
```

```
<PropertyGroup>
  <PackageTargetFallback>dnxcore50;dotnet</PackageTargetFallback>
</PropertyGroup>
<ItemGroup>
  <PackageReference Include="YamlDotNet" Version="4.0.1-pre309" />
</ItemGroup>
```

dependency type

type: project

```
{  
  "dependencies": {  
    "MyOtherProject": "1.0.0-*",  
    "AnotherProject": {  
      "type": "project"  
    }  
  }  
}
```

```
<ItemGroup>  
  <ProjectReference Include="..\MyOtherProject\MyOtherProject.csproj" />  
  <ProjectReference Include="..\AnotherProject\AnotherProject.csproj" />  
</ItemGroup>
```

NOTE

This will break the way that `dotnet pack --version-suffix $suffix` determines the dependency version of a project reference.

type: build

```
{  
  "dependencies": {  
    "Microsoft.EntityFrameworkCore.Design": {  
      "version": "1.1.0",  
      "type": "build"  
    }  
  }  
}
```

```
<ItemGroup>  
  <PackageReference Include="Microsoft.EntityFrameworkCore.Design" Version="1.1.0" PrivateAssets="All" />  
</ItemGroup>
```

type: platform

```
{  
  "dependencies": {  
    "Microsoft.NETCore.App": {  
      "version": "1.1.0",  
      "type": "platform"  
    }  
  }  
}
```

There is no equivalent in csproj.

runtimes

```
{
  "runtimes": {
    "win7-x64": {},
    "osx.10.11-x64": {},
    "ubuntu.16.04-x64": {}
  }
}
```

```
<PropertyGroup>
  <RuntimeIdentifiers>win7-x64;osx.10.11-x64;ubuntu.16.04-x64</RuntimeIdentifiers>
</PropertyGroup>
```

Standalone apps (self-contained deployment)

In project.json, defining a `runtimes` section means the app was standalone during build and publish. In MSBuild, all projects are *portable* during build, but can be published as standalone.

```
dotnet publish --framework netcoreapp1.0 --runtime osx.10.11-x64
```

For more information, see [Self-contained deployments \(SCD\)](#).

tools

```
{
  "tools": {
    "Microsoft.EntityFrameworkCore.Tools.DotNet": "1.0.0-*"
  }
}
```

```
<ItemGroup>
  <DotNetCliToolReference Include="Microsoft.EntityFrameworkCore.Tools.DotNet" Version="1.0.0" />
</ItemGroup>
```

NOTE

`imports` on tools are not supported in csproj. Tools that need imports will not work with the new `Microsoft.NET.Sdk`.

buildOptions

See also [Files](#).

emitEntryPoint

```
{
  "buildOptions": {
    "emitEntryPoint": true
  }
}
```

```
<PropertyGroup>
  <OutputType>Exe</OutputType>
</PropertyGroup>
```

If `emitEntryPoint` was `false`, the value of `OutputType` is converted to `Library`, which is the default value:

```
{
  "buildOptions": {
    "emitEntryPoint": false
  }
}
```

```
<PropertyGroup>
  <OutputType>Library</OutputType>
  <!-- or, omit altogether. It defaults to 'Library' -->
</PropertyGroup>
```

keyFile

```
{
  "buildOptions": {
    "keyFile": "MyKey.snk"
  }
}
```

The `keyFile` element expands to three properties in MSBuild:

```
<PropertyGroup>
  <AssemblyOriginatorKeyFile>MyKey.snk</AssemblyOriginatorKeyFile>
  <SignAssembly>true</SignAssembly>
  <PublicSign Condition="'$(OS)' != 'Windows_NT'">true</PublicSign>
</PropertyGroup>
```

Other common build options

```
{
  "buildOptions": {
    "warningsAsErrors": true,
    "nowarn": ["CS0168", "CS0219"],
    "xmlDoc": true,
    "preserveCompilationContext": true,
    "outputName": "Different.AssemblyName",
    "debugType": "portable",
    "allowUnsafe": true,
    "define": ["TEST", "OTHERCONDITION"]
  }
}
```

```
<PropertyGroup>
  <TreatWarningsAsErrors>true</TreatWarningsAsErrors>
  <NoWarn>$(NoWarn);CS0168;CS0219</NoWarn>
  <GenerateDocumentationFile>true</GenerateDocumentationFile>
  <PreserveCompilationContext>true</PreserveCompilationContext>
  <AssemblyName>Different.AssemblyName</AssemblyName>
  <DebugType>portable</DebugType>
  <AllowUnsafeBlocks>true</AllowUnsafeBlocks>
  <DefineConstants>$(DefineConstants);TEST;OTHERCONDITION</DefineConstants>
</PropertyGroup>
```

packOptions

See also [Files](#).

Common pack options

```
{  
  "packOptions": {  
    "summary": "numl is a machine learning library intended to ease the use of using standard modeling techniques for both prediction and clustering.",  
    "tags": ["machine learning", "framework"],  
    "releaseNotes": "Version 0.9.12-beta",  
    "iconUrl": "http://numl.net/images/ico.png",  
    "projectUrl": "http://numl.net",  
    "licenseUrl": "https://raw.githubusercontent.com/sethjuarez/numl/master/LICENSE.md",  
    "requireLicenseAcceptance": false,  
    "repository": {  
      "type": "git",  
      "url": "https://raw.githubusercontent.com/sethjuarez/numl"  
    },  
    "owners": ["Seth Juarez"]  
  }  
}
```

```
<PropertyGroup>  
  <!-- summary is not migrated from project.json, but you can use the <Description> property for that if needed. -->  
  <PackageTags>machine learning;framework</PackageTags>  
  <PackageReleaseNotes>Version 0.9.12-beta</PackageReleaseNotes>  
  <PackageIconUrl>http://numl.net/images/ico.png</PackageIconUrl>  
  <PackageProjectUrl>http://numl.net</PackageProjectUrl>  
  <PackageLicenseUrl>https://raw.githubusercontent.com/sethjuarez/numl/master/LICENSE.md</PackageLicenseUrl>  
  <PackageRequireLicenseAcceptance>false</PackageRequireLicenseAcceptance>  
  <RepositoryType>git</RepositoryType>  
  <RepositoryUrl>https://raw.githubusercontent.com/sethjuarez/numl</RepositoryUrl>  
  <!-- owners is not supported in MSBuild -->  
</PropertyGroup>
```

There is no equivalent for the `owners` element in MSBuild. For `summary`, you can use the MSBuild `<Description>` property, even though the value of `summary` is not migrated automatically to that property, since that property is mapped to the `description` element.

scripts

```
{  
  "scripts": {  
    "precompile": "generateCode.cmd",  
    "postpublish": [ "obfuscate.cmd", "removeTempFiles.cmd" ]  
  }  
}
```

Their equivalent in MSBuild are [targets](#):

```
<Target Name="MyPreCompileTarget" BeforeTargets="Build">  
  <Exec Command="generateCode.cmd" />  
</Target>  
  
<Target Name="MyPostCompileTarget" AfterTargets="Publish">  
  <Exec Command="obfuscate.cmd" />  
  <Exec Command="removeTempFiles.cmd" />  
</Target>
```

runtimeOptions

```
{  
  "runtimeOptions": {  
    "configProperties": {  
      "System.GC.Server": true,  
      "System.GC.Concurrent": true,  
      "System.GC.RetainVM": true,  
      "System.Threading.ThreadPool.MinThreads": 4,  
      "System.Threading.ThreadPool.MaxThreads": 25  
    }  
  }  
}
```

All settings in this group, except for the "System.GC.Server" property, are placed into a file called *runtimeconfig.template.json* in the project folder, with options lifted to the root object during the migration process:

```
{  
  "configProperties": {  
    "System.GC.Concurrent": true,  
    "System.GC.RetainVM": true,  
    "System.Threading.ThreadPool.MinThreads": 4,  
    "System.Threading.ThreadPool.MaxThreads": 25  
  }  
}
```

The "System.GC.Server" property is migrated into the csproj file:

```
<PropertyGroup>  
  <ServerGarbageCollection>true</ServerGarbageCollection>  
</PropertyGroup>
```

However, you can set all those values in the csproj as well as MSBuild properties:

```
<PropertyGroup>  
  <ServerGarbageCollection>true</ServerGarbageCollection>  
  <ConcurrentGarbageCollection>true</ConcurrentGarbageCollection>  
  <RetainVMGarbageCollection>true</RetainVMGarbageCollection>  
  <ThreadPoolMinThreads>4</ThreadPoolMinThreads>  
  <ThreadPoolMaxThreads>25</ThreadPoolMaxThreads>  
</PropertyGroup>
```

shared

```
{  
  "shared": "shared/**/*.cs"  
}
```

Not supported in csproj. You must instead create include content files in your *.nuspec* file. For more information, see [Including content files](#).

files

In *project.json*, build and pack could be extended to compile and embed from different folders. In MSBuild, this is done using [items](#). The following example is a common conversion:

```
{
  "buildOptions": {
    "compile": {
      "copyToOutput": "notes.txt",
      "include": "../Shared/*.cs",
      "exclude": "../Shared/Not/*.cs"
    },
    "embed": {
      "include": "../Shared/*.resx"
    }
  },
  "packOptions": {
    "include": "Views/",
    "mappings": {
      "some/path/in/project.txt": "in/package.txt"
    }
  },
  "publishOptions": {
    "include": [
      "files/",
      "publishnotes.txt"
    ]
  }
}
```

```
<ItemGroup>
  <Compile Include=".\\Shared\\*.cs" Exclude=".\\Shared\\Not\\*.cs" />
  <EmbeddedResource Include=".\\Shared\\*.resx" />
  <Content Include="Views\\**\\*" PackagePath="%{Identity}" />
  <None Include="some/path/in/project.txt" Pack="true" PackagePath="in/package.txt" />

  <None Include="notes.txt" CopyToOutputDirectory="Always" />
  <!-- CopyToOutputDirectory = { Always, PreserveNewest, Never } -->

  <Content Include="files\\**\\*" CopyToPublishDirectory="PreserveNewest" />
  <None Include="publishnotes.txt" CopyToPublishDirectory="Always" />
  <!-- CopyToPublishDirectory = { Always, PreserveNewest, Never } -->
</ItemGroup>
```

NOTE

Many of the default [globbing patterns](#) are added automatically by the .NET Core SDK. For more information, see [Default Compile Item Values](#).

All MSBuild `ItemGroup` elements support `Include`, `Exclude`, and `Remove`.

Package layout inside the .nupkg can be modified with `PackagePath="path"`.

Except for `Content`, most item groups require explicitly adding `Pack="true"` to be included in the package.

`Content` will be put in the `content` folder in a package since the MSBuild `<IncludeContentInPack>` property is set to `true` by default. For more information, see [Including content in a package](#).

`PackagePath="%{Identity}"` is a short way of setting package path to the project-relative file path.

testRunner

xUnit

```
{
  "testRunner": "xunit",
  "dependencies": {
    "dotnet-test-xunit": "<any>"
  }
}
```

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.0.0-*" />
  <PackageReference Include="xunit" Version="2.2.0-*" />
  <PackageReference Include="xunit.runner.visualstudio" Version="2.2.0-*" />
</ItemGroup>
```

MSTest

```
{
  "testRunner": "mstest",
  "dependencies": {
    "dotnet-test-mstest": "<any>"
  }
}
```

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.0.0-*" />
  <PackageReference Include="MSTest.TestAdapter" Version="1.1.12-*" />
  <PackageReference Include="MSTest.TestFramework" Version="1.1.11-*" />
</ItemGroup>
```

Migrating from DNX to .NET Core CLI (project.json)

3/14/2019 • 8 minutes to read • [Edit Online](#)

Overview

The RC1 release of .NET Core and ASP.NET Core 1.0 introduced DNX tooling. The RC2 release of .NET Core and ASP.NET Core 1.0 moved from DNX to the .NET Core CLI.

As a slight refresher, let's recap what DNX was about. DNX was a runtime and a toolset used to build .NET Core and, more specifically, ASP.NET Core 1.0 applications. It consisted of 3 main pieces:

1. DNVM - an install script for obtaining DNX
2. DNX (Dotnet Execution Runtime) - the runtime that executes your code
3. DNU (Dotnet Developer Utility) - tooling for managing dependencies, building and publishing your applications

With the introduction of the CLI, all of the above are now part of a single toolset. However, since DNX was available in RC1 timeframe, you might have projects that were built using it that you would want to move off to the new CLI tooling.

This migration guide will cover the essentials on how to migrate projects off of DNX and onto .NET Core CLI. If you are just starting a project on .NET Core from scratch, you can freely skip this document.

Main changes in the tooling

There are some general changes in the tooling that should be outlined first.

No more DNVM

DNVM, short for *DotNet Version Manager* was a bash/PowerShell script used to install a DNX on your machine. It helped users get the DNX they need from the feed they specified (or default ones) as well as mark a certain DNX "active", which would put it on the \$PATH for the given session. This would allow you to use the various tools.

DNVM was discontinued because its feature set was made redundant by changes coming in the .NET Core CLI tools.

The CLI tools come packaged in two main ways:

1. Native installers for a given platform
2. Install script for other situations (like CI servers)

Given this, the DNVM install features are not needed. But what about the runtime selection features?

You reference a runtime in your `project.json` by adding a package of a certain version to your dependencies. With this change, your application will be able to use the new runtime bits. Getting these bits to your machine is the same as with the CLI: you install the runtime via one of the native installers it supports or via its install script.

Different commands

If you were using DNX, you used some commands from one of its three parts (DNX, DNU or DNVM). With the CLI, some of these commands change, some are not available and some are the same but have slightly different semantics.

The table below shows the mapping between the DNX/DNU commands and their CLI counterparts.

DNX COMMAND	CLI COMMAND	DESCRIPTION
dnx run	dotnet run	Run code from source.
dnu build	dotnet build	Build an IL binary of your code.
dnu pack	dotnet pack	Package up a NuGet package of your code.
dnx [command] (for example, "dnx web")	N/A*	In DNX world, run a command as defined in the project.json.
dnu install	N/A*	In the DNX world, install a package as a dependency.
dnu restore	dotnet restore	Restore dependencies specified in your project.json. (see note)
dnu publish	dotnet publish	Publish your application for deployment in one of the three forms (portable, portable with native and standalone).
dnu wrap	N/A*	In DNX world, wrap a project.json in csproj.
dnu commands	N/A*	In DNX world, manage the globally installed commands.

(*) - these features are not supported in the CLI by design.

DNX features that are not supported

As the table above shows, there are features from the DNX world that we decided not to support in the CLI, at least for the time being. This section will go through the most important ones and outline the rationale behind not supporting them as well as workarounds if you do need them.

Global commands

DNX came with a concept called "global commands". These were, essentially, console applications packaged up as NuGet packages with a shell script that would invoke the DNX you specified to run the application.

The CLI does not support this concept. It does, however, support the concept of adding per-project commands that can be invoked using the familiar `dotnet <command>` syntax.

Installing dependencies

As of v1, the .NET Core CLI tools don't have an `install` command for installing dependencies. In order to install a package from NuGet, you would need to add it as a dependency to your `project.json` file and then run `dotnet restore` ([see note](#)).

Running your code

There are two main ways to run your code. One is from source, with `dotnet run`. Unlike `dnx run`, this will not do any in-memory compilation. It will actually invoke `dotnet build` to build your code and then run the built binary.

Another way is using the `dotnet` itself to run your code. This is done by providing a path to your assembly: `dotnet path/to/an/assembly.dll`.

Migrating your DNX project to .NET Core CLI

In addition to using new commands when working with your code, there are three major things left in migrating from DNX:

1. Migrate the `global.json` file if you have it to be able to use CLI.
2. Migrating the project file (`project.json`) itself to the CLI tooling.
3. Migrating off of any DNX APIs to their BCL counterparts.

Changing the `global.json` file

The `global.json` file acts like a solution file for both the RC1 and RC2 (or later) projects. In order for the CLI tools (as well as Visual Studio) to differentiate between RC1 and later versions, they use the `"sdk": { "version" }` property to make the distinction which project is RC1 or later. If `global.json` doesn't have this node at all, it is assumed to be the latest.

In order to update the `global.json` file, either remove the property or set it to the exact version of the tools that you wish to use, in this case **1.0.0-preview2-003121**:

```
{  
  "sdk": {  
    "version": "1.0.0-preview2-003121"  
  }  
}
```

Migrating the project file

The CLI and DNX both use the same basic project system based on `project.json` file. The syntax and the semantics of the project file are pretty much the same, with small differences based on the scenarios. There are also some changes to the schema which you can see in the [schema file](#).

If you are building a console application, you need to add the following snippet to your project file:

```
"buildOptions": {  
  "emitEntryPoint": true  
}
```

This instructs `dotnet build` to emit an entry point for your application, effectively making your code runnable. If you are building a class library, simply omit the above section. Of course, once you add the above snippet to your `project.json` file, you need to add a static entry point. With the move off DNX, the DI services it provided are no longer available and thus this needs to be a basic .NET entry point: `static void Main()`.

If you have a "commands" section in your `project.json`, you can remove it. Some of the commands that used to exist as DNU commands, such as Entity Framework CLI commands, are being ported to be per-project extensions to the CLI. If you built your own commands that you are using in your projects, you need to replace them with CLI extensions. In this case, the `commands` node in `project.json` needs to be replaced by the `tools` node and it needs to list the tools dependencies.

After these things are done, you need to decide which type of portability you wish for your app. With .NET Core, we have invested into providing a spectrum of portability options that you can choose from. For instance, you may want to have a fully *portable* application or you may want to have a *self-contained* application. The portable application option is more like .NET Framework applications work: it needs a shared component to execute it on the target machine (.NET Core). The self-contained application doesn't require .NET Core to be installed on the target, but you have to produce one application for each OS you wish to support. These portability types and more are discussed in the [application portability type document](#).

Once you make a call on what type of portability you want, you need to change your targeted framework(s). If you

were writing applications for .NET Core, you were most likely using `dnxcore50` as your targeted framework. With the CLI and the changes that the new [.NET Standard](#) brought, the framework needs to be one of the following:

1. `netcoreapp1.0` - if you are writing applications on .NET Core (including ASP.NET Core applications)
2. `netstandard1.6` - if you are writing class libraries for .NET Core

If you are using other `dnx` targets, like `dnx451` you will need to change those as well. `dnx451` should be changed to `net451`. Please refer to the [.NET Standard](#) topic for more information.

Your `project.json` is now mostly ready. You need to go through your dependencies list and update the dependencies to their newer versions, especially if you are using ASP.NET Core dependencies. If you were using separate packages for BCL APIs, you can use the runtime package as explained in the [application portability type](#) document.

Once you are ready, you can try restoring with `dotnet restore` ([see note](#)). Depending on the version of your dependencies, you may encounter errors if NuGet cannot resolve the dependencies for one of the targeted frameworks above. This is a "point-in-time" problem; as time progresses, more and more packages will include support for these frameworks. For now, if you run into this, you can use the `imports` statement within the `framework` node to specify to NuGet that it can restore the packages targeting the framework within the "imports" statement. The restoring errors you get in this case should provide enough information to tell you which frameworks you need to import. If you are slightly lost or new to this, in general, specifying `dnxcore50` and `portable-net45+win8` in the `imports` statement should do the trick. The JSON snippet below shows how this looks like:

```
"frameworks": {  
    "netcoreapp1.0": {  
        "imports": ["dnxcore50", "portable-net45+win8"]  
    }  
}
```

Running `dotnet build` will show any eventual build errors, though there shouldn't be too many of them. After your code is building and running properly, you can test it out with the runner. Execute `dotnet <path-to-your-assembly>` and see it run.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

.NET Core application deployment

2/23/2019 • 5 minutes to read • [Edit Online](#)

You can create three types of deployments for .NET Core applications:

- Framework-dependent deployment. As the name implies, framework-dependent deployment (FDD) relies on the presence of a shared system-wide version of .NET Core on the target system. Because .NET Core is already present, your app is also portable between installations of .NET Core. Your app contains only its own code and any third-party dependencies that are outside of the .NET Core libraries. FDDs contain `.dll` files that can be launched by using the [dotnet utility](#) from the command line. For example, `dotnet app.dll` runs an application named `app`.
- Self-contained deployment. Unlike FDD, a self-contained deployment (SCD) doesn't rely on the presence of shared components on the target system. All components, including both the .NET Core libraries and the .NET Core runtime, are included with the application and are isolated from other .NET Core applications. SCDs include an executable (such as `app.exe` on Windows platforms for an application named `app`), which is a renamed version of the platform-specific .NET Core host, and a `.dll` file (such as `app.dll`), which is the actual application.
- Framework-dependent executables. Produces an executable that runs on a target platform. Similar to FDDs, framework-dependent executables (FDE) are platform-specific and aren't self-contained. These deployments still rely on the presence of a shared system-wide version of .NET Core to run. Unlike an SCD, your app only contains your code and any third-party dependencies that are outside of the .NET Core libraries. FDEs produce an executable that runs on the target platform.

Framework-dependent deployments (FDD)

For an FDD, you deploy only your app and third-party dependencies. Your app will use the version of .NET Core that's present on the target system. This is the default deployment model for .NET Core and ASP.NET Core apps that target .NET Core.

Why create a framework-dependent deployment?

Deploying an FDD has a number of advantages:

- You don't have to define the target operating systems that your .NET Core app will run on in advance. Because .NET Core uses a common PE file format for executables and libraries regardless of operating system, .NET Core can execute your app regardless of the underlying operating system. For more information on the PE file format, see [.NET Assembly File Format](#).
- The size of your deployment package is small. You only deploy your app and its dependencies, not .NET Core itself.
- Unless overridden, FDDs will use the latest serviced runtime installed on the target system. This allows your application to use the latest patched version of the .NET Core runtime.
- Multiple apps use the same .NET Core installation, which reduces both disk space and memory usage on host systems.

There are also a few disadvantages:

- Your app can run only if the version of .NET Core your app targets, [or a later version](#), is already installed on the host system.

- It's possible for the .NET Core runtime and libraries to change without your knowledge in future releases. In rare cases, this may change the behavior of your app.

Self-contained deployments (SCD)

For a self-contained deployment, you deploy your app and any required third-party dependencies along with the version of .NET Core that you used to build the app. Creating an SCD doesn't include the [native dependencies of .NET Core](#) on various platforms, so these must be present before the app runs. For more information on version binding at runtime, see the article on [version binding in .NET Core](#).

Starting with .NET Core 2.1 SDK (version 2.1.300), .NET Core supports *patch version roll forward*. When you create a self-contained deployment, .NET Core tools automatically include the latest serviced runtime of the .NET Core version that your application targets. (The latest serviced runtime includes security patches and other bug fixes.) The serviced runtime does not have to be present on your build system; it is downloaded automatically from NuGet.org. For more information, including instructions on how to opt out of patch version roll forward, see [Self-contained deployment runtime roll forward](#).

FDD and SCD deployments use separate host executables, so you can sign a host executable for an SCD with your publisher signature.

Why deploy a self-contained deployment?

Deploying a Self-contained deployment has two major advantages:

- You have sole control of the version of .NET Core that is deployed with your app..NET Core can be serviced only by you.
- You can be assured that the target system can run your .NET Core app, since you're providing the version of .NET Core that it will run on.

It also has a number of disadvantages:

- Because .NET Core is included in your deployment package, you must select the target platforms for which you build deployment packages in advance.
- The size of your deployment package is relatively large, since you have to include .NET Core as well as your app and its third-party dependencies.

Starting with .NET Core 2.0, you can reduce the size of your deployment on Linux systems by approximately 28 MB by using .NET Core [globalization invariant mode](#). Ordinarily, .NET Core on Linux relies on the [ICU libraries](#) for globalization support. In invariant mode, the libraries are not included with your deployment, and all cultures behave like the [invariant culture](#).

- Deploying numerous self-contained .NET Core apps to a system can consume significant amounts of disk space, since each app duplicates .NET Core files.

Framework-dependent executables (FDE)

Starting with .NET Core 2.2, you can deploy your app as an FDE, along with any required third-party dependencies. Your app will use the version of .NET Core that's installed on the target system.

Why deploy a framework-dependent executable?

Deploying an FDE has a number of advantages:

- The size of your deployment package is small. You only deploy your app and its dependencies, not .NET Core itself.
- Multiple apps use the same .NET Core installation, which reduces both disk space and memory usage on host systems.

- Your app can be run by calling the published executable without invoking the `dotnet` utility directly.

There are also a few disadvantages:

- Your app can run only if the version of .NET Core your app targets, [or a later version](#), is already installed on the host system.
- It's possible for the .NET Core runtime and libraries to change without your knowledge in future releases. In rare cases, this may change the behavior of your app.
- You must publish your app for each target platform.

Step-by-step examples

For step-by-step examples of deploying .NET Core apps with CLI tools, see [Deploying .NET Core Apps with CLI Tools](#). For step-by-step examples of deploying .NET Core apps with Visual Studio, see [Deploying .NET Core Apps with Visual Studio](#).

Publish .NET Core apps with the CLI

3/25/2019 • 7 minutes to read • [Edit Online](#)

This article demonstrates how you can publish your .NET Core application from the command line. .NET Core provides three ways to publish your applications. Framework-dependent deployment produces a cross-platform .dll file that uses the locally installed .NET Core runtime. Framework-dependent executable produces a platform-specific executable that uses the locally installed .NET Core runtime. Self-contained executable produces a platform-specific executable and includes a local copy of the .NET Core runtime.

For an overview of these publishing modes, see [.NET Core Application Deployment](#).

Looking for some quick help on using the CLI? The following table shows some examples of how to publish your app. You can specify the target framework with the `-f <TFM>` parameter or by editing the project file. For more information, see [Publishing basics](#).

PUBLISH MODE	SDK VERSION	COMMAND
Framework-dependent deployment	2.x	<code>dotnet publish -c Release</code>
Framework-dependent executable	2.2	<code>dotnet publish -c Release -r <RID> --self-contained false</code>
	3.0	<code>dotnet publish -c Release -r <RID> --self-contained false</code>
	3.0*	<code>dotnet publish -c Release</code>
Self-contained deployment	2.1	<code>dotnet publish -c Release -r <RID> --self-contained true</code>
	2.2	<code>dotnet publish -c Release -r <RID> --self-contained true</code>
	3.0	<code>dotnet publish -c Release -r <RID> --self-contained true</code>

IMPORTANT

*When using SDK version 3.0, framework-dependent executable this is the default publishing mode when running the basic `dotnet publish` command. This only applies to projects that target **.NET Core 2.1** or **.NET Core 3.0**.

Publishing basics

The `<TargetFramework>` setting of the project file specifies the default target framework when you publish your app. You can change the target framework to any valid [Target Framework Moniker \(TFM\)](#). For example, if your project uses `<TargetFramework>netcoreapp2.2</TargetFramework>`, a binary that targets .NET Core 2.2 is created. The TFM specified in this setting is the default target used by the `dotnet publish` command.

If you want to target more than one framework, you can set the `<TargetFrameworks>` setting to more than one TFM value separated by a semicolon. You can publish one of the frameworks with the `dotnet publish -f <TFM>` command. For example, if you have `<TargetFrameworks>netcoreapp2.1;netcoreapp2.2</TargetFrameworks>` and run

```
dotnet publish -f netcoreapp2.1
```

, a binary that targets .NET Core 2.1 is created.

Unless otherwise set, the output directory of the `dotnet publish` command is

`./bin/<BUILD-CONFIGURATION>/<TFM>/publish/`. The default **BUILD-CONFIGURATION** mode is **Debug** unless changed with the `-c` parameter. For example, `dotnet publish -c Release -f netcoreapp2.1` publishes to `myfolder/bin/Release/netcoreapp2.1/publish/`.

If you use .NET Core SDK 3.0, the default publish mode for apps that target .NET Core versions 2.1, 2.2, or 3.0 is framework-dependent executable.

If you use .NET Core SDK 2.1, the default publish mode for apps that target .NET Core versions 2.1, 2.2 is framework-dependent deployment.

Native dependencies

If your app has native dependencies, it may not run on a different operating system. For example, if your app uses the native Windows API, it won't run on macOS or Linux. You would need to provide platform-specific code and compile an executable for each platform.

Consider also, if a library you referenced has a native dependency, your app may not run on every platform. However, it's possible a NuGet package you're referencing has included platform-specific versions to handle the required native dependencies for you.

When distributing an app with native dependencies, you may need to use the `dotnet publish -r <RID>` switch to specify the target platform you want to publish for. For a list of runtime identifiers, see [Runtime Identifier \(RID\) catalog](#).

More information about platform-specific binaries is covered in the [Framework-dependent executable](#) and [Self-contained deployment](#) sections.

Sample app

You can use either the following app to explore the publishing commands. The app is created by running the following commands in your terminal:

```
mkdir apptest1
cd apptest1
dotnet new console
dotnet add package Figgle
```

The `Program.cs` or `Program.vb` file that is generated by the console template needs to be changed to the following:

```
using System;

namespace apptest1
{
    class Program
    {
        static void Main(string[] args)
        {
            Console.WriteLine(Figgle.FiggleFonts.Standard.Render("Hello, World!"));
        }
    }
}
```

```
Imports System

Module Program
    Sub Main(args As String())
        Console.WriteLine(Figgle.FiggleFonts.Standard.Render("Hello, World!"))
    End Sub
End Module
```

When you run the app (`dotnet run`), the following output is displayed:

Framework-dependent deployment

For the .NET Core SDK 2.x CLI, framework-dependent deployment (FDD) is the default mode for the basic `dotnet publish` command.

When you publish your app as an FDD, a `<PROJECT-NAME>.dll` file is created in the `./bin/<BUILD-CONFIGURATION>/<TFM>/publish/` folder. To run your app, navigate to the output folder and use the `dotnet <PROJECT-NAME>.dll` command.

Your app is configured to target a specific version of .NET Core. That targeted .NET Core runtime is required to be on the machine where you want to run your app. For example, if your app targets .NET Core 2.2, any machine that your app runs on must have the .NET Core 2.2 runtime installed. As stated in the [Publishing basics](#) section, you can edit your project file to change the default target framework or to target more than one framework.

Publishing an FDD creates an app that automatically rolls-forward to the latest .NET Core security patch available on the system that runs the app. For more information on version binding at compile time, see [Select the .NET Core version to use](#).

Framework-dependent executable

For the .NET Core SDK 3.x CLI, framework-dependent executable (FDE) the default mode for the basic `dotnet publish` command. You don't need to specify any other parameters as long as you want to target the current operating system.

In this mode, a platform-specific executable host is created to host your cross-platform app. This mode is similar to FDD as FDD requires a host in the form of the `dotnet` command. The host executable filename varies per platform, and is named something similar to `<PROJECT-FILE>.exe`. You can run this executable directly instead of calling `dotnet <PROJECT-FILE>.dll` which is still an acceptable way to run the app.

Your app is configured to target a specific version of .NET Core. That targeted .NET Core runtime is required to be on the machine where you want to run your app. For example, if your app targets .NET Core 2.2, any machine that your app runs on must have the .NET Core 2.2 runtime installed. As stated in the [Publishing basics](#) section, you can edit your project file to change the default target framework or to target more than one framework.

Publishing an FDE creates an app that automatically rolls-forward to the latest .NET Core security patch available on the system that runs the app. For more information on version binding at compile time, see [Select the .NET Core version to use](#).

You must (except for .NET Core 3.x when you target the current platform) use the following switches with the

`dotnet publish` command to publish an FDE:

- `-r <RID>` This switch uses an identifier (RID) to specify the target platform. For a list of runtime identifiers, see [Runtime Identifier \(RID\) catalog](#).
- `--self-contained false` This switch tells the .NET Core SDK to create an executable as an FDE.

Whenever you use the `-r` switch, the output folder path changes to:

```
./bin/<BUILD-CONFIGURATION>/<TFM>/<RID>/publish/
```

If you use the [example app](#), run `dotnet publish -f netcoreapp2.2 -r win10-x64 --self-contained false`. This command creates the following executable: `./bin/Debug/netcoreapp2.2/win10-x64/publish/apptest1.exe`

NOTE

You can reduce the total size of your deployment by enabling **globalization invariant mode**. This mode is useful for applications that are not globally aware and that can use the formatting conventions, casing conventions, and string comparison and sort order of the [invariant culture](#). For more information about **globalization invariant mode** and how to enable it, see [.NET Core Globalization Invariant Mode](#)

Self-contained deployment

When you publish a self-contained deployment (SCD), the .NET Core SDK creates a platform-specific executable. Publishing an SCD includes all required .NET Core files to run your app but it doesn't include the [native dependencies of .NET Core](#). These dependencies must be present on the system before the app runs.

Publishing an SCD creates an app that doesn't roll-forward to the latest available .NET Core security patch. For more information on version binding at compile time, see [Select the .NET Core version to use](#).

You must use the following switches with the `dotnet publish` command to publish an SCD:

- `-r <RID>` This switch uses an identifier (RID) to specify the target platform. For a list of runtime identifiers, see [Runtime Identifier \(RID\) catalog](#).
- `--self-contained true` This switch tells the .NET Core SDK to create an executable as an SCD.

NOTE

You can reduce the total size of your deployment by enabling **globalization invariant mode**. This mode is useful for applications that are not globally aware and that can use the formatting conventions, casing conventions, and string comparison and sort order of the [invariant culture](#). For more information about **globalization invariant mode** and how to enable it, see [.NET Core Globalization Invariant Mode](#)

Deploy .NET Core apps with Visual Studio

1/23/2019 • 15 minutes to read • [Edit Online](#)

You can deploy a .NET Core application either as a *framework-dependent deployment*, which includes your application binaries but depends on the presence of .NET Core on the target system, or as a *self-contained deployment*, which includes both your application and .NET Core binaries. For an overview of .NET Core application deployment, see [.NET Core Application Deployment](#).

The following sections show how to use Microsoft Visual Studio to create the following kinds of deployments:

- Framework-dependent deployment
- Framework-dependent deployment with third-party dependencies
- Self-contained deployment
- Self-contained deployment with third-party dependencies

For information on using Visual Studio to develop .NET Core applications, see [Prerequisites for .NET Core on Windows](#).

Framework-dependent deployment

Deploying a framework-dependent deployment with no third-party dependencies simply involves building, testing, and publishing the app. A simple example written in C# illustrates the process.

1. Create the project.

Select **File > New > Project**. In the **New Project** dialog, expand your language's (C# or Visual Basic) project categories in the **Installed** project types pane, choose **.NET Core**, and then select the **Console App (.NET Core)** template in the center pane. Enter a project name, such as "FDD", in the **Name** text box. Select the **OK** button.

2. Add the application's source code.

Open the *Program.cs* or *Program.vb* file in the editor and replace the auto-generated code with the following code. It prompts the user to enter text and displays the individual words entered by the user. It uses the regular expression `\w+` to separate the words in the input text.

```
using System;
using System.Text.RegularExpressions;

namespace Applications.ConsoleApps
{
    public class ConsoleParser
    {
        public static void Main()
        {
            Console.WriteLine("Enter any text, followed by <Enter>:\n");
            String s = Console.ReadLine();
            ShowWords(s);
            Console.Write("\nPress any key to continue... ");
            Console.ReadKey();
        }

        private static void ShowWords(String s)
        {
            String pattern = @"\w+";
            var matches = Regex.Matches(s, pattern);
            if (matches.Count == 0)
            {
                Console.WriteLine("\nNo words were identified in your input.");
            }
            else
            {
                Console.WriteLine($"\\nThere are {matches.Count} words in your string:");
                for (int ctr = 0; ctr < matches.Count; ctr++)
                {
                    Console.WriteLine($"    #{ctr,2}: '{matches[ctr].Value}' at position
{matches[ctr].Index}");
                }
            }
        }
    }
}
```

```

Imports System.Text.RegularExpressions

Namespace Applications.ConsoleApps
    Public Module ConsoleParser
        Public Sub Main()
            Console.WriteLine("Enter any text, followed by <Enter>:")
            Console.WriteLine()
            Dim s = Console.ReadLine()
            ShowWords(s)
            Console.Write("\nPress any key to continue... ")
            Console.ReadKey()
        End Sub

        Private Sub ShowWords(s As String)
            Dim pattern = "\w+"
            Dim matches = Regex.Matches(s, pattern)
            Console.WriteLine()
            If matches.Count = 0 Then
                Console.WriteLine("No words were identified in your input.")
            Else
                Console.WriteLine($"There are {matches.Count} words in your string:")
                For ctr = 0 To matches.Count - 1
                    Console.WriteLine($"    #{ctr,2}: '{matches(ctr).Value}' at position
{matches(ctr).Index}")
                Next
            End If
            Console.WriteLine()
        End Sub
    End Module
End Namespace

```

3. Create a Debug build of your app.

Select **Build > Build Solution**. You can also compile and run the Debug build of your application by selecting **Debug > Start Debugging**.

4. Deploy your app.

After you've debugged and tested the program, create the files to be deployed with your app. To publish from Visual Studio, do the following:

- Change the solution configuration from **Debug** to **Release** on the toolbar to build a Release (rather than a Debug) version of your app.
- Right-click on the project (not the solution) in **Solution Explorer** and select **Publish**.
- In the **Publish** tab, select **Publish**. Visual Studio writes the files that comprise your application to the local file system.
- The **Publish** tab now shows a single profile, **FolderProfile**. The profile's configuration settings are shown in the **Summary** section of the tab.

The resulting files are placed in a directory named `publish` on Windows and `publish` on Unix systems that is in a subdirectory of your project's `.\bin\release\netcoreapp2.1` subdirectory.

Along with your application's files, the publishing process emits a program database (.pdb) file that contains debugging information about your app. The file is useful primarily for debugging exceptions. You can choose not to package it with your application's files. You should, however, save it in the event that you want to debug the Release build of your app.

Deploy the complete set of application files in any way you like. For example, you can package them in a Zip file,

use a simple `copy` command, or deploy them with any installation package of your choice. Once installed, users can then execute your application by using the `dotnet` command and providing the application filename, such as `dotnet fdd.dll`.

In addition to the application binaries, your installer should also either bundle the shared framework installer or check for it as a prerequisite as part of the application installation. Installation of the shared framework requires Administrator/root access since it is machine-wide.

Framework-dependent deployment with third-party dependencies

Deploying a framework-dependent deployment with one or more third-party dependencies requires that any dependencies be available to your project. The following additional steps are required before you can build your app:

1. Use the **NuGet Package Manager** to add a reference to a NuGet package to your project; and if the package is not already available on your system, install it. To open the package manager, select **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
2. Confirm that `Newtonsoft.Json` is installed on your system and, if it is not, install it. The **Installed** tab lists NuGet packages installed on your system. If `Newtonsoft.Json` is not listed there, select the **Browse** tab and enter "Newtonsoft.Json" in the search box. Select `Newtonsoft.Json` and, in the right pane, select your project before selecting **Install**.
3. If `Newtonsoft.Json` is already installed on your system, add it to your project by selecting your project in the right pane of the **Manage Packages for Solution** tab.

Note that a framework-dependent deployment with third-party dependencies is only as portable as its third-party dependencies. For example, if a third-party library only supports macOS, the app isn't portable to Windows systems. This happens if the third-party dependency itself depends on native code. A good example of this is [Kestrel server](#), which requires a native dependency on [libuv](#). When an FDD is created for an application with this kind of third-party dependency, the published output contains a folder for each [Runtime Identifier \(RID\)](#) that the native dependency supports (and that exists in its NuGet package).

Self-contained deployment without third-party dependencies

Deploying a self-contained deployment with no third-party dependencies involves creating the project, modifying the `csproj` file, building, testing, and publishing the app. A simple example written in C# illustrates the process. You begin by creating, coding, and testing your project just as you would a framework-dependent deployment:

1. Create the project.

Select **File** > **New** > **Project**. In the **New Project** dialog, expand your language's (C# or Visual Basic) project categories in the **Installed** project types pane, choose **.NET Core**, and then select the **Console App (.NET Core)** template in the center pane. Enter a project name, such as "SCD", in the **Name** text box, and select the **OK** button.

2. Add the application's source code.

Open the `Program.cs` or file in your editor, and replace the auto-generated code with the following code. It prompts the user to enter text and displays the individual words entered by the user. It uses the regular expression `\w+` to separate the words in the input text.

```
using System;
using System.Text.RegularExpressions;

namespace Applications.ConsoleApps
{
    public class ConsoleParser
    {
        public static void Main()
        {
            Console.WriteLine("Enter any text, followed by <Enter>:\n");
            String s = Console.ReadLine();
            ShowWords(s);
            Console.Write("\nPress any key to continue... ");
            Console.ReadKey();
        }

        private static void ShowWords(String s)
        {
            String pattern = @"\w+";
            var matches = Regex.Matches(s, pattern);
            if (matches.Count == 0)
            {
                Console.WriteLine("\nNo words were identified in your input.");
            }
            else
            {
                Console.WriteLine($"\\nThere are {matches.Count} words in your string:");
                for (int ctr = 0; ctr < matches.Count; ctr++)
                {
                    Console.WriteLine($"    #{ctr,2}: '{matches[ctr].Value}' at position
{matches[ctr].Index}");
                }
            }
        }
    }
}
```

```

Imports System.Text.RegularExpressions

Namespace Applications.ConsoleApps
    Public Module ConsoleParser
        Public Sub Main()
            Console.WriteLine("Enter any text, followed by <Enter>:")
            Console.WriteLine()
            Dim s = Console.ReadLine()
            ShowWords(s)
            Console.Write("\nPress any key to continue... ")
            Console.ReadKey()
        End Sub

        Private Sub ShowWords(s As String)
            Dim pattern = "\w+"
            Dim matches = Regex.Matches(s, pattern)
            Console.WriteLine()
            If matches.Count = 0 Then
                Console.WriteLine("No words were identified in your input.")
            Else
                Console.WriteLine($"There are {matches.Count} words in your string:")
                For ctr = 0 To matches.Count - 1
                    Console.WriteLine($"{ctr + 1}: '{matches(ctr).Value}' at position {matches(ctr).Index}")
                Next
            End If
            Console.WriteLine()
        End Sub
    End Module
End Namespace

```

3. Determine whether you want to use globalization invariant mode.

Particularly if your app targets Linux, you can reduce the total size of your deployment by taking advantage of [globalization invariant mode](#). Globalization invariant mode is useful for applications that are not globally aware and that can use the formatting conventions, casing conventions, and string comparison and sort order of the [invariant culture](#).

To enable invariant mode, right-click on your project (not the solution) in **Solution Explorer**, and select **Edit SCD.csproj** or **Edit SCD.vbproj**. Then add the following highlighted lines to the file:

```

<Project Sdk="Microsoft.NET.Sdk">
    <PropertyGroup>
        <OutputType>Exe</OutputType>
        <TargetFramework>netcoreapp2.2</TargetFramework>
    </PropertyGroup>
    <ItemGroup>
        <RuntimeHostConfigurationOption Include="System.Globalization.Invariant" Value="true" />
    </ItemGroup>
</Project>

```

1. Create a Debug build of your application.

Select **Build > Build Solution**. You can also compile and run the Debug build of your application by selecting **Debug > Start Debugging**. This debugging step lets you identify problems with your application when it's running on your host platform. You still will have to test it on each of your target platforms.

If you've enabled globalization invariant mode, be particularly sure to test whether the absence of culture-sensitive data is suitable for your application.

Once you've finished debugging, you can publish your self-contained deployment:

- [Visual Studio 15.6 and earlier](#)
- [Visual Studio 15.7 and later](#)

After you've debugged and tested the program, create the files to be deployed with your app for each platform that it targets.

To publish your app from Visual Studio, do the following:

1. Define the platforms that your app will target.
 - a. Right-click on your project (not the solution) in **Solution Explorer** and select **Edit SCD.csproj**.
 - b. Create a `<RuntimeIdentifiers>` tag in the `<PropertyGroup>` section of your `csproj` file that defines the platforms your app targets, and specify the runtime identifier (RID) of each platform that you target. Note that you also need to add a semicolon to separate the RIDs. See [Runtime IDentifier catalog](#) for a list of runtime identifiers.

For example, the following example indicates that the app runs on 64-bit Windows 10 operating systems and the 64-bit OS X Version 10.11 operating system.

```
<PropertyGroup>
  <RuntimeIdentifiers>win10-x64;osx.10.11-x64</RuntimeIdentifiers>
</PropertyGroup>
```

Note that the `<RuntimeIdentifiers>` element can go into any `<PropertyGroup>` that you have in your `csproj` file. A complete sample `csproj` file appears later in this section.

2. Publish your app.

After you've debugged and tested the program, create the files to be deployed with your app for each platform that it targets.

To publish your app from Visual Studio, do the following:

- a. Change the solution configuration from **Debug** to **Release** on the toolbar to build a Release (rather than a Debug) version of your app.
- b. Right-click on the project (not the solution) in **Solution Explorer** and select **Publish**.
- c. In the **Publish** tab, select **Publish**. Visual Studio writes the files that comprise your application to the local file system.
- d. The **Publish** tab now shows a single profile, **FolderProfile**. The profile's configuration settings are shown in the **Summary** section of the tab. **Target Runtime** identifies which runtime has been published, and **Target Location** identifies where the files for the self-contained deployment were written.
- e. Visual Studio by default writes all published files to a single directory. For convenience, it's best to create separate profiles for each target runtime and to place published files in a platform-specific directory. This involves creating a separate publishing profile for each target platform. So now rebuild the application for each platform by doing the following:
 - a. Select **Create new profile** in the **Publish** dialog.
 - b. In the **Pick a publish target** dialog, change the **Choose a folder** location to `bin\Release\PublishOutput\win10-x64`. Select **OK**.
 - c. Select the new profile (**FolderProfile1**) in the list of profiles, and make sure that the **Target Runtime** is `win10-x64`. If it isn't, select **Settings**. In the **Profile Settings** dialog, change the

Target Runtime to `win10-x64` and select **Save**. Otherwise, select **Cancel**.

- d. Select **Publish** to publish your app for 64-bit Windows 10 platforms.
- e. Follow the previous steps again to create a profile for the `osx.10.11-x64` platform. The **Target Location** is `bin\Release\PublishOutput\osx.10.11-x64`, and the **Target Runtime** is `osx.10.11-x64`. The name that Visual Studio assigns to this profile is **FolderProfile2**.

Note that each target location contains the complete set of files (both your app files and all .NET Core files) needed to launch your app.

Along with your application's files, the publishing process emits a program database (.pdb) file that contains debugging information about your app. The file is useful primarily for debugging exceptions. You can choose not to package it with your application's files. You should, however, save it in the event that you want to debug the Release build of your app.

Deploy the published files in any way you like. For example, you can package them in a Zip file, use a simple `copy` command, or deploy them with any installation package of your choice.

The following is the complete *csproj* file for this project.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>netcoreapp2.1</TargetFramework>
    <RuntimeIdentifiers>win10-x64;osx.10.11-x64</RuntimeIdentifiers>
  </PropertyGroup>
</Project>
```

Self-contained deployment with third-party dependencies

Deploying a self-contained deployment with one or more third-party dependencies involves adding the dependencies. The following additional steps are required before you can build your app:

1. Use the **NuGet Package Manager** to add a reference to a NuGet package to your project; and if the package is not already available on your system, install it. To open the package manager, select **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
2. Confirm that `Newtonsoft.Json` is installed on your system and, if it is not, install it. The **Installed** tab lists NuGet packages installed on your system. If `Newtonsoft.Json` is not listed there, select the **Browse** tab and enter "Newtonsoft.Json" in the search box. Select `Newtonsoft.Json` and, in the right pane, select your project before selecting **Install**.
3. If `Newtonsoft.Json` is already installed on your system, add it to your project by selecting your project in the right pane of the **Manage Packages for Solution** tab.

The following is the complete *csproj* file for this project:

- [Visual Studio 15.6 and earlier](#)
- [Visual Studio 15.7 and later](#)

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>netcoreapp2.1</TargetFramework>
    <RuntimeIdentifiers>win10-x64;osx.10.11-x64</RuntimeIdentifiers>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="Newtonsoft.Json" Version="10.0.2" />
  </ItemGroup>
</Project>
```

When you deploy your application, any third-party dependencies used in your app are also contained with your application files. Third-party libraries aren't required on the system on which the app is running.

Note that you can only deploy a self-contained deployment with a third-party library to platforms supported by that library. This is similar to having third-party dependencies with native dependencies in your framework-dependent deployment, where the native dependencies won't exist on the target platform unless they were previously installed there.

How to create a NuGet package with .NET Core command-line interface (CLI) tools

3/1/2019 • 2 minutes to read • [Edit Online](#)

NOTE

The following shows command-line samples using Unix. The `dotnet pack` command as shown here works the same way on Windows.

.NET Standard and .NET Core libraries are expected to be distributed as NuGet packages. This is in fact how all of the .NET Standard libraries are distributed and consumed. This is most easily done with the `dotnet pack` command.

Imagine that you just wrote an awesome new library that you would like to distribute over NuGet. You can create a NuGet package with cross platform tools to do exactly that! The following example assumes a library called

SuperAwesomeLibrary which targets `netstandard1.0`.

If you have transitive dependencies; that is, a project which depends on another package, you'll need to make sure to restore packages for your entire solution with the `dotnet restore` command before creating a NuGet package. Failing to do so will result in the `dotnet pack` command to not work properly.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

After ensuring packages are restored, you can navigate to the directory where a library lives:

```
cd src/SuperAwesomeLibrary
```

Then it's just a single command from the command line:

```
dotnet pack
```

Your `/bin/Debug` folder will now look like this:

```
$ ls bin/Debug  
netstandard1.0/  
SuperAwesomeLibrary.1.0.0.nupkg  
SuperAwesomeLibrary.1.0.0.symbols.nupkg
```

Note that this will produce a package which is capable of being debugged. If you want to build a NuGet package with release binaries, all you need to do is add the `--configuration` (or `-c`) switch and use `release` as the argument.

```
dotnet pack --configuration release
```

Your `/bin` folder will now have a `release` folder containing your NuGet package with release binaries:

```
$ ls bin/release  
  
netstandard1.0/  
SuperAwesomeLibrary.1.0.0.nupkg  
SuperAwesomeLibrary.1.0.0.symbols.nupkg
```

And now you have the necessary files to publish a NuGet package!

Don't confuse `dotnet pack` with `dotnet publish`

It is important to note that at no point is the `dotnet publish` command involved. The `dotnet publish` command is for deploying applications with all of their dependencies in the same bundle -- not for generating a NuGet package to be distributed and consumed via NuGet.

Self-contained deployment runtime roll forward

12/20/2018 • 2 minutes to read • [Edit Online](#)

.NET Core [self-contained application deployments](#) include both the .NET Core libraries and the .NET Core runtime. Starting in .NET Core 2.1 SDK (version 2.1.300), a self-contained application deployment [publishes the highest patch runtime on your machine](#). By default, `dotnet publish` for a self-contained deployment selects the latest version installed as part of the SDK on the publishing machine. This enables your deployed application to run with security fixes (and other fixes) available during `publish`. The application must be re-published to obtain a new patch. Self-contained applications are created by specifying `-r <RID>` on the `dotnet publish` command or by specifying the [runtime identifier \(RID\)](#) in the project file (csproj / vbproj) or on the command line.

Patch version roll forward overview

`restore`, `build` and `publish` are `dotnet` commands that can run separately. The runtime choice is part of the `restore` operation, not `publish` or `build`. If you call `publish`, the latest patch version will be chosen. If you call `publish` with the `--no-restore` argument, then you may not get the desired patch version because a prior `restore` may not have been executed with the new self-contained application publishing policy. In this case, a build error is generated with text similar to the following:

"The project was restored using Microsoft.NETCore.App version 2.0.0, but with current settings, version 2.0.6 would be used instead. To resolve this issue, make sure the same settings are used for restore and for subsequent operations such as build or publish. Typically this issue can occur if the RuntimeIdentifier property is set during build or publish but not during restore."

NOTE

`restore` and `build` can be run implicitly as part of another command, like `publish`. When run implicitly as part of another command, they are provided with additional context so that the right artifacts are produced. When you `publish` with a runtime (for example, `dotnet publish -r linux-x64`), the implicit `restore` restores packages for the linux-x64 runtime. If you call `restore` explicitly, it does not restore runtime packages by default, because it doesn't have that context.

How to avoid restore during publish

Running `restore` as part of the `publish` operation may be undesirable for your scenario. To avoid `restore` during `publish` while creating self-contained applications, do the following:

- Set the `RuntimeIdentifiers` property to a semicolon-separated list of all the [RIDs](#) to be published.
- Set the `TargetLatestRuntimePatch` property to `true`.

No-restore argument with dotnet publish options

If you want to create both self-contained applications and [framework-dependent applications](#) with the same project file, and you want to use the `--no-restore` argument with `dotnet publish`, then choose one of the following:

1. Prefer the framework-dependent behavior. If the application is framework-dependent, this is the default behavior. If the application is self-contained, and can use an unpatched 2.1.0 local runtime, set the `TargetLatestRuntimePatch` to `false` in the project file.
2. Prefer the self-contained behavior. If the application is self-contained, this is the default behavior. If the

application is framework-dependent, and requires the latest patch installed, set `TargetLatestRuntimePatch` to `true` in the project file.

3. Take explicit control of the runtime framework version by setting `RuntimeFrameworkVersion` to the specific patch version in the project file.

Runtime package store

1/23/2019 • 5 minutes to read • [Edit Online](#)

Starting with .NET Core 2.0, it's possible to package and deploy apps against a known set of packages that exist in the target environment. The benefits are faster deployments, lower disk space usage, and improved startup performance in some cases.

This feature is implemented as a *runtime package store*, which is a directory on disk where packages are stored (typically at `/usr/local/share/dotnet/store` on macOS/Linux and `C:/Program Files/dotnet/store` on Windows). Under this directory, there are subdirectories for architectures and [target frameworks](#). The file layout is similar to the way that [NuGet assets are laid out on disk](#):

```
\dotnet
  \store
    \x64
      \netcoreapp2.0
        \microsoft.applicationinsights
        \microsoft.aspnetcore
        ...
    \x86
      \netcoreapp2.0
        \microsoft.applicationinsights
        \microsoft.aspnetcore
        ...
```

A *target manifest* file lists the packages in the runtime package store. Developers can target this manifest when publishing their app. The target manifest is typically provided by the owner of the targeted production environment.

Preparing a runtime environment

The administrator of a runtime environment can optimize apps for faster deployments and lower disk space use by building a runtime package store and the corresponding target manifest.

The first step is to create a *package store manifest* that lists the packages that compose the runtime package store. This file format is compatible with the project file format (`csproj`).

```
<Project Sdk="Microsoft.NET.Sdk">
  <ItemGroup>
    <PackageReference Include="<NUGET_PACKAGE>" Version="<VERSION>" />
    <!-- Include additional packages here -->
  </ItemGroup>
</Project>
```

Example

The following example package store manifest (`packages.csproj`) is used to add `Newtonsoft.Json` and `Moq` to a runtime package store:

```
<Project Sdk="Microsoft.NET.Sdk">
  <ItemGroup>
    <PackageReference Include="Newtonsoft.Json" Version="10.0.3" />
    <PackageReference Include="Moq" Version="4.7.63" />
  </ItemGroup>
</Project>
```

Provision the runtime package store by executing `dotnet store` with the package store manifest, runtime, and framework:

```
dotnet store --manifest <PATH_TO_MANIFEST_FILE> --runtime <RUNTIME_IDENTIFIER> --framework <FRAMEWORK>
```

Example

```
dotnet store --manifest packages.csproj --runtime win10-x64 --framework netcoreapp2.0 --framework-version 2.0.0
```

You can pass multiple target package store manifest paths to a single `dotnet store` command by repeating the option and path in the command.

By default, the output of the command is a package store under the `.dotnet/store` subdirectory of the user's profile. You can specify a different location using the `--output <OUTPUT_DIRECTORY>` option. The root directory of the store contains a target manifest `artifact.xml` file. This file can be made available for download and be used by app authors who want to target this store when publishing.

Example

The following `artifact.xml` file is produced after running the previous example. Note that `Castle.Core` is a dependency of `Moq`, so it's included automatically and appears in the `artifacts.xml` manifest file.

```
<StoreArtifacts>
  <Package Id="Newtonsoft.Json" Version="10.0.3" />
  <Package Id="Castle.Core" Version="4.1.0" />
  <Package Id="Moq" Version="4.7.63" />
</StoreArtifacts>
```

Publishing an app against a target manifest

If you have a target manifest file on disk, you specify the path to the file when publishing your app with the `dotnet publish` command:

```
dotnet publish --manifest <PATH_TO_MANIFEST_FILE>
```

Example

```
dotnet publish --manifest manifest.xml
```

You deploy the resulting published app to an environment that has the packages described in the target manifest. Failing to do so results in the app failing to start.

Specify multiple target manifests when publishing an app by repeating the option and path (for example, `--manifest manifest1.xml --manifest manifest2.xml`). When you do so, the app is trimmed for the union of packages specified in the target manifest files provided to the command.

Specifying target manifests in the project file

An alternative to specifying target manifests with the `dotnet publish` command is to specify them in the project file as a semicolon-separated list of paths under a `<TargetManifestFiles>` tag.

```
<PropertyGroup>
  <TargetManifestFiles>manifest1.xml;manifest2.xml</TargetManifestFiles>
</PropertyGroup>
```

Specify the target manifests in the project file only when the target environment for the app is well-known, such as for .NET Core projects. This isn't the case for open-source projects. The users of an open-source project typically deploy it to different production environments. These production environments generally have different sets of packages pre-installed. You can't make assumptions about the target manifest in such environments, so you should use the `--manifest` option of `dotnet publish`.

ASP.NET Core implicit store

The ASP.NET Core implicit store applies only to ASP.NET Core 2.0. We strongly recommend applications use ASP.NET Core 2.1 and later, which does **not** use the implicit store. ASP.NET Core 2.1 and later use the shared framework.

The runtime package store feature is used implicitly by an ASP.NET Core app when the app is deployed as a [framework-dependent deployment \(FDD\)](#) app. The targets in `Microsoft.NET.Sdk.Web` include manifests referencing the implicit package store on the target system. Additionally, any FDD app that depends on the `Microsoft.AspNetCore.All` package results in a published app that contains only the app and its assets and not the packages listed in the `Microsoft.AspNetCore.All` metapackage. It's assumed that those packages are present on the target system.

The runtime package store is installed on the host when the .NET Core SDK is installed. Other installers may provide the runtime package store, including Zip/tarball installations of the .NET Core SDK, `apt-get`, Red Hat Yum, the .NET Core Windows Server Hosting bundle, and manual runtime package store installations.

When deploying a [framework-dependent deployment \(FDD\)](#) app, make sure that the target environment has the .NET Core SDK installed. If the app is deployed to an environment that doesn't include ASP.NET Core, you can opt out of the implicit store by specifying `<PublishWithAspNetCoreTargetManifest>` set to `false` in the project file as in the following example:

```
<PropertyGroup>
  <PublishWithAspNetCoreTargetManifest>false</PublishWithAspNetCoreTargetManifest>
</PropertyGroup>
```

NOTE

For [self-contained deployment \(SCD\)](#) apps, it's assumed that the target system doesn't necessarily contain the required manifest packages. Therefore, `<PublishWithAspNetCoreTargetManifest>` cannot be set to `true` for an SCD app.

If you deploy an application with a manifest dependency that's present in the deployment (the assembly is present in the `bin` folder), the runtime package store *isn't used* on the host for that assembly. The `bin` folder assembly is used regardless of its presence in the runtime package store on the host.

The version of the dependency indicated in the manifest must match the version of the dependency in the runtime package store. If you have a version mismatch between the dependency in the target manifest and the version that exists in the runtime package store and the app doesn't include the required version of the package in its

deployment, the app fails to start. The exception includes the name of the target manifest that called for the runtime package store assembly, which helps you troubleshoot the mismatch.

When the deployment is *trimmed* on publish, only the specific versions of the manifest packages you indicate are withheld from the published output. The packages at the versions indicated must be present on the host for the app to start.

Introduction to .NET and Docker

3/8/2019 • 6 minutes to read • [Edit Online](#)

This article provides an introduction and conceptual background to working with .NET on Docker.

Docker: Packaging your apps to deploy and run anywhere

Docker is an open platform that enables developers and administrators to build [images](#), ship, and run distributed applications in a loosely isolated environment called a [container](#). This approach enables efficient application lifecycle management between development, QA, and production environments.

The [Docker platform](#) uses the [Docker Engine](#) to quickly build and package apps as [Docker images](#) created using files written in the [Dockerfile](#) format that then is deployed and run in a [layered container](#).

You can either create your own [layered images](#) as dockerfiles or use existing ones from a [registry](#), like [Docker Hub](#).

The [relationship between Docker containers, images, and registries](#) is an important concept when [architecting and building containerized applications or microservices](#). This approach greatly shortens the time between development and deployment.

Getting .NET Docker images

The Official .NET Docker images are created and optimized by Microsoft. They are publicly available in the Microsoft repositories on Docker Hub. Each repository can contain multiple images, depending on .NET versions, and on OS versions. Most image repos provide extensive tagging to help you select both a specific framework version and an OS (Linux distro or Windows version).

Scenario based guidance

Microsoft's intent for .NET repositories is to have granular and focused repos, which represent a specific scenario or workload.

The `microsoft/aspnetcore` images are optimized for ASP.NET Core apps on Docker, so containers can start faster.

The .NET Core images (`microsoft/dotnet`) are intended for console apps based on .NET Core. For example, batch processes, Azure WebJobs, and other console scenarios should use optimized .NET Core images.

The most obvious horizontal scenario for using Docker and .NET applications is for production deployment and hosting. It turns out that production is just one scenario and the other ones are equally useful. These scenarios are not specific to .NET, but should apply to most developer platforms.

- **Low friction install** — You can try out .NET without a local install. Just download a Docker image with .NET in it.
- **Develop in a container** — You can develop in a consistent environment, making development and production environments similar (avoiding issues like global state on developer machines). Visual Studio

Tools for Docker even enable you to start a container directly from Visual Studio.

- **Test in a container** — You can test in a container, reducing failures due to incorrectly configured environments or other changes left behind from the last test.
- **Build in a container** — You can build code in a container, avoiding the need to correctly configure shared build machines for multiple environments but instead move to a "BYOC" (bring your own container) approach.
- **Deployment in all environments** — You can deploy an image through all of your environments. This approach reduces failures due to configuration differences, typically changing the image behavior via external configuration (for example, injected environment variables).

General guidance for deciding between .NET Core and .NET Framework for Docker container development.

Common Docker development scenarios

.NET Core

.NET Core resources

Pick the .NET Core samples that fit your scenarios of interest. All sample instructions describe how to target Windows or Linux Docker images from Windows, Linux, or macOS hosts.

The samples use .NET Core 2.0. They use Docker [multi-stage build](#) and [multi-arch tags](#) where appropriate.

How to containerize a .NET Core application

3/5/2019 • 6 minutes to read • [Edit Online](#)

This tutorial teaches the Docker container build and deploy tasks for a .NET Core application. The [Docker platform](#) uses the [Docker Engine](#) to quickly build and package apps as [Docker images](#). These images are written in the [Dockerfile](#) format to be deployed and run in a [layered container](#).

During the course of this tutorial, you learn:

- How to create a Dockerfile
- How to create a .NET Core app.
- How to deploy your app into a Docker container.

.NET Core: Easiest way to get started

Before creating the Docker image, you need an application to containerize. You can create it on Linux, MacOS, or Windows. The quickest and easiest way to do that is to use .NET Core.

If you're unfamiliar with the .NET Core CLI toolset, read the [.NET Core SDK overview](#).

You can build both Windows and Linux containers with [multi-arch based tags](#).

Your first .NET Core Docker app

Prerequisites

To complete this tutorial:

.NET Core SDK

- Install [.NET Core 2.1 SDK](#) or later.

See [.NET Core 2.1 Supported OS Versions](#) for the complete list of .NET Core 2.1 supported operating systems, out of support OS versions, and lifecycle policy links.

- Install your favorite code editor, if you haven't already.

TIP

Need to install a code editor? Try [Visual Studio Code!](#)

Installing Docker Client

Install [Docker 18.06](#) or later of the Docker client.

The Docker client can be installed in:

- Linux distributions
 - [CentOS](#)
 - [Debian](#)
 - [Fedora](#)
 - [Ubuntu](#)

- macOS

- Windows.

Create a .NET Core 2.1 console app for Dockerization

Open a command prompt and create a folder named *Hello*. Navigate to the folder you created and type the following commands:

```
dotnet new console  
dotnet run
```

Let's do a quick walkthrough:

1. `$ dotnet new console`

`dotnet new` creates an up-to-date `Hello.csproj` project file with the dependencies necessary to build a console app. It also creates a `Program.cs`, a basic file containing the entry point for the application.

`Hello.csproj`:

The project file specifies everything that's needed to restore dependencies and build the program.

- The `OutputType` tag specifies that we're building an executable, in other words a console application.
- The `TargetFramework` tag specifies what .NET implementation we're targeting. In an advanced scenario, you can specify multiple target frameworks and build to the specified frameworks in a single operation. In this tutorial, we build for .NET Core 2.1.

`Program.cs`:

The program starts by `using System`. This statement means, "Bring everything in the `System` namespace into scope for this file." The `System` namespace includes basic constructs such as `string`, or numeric types.

We then define a namespace called `Hello`. You can change namespace to anything you want. A class named `Program` is defined within that namespace, with a `Main` method that takes an array of strings as its argument. This array contains the list of arguments passed in when the compiled program is called. In our example, the program only writes "Hello World!" to the console.

`dotnet new` runs the `dotnet restore` command. **Dotnet restore** restores the tree of dependencies with a `NuGet`(.NET package manager) call. NuGet performs the following tasks:

- analyzes the `Hello.csproj` file.
- downloads the file dependencies (or grabs from your machine cache).
- writes the `obj/project.assets.json` file.

The `project.assets.json` file is a complete set of the NuGet dependencies graph, binding resolutions, and other app metadata. This required file is used by other tools, such as `dotnet build` and `dotnet run`, to correctly process the source code.

2. `$ dotnet run`

`dotnet run` calls `dotnet build` to confirm a successful build, and then calls `dotnet <assembly.dll>` to run the application.

```
$ dotnet run  
  
Hello World!
```

For advanced scenarios, see [.NET Core Application Deployment](#) for details.

Dockerize the .NET Core application

The Hello .NET Core console app successfully runs locally. Now let's take it a step further and build and run the app in Docker.

Your first Dockerfile

Open your text editor and let's get started! We're still working from the Hello directory we built the app in.

Add the following Docker instructions for either Linux or [Windows Containers](#) to a new file. When finished, save it in the root of your Hello directory as **Dockerfile**, with no extension (You may need to set your file type to

All types (*.*) or something similar).

```
FROM microsoft/dotnet:2.1-sdk
WORKDIR /app

# copy csproj and restore as distinct layers
COPY *.csproj .
RUN dotnet restore

# copy and build everything else
COPY . .
RUN dotnet publish -c Release -o out
ENTRYPOINT ["dotnet", "out/Hello.dll"]
```

The Dockerfile contains Docker build instructions that run sequentially.

The first instruction must be **FROM**. This instruction initializes a new build stage and sets the Base Image for the remaining instructions. The multi-arch tags pull either Windows or Linux containers depending on the Docker for Windows [container mode](#). The Base Image for our sample is the 2.1-sdk image from the microsoft/dotnet repository,

```
FROM microsoft/dotnet:2.1-sdk
```

The **WORKDIR** instruction sets the working directory for any remaining RUN, CMD, ENTRYPOINT, COPY, and ADD Dockerfile instructions. If the directory doesn't exist, it's created. In this case, WORKDIR is set to the app directory.

```
WORKDIR /app
```

The **COPY** instruction copies new files or directories from the source path and adds them to the destination container filesystem. With this instruction, we are copying the C# project file to the container.

```
COPY *.csproj .
```

The **RUN** instruction executes any commands in a new layer on top of the current image and commit the results. The resulting committed image is used for the next step in the Dockerfile. We are running **dotnet restore** to get the needed dependencies of the C# project file.

```
RUN dotnet restore
```

This **COPY** instruction copies the rest of the files into our container into new [layers](#).

```
COPY . .
```

We are publishing the app with this **RUN** instruction. The **dotnet publish** command compiles the application, reads through its dependencies specified in the project file, and publishes the resulting set of files to a directory. Our app is published with a **Release** configuration and output to the default directory.

```
RUN dotnet publish -c Release -o out
```

The **ENTRYPOINT** instruction allows the container to run as an executable.

```
ENTRYPOINT ["dotnet", "out/Hello.dll"]
```

Now you have a Dockerfile that:

- copies your app to the image
- your app's dependencies to the image
- builds the app to run as an executable

Build and run the Hello .NET Core app

Essential Docker commands

These Docker commands are essential:

- [docker build](#)
- [docker run](#)
- [docker ps](#)
- [docker stop](#)
- [docker rm](#)
- [docker rmi](#)
- [docker image](#)

Build and run

You wrote the dockerfile; now Docker builds your app and then runs the container.

```
docker build -t dotnetapp-dev .
docker run --rm dotnetapp-dev Hello from Docker
```

The output from the `docker build` command should be similar to the following console output:

```
Sending build context to Docker daemon 173.1kB
Step 1/7 : FROM microsoft/dotnet:2.1-sdk
--> 288f8c45f7c2
Step 2/7 : WORKDIR /app
--> Using cache
--> 9af1fbdc7972
Step 3/7 : COPY *.csproj ./
--> Using cache
--> 86c8c332d4b3
Step 4/7 : RUN dotnet restore
--> Using cache
--> 86fcfd7dd0ea4
Step 5/7 : COPY . ./
--> Using cache
--> 6faf0a53607f
Step 6/7 : RUN dotnet publish -c Release -o out
--> Using cache
--> f972328318c8
Step 7/7 : ENTRYPOINT dotnet out/Hello.dll
--> Using cache
--> 53c337887e18
Successfully built 46db075bd98d
Successfully tagged dotnetapp-dev:latest
```

As you can see from the output, the Docker Engine used the Dockerfile to build our container.

The output from the `docker run` command should be similar to the following console output:

```
Hello World!
```

Congratulations! You have just:

- Created a local .NET Core app
- Created a Dockerfile to build your first container
- Built and ran your Dockerized app

Next steps

Here are some next steps you can take:

- [Introduction to .NET Docker Images Video](#)
- [Visual Studio, Docker & Azure Container Instances better together!](#)
- [Docker for Azure Quickstarts](#)
- [Deploy your app on Docker for Azure](#)

NOTE

If you do not have an Azure subscription, [sign up today](#) for a free 30-day account and get \$200 in Azure Credits to try out any combination of Azure services.

Docker Images used in this sample

The following Docker images are used in this sample

- `microsoft/dotnet:2.1-sdk`

Learn about Docker images for .NET Core

12/20/2018 • 8 minutes to read • [Edit Online](#)

In this tutorial, we focus on how to use .NET Core on Docker. First, we explore the different Docker images offered and maintained by Microsoft, and use cases. We then learn how to build and dockerize an ASP.NET Core app.

During the course of this tutorial, you learn:

- Learn about Microsoft .NET Core Docker images
- Get an ASP.NET Core sample app to Dockerize
- Run the ASP.NET sample app locally
- Build and run the sample with Docker for Linux containers
- Build and run the sample with Docker for Windows containers

Docker Image Optimizations

When building Docker images for developers, we focused on three main scenarios:

- Images used to develop .NET Core apps
- Images used to build .NET Core apps
- Images used to run .NET Core apps

Why three images? When developing, building, and running containerized applications, we have different priorities.

- **Development:** The priority focuses on quickly iterate changes, and the ability to debug the changes. The size of the image isn't as important, rather can you make changes to your code and see them quickly?
- **Build:** This image contains everything needed to compile your app, which includes the compiler and any other dependencies to optimize the binaries. You use the build image to create the assets you place into a production image. The build image would be used for continuous integration, or in a build environment. This approach allows a build agent to compile and build the application (with all the required dependencies) in a build image instance. Your build agent only needs to know how to run this Docker image.
- **Production:** How fast you can deploy and start your image? This image is small so network performance from your Docker Registry to your Docker hosts is optimized. The contents are ready to run enabling the fastest time from Docker run to processing results. Dynamic code compilation isn't needed in the Docker model. The content you place in this image would be limited to the binaries and content needed to run the application.

For example, the `dotnet publish` output contains:

- the compiled binaries
- .js and .css files

The reason to include the `dotnet publish` command output in your production image is to keep its size to a minimum.

Some .NET Core images share layers between different tags so downloading the latest tag is a relatively lightweight process. If you already have an older version on your machine, this architecture decreases the needed disk space.

When multiple applications use common images on the same machine, memory is shared between the common

images. The images must be the same to be shared.

Docker image variations

To achieve the goals above, we provide image variants under `microsoft/dotnet`.

- `microsoft/dotnet:<version>-sdk` (`microsoft/dotnet:2.1-sdk`) This image contains the .NET Core SDK, which includes the .NET Core and Command Line Tools (CLI). This image maps to the **development scenario**. You use this image for local development, debugging, and unit testing. This image can also be used for your **build** scenarios. Using `microsoft/dotnet:sdk` always gives you the latest version.

TIP

If you are unsure about your needs, you want to use the `microsoft/dotnet:<version>-sdk` image. As the "de facto" image, it's designed to be used as a throw away container (mount your source code and start the container to start your app), and as the base image to build other images from.

- `microsoft/dotnet:<version>-runtime`: This image contains the .NET Core (runtime and libraries) and is optimized for running .NET Core apps in **production**.

Alternative images

In addition to the optimized scenarios of development, build and production, we provide additional images:

- `microsoft/dotnet:<version>-runtime-deps`: The **runtime-deps** image contains the operating system with all of the native dependencies needed by .NET Core. This image is for [self-contained applications](#).

Latest versions of each variant:

- `microsoft/dotnet` or `microsoft/dotnet:latest` (alias for the SDK image)
- `microsoft/dotnet:sdk`
- `microsoft/dotnet:runtime`
- `microsoft/dotnet:runtime-deps`

Samples to explore

- [This ASP.NET Core Docker sample](#) demonstrates a best practice pattern for building Docker images for ASP.NET Core apps for production. The sample works with both Linux and Windows containers.
- This .NET Core Docker sample demonstrates a best practice pattern for [building Docker images for .NET Core apps for production](#).

Forward the request scheme and original IP address

Proxy servers, load balancers, and other network appliances often obscure information about a request before it reaches the containerized app:

- When HTTPS requests are proxied over HTTP, the original scheme (HTTPS) is lost and must be forwarded in a header.
- Because an app receives a request from the proxy and not its true source on the Internet or corporate network, the original client IP address must also be forwarded in a header.

This information may be important in request processing, for example in redirects, authentication, link generation, policy evaluation, and client geolocation.

To forward the scheme and original IP address to a containerized ASP.NET Core app, use Forwarded Headers Middleware. For more information, see [Configure ASP.NET Core to work with proxy servers and load balancers](#).

Your first ASP.NET Core Docker app

For this tutorial, let's use an ASP.NET Core Docker sample application for the app we want to dockerize. This ASP.NET Core Docker sample application demonstrates a best practice pattern for building Docker images for ASP.NET Core apps for production. The sample works with both Linux and Windows containers.

The sample Dockerfile creates an ASP.NET Core application Docker image based off of the ASP.NET Core Runtime Docker base image.

It uses the [Docker multi-stage build feature](#) to:

- build the sample in a container based on the **larger** ASP.NET Core Build Docker base image
- copies the final build result into a Docker image based on the **smaller** ASP.NET Core Docker Runtime base image

NOTE

The build image contains required tools to build applications while the runtime image does not.

Prerequisites

To build and run, install the following items:

.NET Core 2.1 SDK

- Install [.NET Core 2.1 SDK](#).
- Install your favorite code editor, if you haven't already.

TIP

Need to install a code editor? Try [Visual Studio!](#)

Installing Docker Client

Install [Docker 18.03](#) or later of the Docker client.

The Docker client can be installed in:

- Linux distributions
 - [CentOS](#)
 - [Debian](#)
 - [Fedora](#)
 - [Ubuntu](#)
- [macOS](#)
- [Windows](#).

Installing Git for sample repository

- Install [git](#) if you wish to clone the repository.

Getting the sample application

The easiest way to get the sample is by cloning the [.NET Core Docker repository](#) with git, using the following

instructions:

```
git clone https://github.com/dotnet/dotnet-docker
```

You can also download the repository (it is small) as a zip from the .NET Core Docker repository.

Run the ASP.NET app locally

For a reference point, before we containerize the application, first run the application locally.

You can build and run the application locally with the .NET Core 2.1 SDK using the following commands (The instructions assume the root of the repository):

```
cd dotnet-docker
cd samples
cd aspnetapp // solution scope where the dockerfile is located
cd aspnetapp // project scope

dotnet run
```

After the application starts, visit **http://localhost:5000** in your web browser.

Build and run the sample with Docker for Linux containers

You can build and run the sample in Docker using Linux containers using the following commands (The instructions assume the root of the repository):

```
cd dotnet-docker
cd samples
cd aspnetapp // solution scope where the dockerfile is located

docker build -t aspnetapp .
docker run -it --rm -p 5000:80 --name aspnetcore_sample aspnetapp
```

NOTE

The `docker run` '`-p`' argument maps port 5000 on your local machine to port 80 in the container (the port mapping form is `host:container`). For more information, see the [docker run](#) reference on command-line parameters.

After the application starts, visit **http://localhost:5000** in your web browser.

Build and run the sample with Docker for Windows containers

You can build and run the sample in Docker using Windows containers using the following commands (The instructions assume the root of the repository):

```
cd dotnet-docker
cd samples
cd aspnetapp // solution scope where the dockerfile is located

docker build -t aspnetapp .
docker run -it --rm --name aspnetcore_sample aspnetapp
```

IMPORTANT

You must navigate to the **container IP address** (as opposed to `http://localhost`) in your browser directly when using Windows containers. You can get the IP address of your container with the following steps:

- Open up another command prompt.
- Run `docker ps` to see your running containers. The "aspnetcore_sample" container should be there.
- Run `docker exec aspnetcore_sample ipconfig`.
- Copy the container IP address and paste into your browser (for example, 172.29.245.43).

NOTE

Docker exec supports identifying containers with name or hash. The name (aspnetcore_sample) is used in our example.

See the following example of how to get the IP address of a running Windows container.

```
docker exec aspnetcore_sample ipconfig

Windows IP Configuration

Ethernet adapter Ethernet:

Connection-specific DNS Suffix  . : contoso.com
Link-local IPv6 Address  . . . . . : fe80::1967:6598:124:cfa3%4
IPv4 Address. . . . . : 172.29.245.43
Subnet Mask . . . . . : 255.255.240.0
Default Gateway . . . . . : 172.29.240.1
```

NOTE

Docker exec runs a new command in a running container. For more information, see the [docker exec reference](#) on command-line parameters.

You can produce an application that is ready to deploy to production locally using the `dotnet publish` command.

```
dotnet publish -c Release -o published
```

NOTE

The `-c Release` argument builds the application in release mode (the default is debug mode). For more information, see the [dotnet run reference](#) on command-line parameters.

You can run the application on **Windows** using the following command.

```
dotnet published\aspnetapp.dll
```

You can run the application on **Linux** or **macOS** using the following command.

```
dotnet published/aspnetapp.dll
```

Docker Images used in this sample

The following Docker images are used in this sample's dockerfile.

- `microsoft/dotnet:2.1-sdk`
- `microsoft/dotnet:2.1-aspnetcore-runtime`

Congratulations! you have just:

- Learned about Microsoft .NET Core Docker images
- Got an ASP.NET Core sample app to Dockerize
- Ran the ASP.NET sample app locally
- Built and ran the sample with Docker for Linux containers
- Built and ran the sample with Docker for Windows containers

Next Steps

Here are some next steps you can take:

- [Working with Visual Studio Docker Tools](#)
- [Deploying Docker Images from the Azure Container Registry to Azure Container Instances](#)
- [Debugging with Visual Studio Code](#)
- [Getting hands on with Visual Studio for Mac, containers, and serverless code in the cloud](#)
- [Getting Started with Docker and Visual Studio for Mac Lab](#)

NOTE

If you do not have an Azure subscription, [sign up today](#) for a free 30-day account and get \$200 in Azure Credits to try out any combination of Azure services.

Unit testing in .NET Core and .NET Standard

3/19/2019 • 2 minutes to read • [Edit Online](#)

.NET Core makes it easy to create unit tests. This article introduces unit tests and illustrates how they differ from other kinds of tests. The linked resources near the bottom of the page show you how to add a test project to your solution. After you set up your test project, you will be able to run your unit tests using the command line or Visual Studio.

.NET Core 2.0 and later supports [.NET Standard 2.0](#), and we will use its libraries to demonstrate unit tests.

You are able to use built-in .NET Core 2.0 and later unit test project templates for C#, F# and Visual Basic as a starting point for your personal project.

What are unit tests?

Having automated tests is a great way to ensure a software application does what its authors intend it to do. There are multiple types of tests for software applications. These include integration tests, web tests, load tests, and others. **Unit tests** test individual software components and methods. Unit tests should only test code within the developer's control. They should not test infrastructure concerns. Infrastructure concerns include databases, file systems, and network resources.

Also, keep in mind there are best practices for writing tests. For example, [Test Driven Development \(TDD\)](#) is when a unit test is written before the code it is meant to check. TDD is like creating an outline for a book before we write it. It is meant to help developers write simpler, more readable, and efficient code.

NOTE

The ASP.NET team follows [these conventions](#) to help developers come up with good names for test classes and methods.

Try not to introduce dependencies on infrastructure when writing unit tests. These make the tests slow and brittle, and should be reserved for integration tests. You can avoid these dependencies in your application by following the [Explicit Dependencies Principle](#) and using [Dependency Injection](#). You can also keep your unit tests in a separate project from your integration tests. This ensures your unit test project doesn't have references to or dependencies on infrastructure packages.

Next steps

More information on unit testing in .NET Core projects:

.NET Core unit test projects are supported for:

- [C#](#)
- [F#](#)
- [Visual Basic](#)

You can also choose between:

- [xUnit](#)
- [NUnit](#)
- [MSTest](#)

You can learn more in the following walkthroughs:

- Create unit tests using [xUnit](#) and [C#](#) with the .NET Core CLI.
- Create unit tests using [NUnit](#) and [C#](#) with the .NET Core CLI.
- Create unit tests using [MSTest](#) and [C#](#) with the .NET Core CLI.
- Create unit tests using [xUnit](#) and [F#](#) with the .NET Core CLI.
- Create unit tests using [NUnit](#) and [F#](#) with the .NET Core CLI.
- Create unit tests using [MSTest](#) and [F#](#) with the .NET Core CLI.
- Create unit tests using [xUnit](#) and [Visual Basic](#) with the .NET Core CLI.
- Create unit tests using [NUnit](#) and [Visual Basic](#) with the .NET Core CLI.
- Create unit tests using [MSTest](#) and [Visual Basic](#) with the .NET Core CLI.

You can learn more in the following articles:

- Visual Studio Enterprise offers great testing tools for .NET Core. Check out [Live Unit Testing](#) or [code coverage](#) to learn more.

Unit testing best practices with .NET Core and .NET Standard

3/5/2019 • 14 minutes to read • [Edit Online](#)

There are numerous benefits to writing unit tests; they help with regression, provide documentation, and facilitate good design. However, hard to read and brittle unit tests can wreak havoc on your code base. This article describes some best practices regarding unit test design for your .NET Core and .NET Standard projects.

In this guide, you'll learn some best practices when writing unit tests to keep your tests resilient and easy to understand.

By [John Reese](#) with special thanks to [Roy Osherove](#)

Why unit test?

Less time performing functional tests

Functional tests are expensive. They typically involve opening up the application and performing a series of steps that you (or someone else), must follow in order to validate the expected behavior. These steps may not always be known to the tester, which means they will have to reach out to someone more knowledgeable in the area in order to carry out the test. Testing itself could take seconds for trivial changes, or minutes for larger changes. Lastly, this process must be repeated for every change that you make in the system.

Unit tests, on the other hand, take milliseconds, can be run at the press of a button and do not necessarily require any knowledge of the system at large. Whether or not the test passes or fails is up to the test runner, not the individual.

Protection against regression

Regression defects are defects that are introduced when a change is made to the application. It is common for testers to not only test their new feature but also features that existed beforehand in order to verify that previously implemented features still function as expected.

With unit testing, it's possible to rerun your entire suite of tests after every build or even after you change a line of code. Giving you confidence that your new code does not break existing functionality.

Executable documentation

It may not always be obvious what a particular method does or how it behaves given a certain input. You may ask yourself: How does this method behave if I pass it a blank string? Null?

When you have a suite of well-named unit tests, each test should be able to clearly explain the expected output for a given input. In addition, it should be able to verify that it actually works.

Less coupled code

When code is tightly coupled, it can be difficult to unit test. Without creating unit tests for the code that you're writing, coupling may be less apparent.

Writing tests for your code will naturally decouple your code, because it would be more difficult to test otherwise.

Characteristics of a good unit test

- **Fast.** It is not uncommon for mature projects to have thousands of unit tests. Unit tests should take very little time to run. Milliseconds.

- **Isolated.** Unit tests are standalone, can be run in isolation, and have no dependencies on any outside factors such as a file system or database.
- **Repeatable.** Running a unit test should be consistent with its results, that is, it always returns the same result if you do not change anything in between runs.
- **Self-Checking.** The test should be able to automatically detect if it passed or failed without any human interaction.
- **Timely.** A unit test should not take a disproportionately long time to write compared to the code being tested. If you find testing the code taking a large amount of time compared to writing the code, consider a design that is more testable.

Let's speak the same language

The term *mock* is unfortunately very misused when talking about testing. The following defines the most common types of *fakes* when writing unit tests:

Fake - A fake is a generic term which can be used to describe either a stub or a mock object. Whether it is a stub or a mock depends on the context in which it's used. So in other words, a fake can be a stub or a mock.

Mock - A mock object is a fake object in the system that decides whether or not a unit test has passed or failed. A mock starts out as a Fake until it is asserted against.

Stub - A stub is a controllable replacement for an existing dependency (or collaborator) in the system. By using a stub, you can test your code without dealing with the dependency directly. By default, a fake starts out as a stub.

Consider the following code snippet:

```
var mockOrder = new MockOrder();
var purchase = new Purchase(mockOrder);

purchase.ValidateOrders();

Assert.True(purchase.CanBeShipped);
```

This would be an example of stub being referred to as a mock. In this case, it is a stub. You're just passing in the Order as a means to be able to instantiate `Purchase` (the system under test). The name `MockOrder` is also very misleading because again, the order is not a mock.

A better approach would be

```
var stubOrder = new FakeOrder();
var purchase = new Purchase(stubOrder);

purchase.ValidateOrders();

Assert.True(purchase.CanBeShipped);
```

By renaming the class to `FakeOrder`, you've made the class a lot more generic, the class can be used as a mock or a stub. Whichever is better for the test case. In the above example, `FakeOrder` is used as a stub. You're not using the `FakeOrder` in any shape or form during the assert. `FakeOrder` was just passed into the `Purchase` class to satisfy the requirements of the constructor.

To use it as a Mock, you could do something like this

```
var mockOrder = new FakeOrder();
var purchase = new Purchase(mockOrder);

purchase.ValidateOrders();

Assert.True(mockOrder.Validated);
```

In this case, you are checking a property on the Fake (asserting against it), so in the above code snippet, the `mockOrder` is a Mock.

IMPORTANT

It's important to get this terminology correct. If you call your stubs "Mocks", other developers are going to make false assumptions about your intent.

The main thing to remember about mocks versus stubs is that mocks are just like stubs, but you assert against the mock object, whereas you do not assert against a stub.

Best practices

Naming your tests

The name of your test should consist of three parts:

- The name of the method being tested.
- The scenario under which it's being tested.
- The expected behavior when the scenario is invoked.

Why?

- Naming standards are important because they explicitly express the intent of the test.

Tests are more than just making sure your code works, they also provide documentation. Just by looking at the suite of unit tests, you should be able to infer the behavior of your code without even looking at the code itself. Additionally, when tests fail, you can see exactly which scenarios do not meet your expectations.

Bad:

```
[Fact]
public void Test_Single()
{
    var stringCalculator = new StringCalculator();

    var actual = stringCalculator.Add("0");

    Assert.Equal(0, actual);
}
```

Better:

```
[Fact]
public void Add_SingleNumber_ReturnsSameNumber()
{
    var stringCalculator = new StringCalculator();

    var actual = stringCalculator.Add("0");

    Assert.Equal(0, actual);
}
```

Arranging your tests

Arrange, Act, Assert is a common pattern when unit testing. As the name implies, it consists of three main actions:

- *Arrange* your objects, creating and setting them up as necessary.
- *Act* on an object.
- *Assert* that something is as expected.

Why?

- Clearly separates what is being tested from the *arrange* and *assert* steps.
- Less chance to intermix assertions with "Act" code.

Readability is one of the most important aspects when writing a test. Separating each of these actions within the test clearly highlight the dependencies required to call your code, how your code is being called, and what you are trying to assert. While it may be possible to combine some steps and reduce the size of your test, the primary goal is to make the test as readable as possible.

Bad:

```
[Fact]
public void Add_EmptyString_ReturnsZero()
{
    // Arrange
    var stringCalculator = new StringCalculator();

    // Assert
    Assert.Equal(0, stringCalculator.Add(""));
}
```

Better:

```
[Fact]
public void Add_EmptyString_ReturnsZero()
{
    // Arrange
    var stringCalculator = new StringCalculator();

    // Act
    var actual = stringCalculator.Add("");

    // Assert
    Assert.Equal(0, actual);
}
```

Write minimally passing tests

The input to be used in a unit test should be the simplest possible in order to verify the behavior that you are currently testing.

Why?

- Tests become more resilient to future changes in the codebase.
- Closer to testing behavior over implementation.

Tests that include more information than required to pass the test have a higher chance of introducing errors into the test and can make the intent of the test less clear. When writing tests you want to focus on the behavior. Setting extra properties on models or using non-zero values when not required, only detracts from what you are trying to prove.

Bad:

```
[Fact]
public void Add_SingleNumber_ReturnsSameNumber()
{
    var stringCalculator = new StringCalculator();

    var actual = stringCalculator.Add("42");

    Assert.Equal(42, actual);
}
```

Better:

```
[Fact]
public void Add_SingleNumber_ReturnsSameNumber()
{
    var stringCalculator = new StringCalculator();

    var actual = stringCalculator.Add("0");

    Assert.Equal(0, actual);
}
```

Avoid magic strings

Naming variables in unit tests is as important, if not more important, than naming variables in production code. Unit tests should not contain magic strings.

Why?

- Prevents the need for the reader of the test to inspect the production code in order to figure out what makes the value special.
- Explicitly shows what you're trying to *prove* rather than trying to *accomplish*.

Magic strings can cause confusion to the reader of your tests. If a string looks out of the ordinary, they may wonder why a certain value was chosen for a parameter or return value. This may lead them to take a closer look at the implementation details, rather than focus on the test.

TIP

When writing tests, you should aim to express as much intent as possible. In the case of magic strings, a good approach is to assign these values to constants.

Bad:

```
[Fact]
public void Add_BigNumber_ThrowsException()
{
    var stringCalculator = new StringCalculator();

    Action actual = () => stringCalculator.Add("1001");

    Assert.Throws<OverflowException>(actual);
}
```

Better:

```

[Fact]
void Add_MaximumSumResult_ThrowsOverflowException()
{
    var stringCalculator = new StringCalculator();
    const string MAXIMUM_RESULT = "1001";

    Action actual = () => stringCalculator.Add(MAXIMUM_RESULT);

    Assert.Throws<OverflowException>(actual);
}

```

Avoid logic in tests

When writing your unit tests avoid manual string concatenation and logical conditions such as `if`, `while`, `for`, `switch`, etc.

Why?

- Less chance to introduce a bug inside of your tests.
- Focus on the end result, rather than implementation details.

When you introduce logic into your test suite, the chance of introducing a bug into it increases dramatically. The last place that you want to find a bug is within your test suite. You should have a high level of confidence that your tests work, otherwise, you will not trust them. Tests that you do not trust, do not provide any value. When a test fails, you want to have a sense that something is actually wrong with your code and that it cannot be ignored.

TIP

If logic in your test seems unavoidable, consider splitting the test up into two or more different tests.

Bad:

```

[Fact]
public void Add_MultipleNumbers_ReturnsCorrectResults()
{
    var stringCalculator = new StringCalculator();
    var expected = 0;
    var testCases = new[]
    {
        "0,0,0",
        "0,1,2",
        "1,2,3"
    };

    foreach (var test in testCases)
    {
        Assert.Equal(expected, stringCalculator.Add(test));
        expected += 3;
    }
}

```

Better:

```
[Theory]
[InlineData("0,0,0", 0)]
[InlineData("0,1,2", 3)]
[InlineData("1,2,3", 6)]
public void Add_MultipleNumbers_ReturnsSumOfNumbers(string input, int expected)
{
    var stringCalculator = new StringCalculator();

    var actual = stringCalculator.Add(input);

    Assert.Equal(expected, actual);
}
```

Prefer helper methods to setup and teardown

If you require a similar object or state for your tests, prefer a helper method than leveraging Setup and Teardown attributes if they exist.

Why?

- Less confusion when reading the tests since all of the code is visible from within each test.
- Less chance of setting up too much or too little for the given test.
- Less chance of sharing state between tests which creates unwanted dependencies between them.

In unit testing frameworks, `Setup` is called before each and every unit test within your test suite. While some may see this as a useful tool, it generally ends up leading to bloated and hard to read tests. Each test will generally have different requirements in order to get the test up and running. Unfortunately, `Setup` forces you to use the exact same requirements for each test.

NOTE

xUnit has removed both SetUp and TearDown as of version 2.x

Bad:

```
private readonly StringCalculator stringCalculator;
public StringCalculatorTests()
{
    stringCalculator = new StringCalculator();
}
```

```
// more tests...
```

```
[Fact]
public void Add_TwoNumbers_ReturnsSumOfNumbers()
{
    var result = stringCalculator.Add("0,1");

    Assert.Equal(1, result);
}
```

Better:

```
[Fact]
public void Add_TwoNumbers_ReturnsSumOfNumbers()
{
    var stringCalculator = CreateDefaultStringCalculator();

    var actual = stringCalculator.Add("0,1");

    Assert.Equal(1, actual);
}
```

```
// more tests...
```

```
private StringCalculator CreateDefaultStringCalculator()
{
    return new StringCalculator();
}
```

Avoid multiple asserts

When writing your tests, try to only include one Assert per test. Common approaches to using only one assert include:

- Create a separate test for each assert.
- Use parameterized tests.

Why?

- If one Assert fails, the subsequent Asserts will not be evaluated.
- Ensures you are not asserting multiple cases in your tests.
- Gives you the entire picture as to why your tests are failing.

When introducing multiple asserts into a test case, it is not guaranteed that all of the asserts will be executed. In most unit testing frameworks, once an assertion fails in a unit test, the proceeding tests are automatically considered to be failing. This can be confusing as functionality that is actually working, will be shown as failing.

NOTE

A common exception to this rule is when asserting against an object. In this case, it is generally acceptable to have multiple asserts against each property to ensure the object is in the state that you expect it to be in.

Bad:

```
[Fact]
public void Add_EdgeCases_ThrowsArgumentExceptions()
{
    Assert.Throws<ArgumentException>(() => stringCalculator.Add(null));
    Assert.Throws<ArgumentException>(() => stringCalculator.Add("a"));
}
```

Better:

```

[Theory]
[InlineData(null)]
[InlineData("a")]
public void Add_InputNullOrEmptyOrAlphabetic_ThrowsArgumentException(string input)
{
    var stringCalculator = new StringCalculator();

    Action actual = () => stringCalculator.Add(input);

    Assert.Throws<ArgumentException>(actual);
}

```

Validate private methods by unit testing public methods

In most cases, there should not be a need to test a private method. Private methods are an implementation detail. You can think of it this way: private methods never exist in isolation. At some point, there is going to be a public facing method that calls the private method as part of its implementation. What you should care about is the end result of the public method that calls into the private one.

Consider the following case

```

public string ParseLogLine(string input)
{
    var sanitizedInput = trimInput(input);
    return sanitizedInput;
}

private string trimInput(string input)
{
    return input.Trim();
}

```

Your first reaction may be to start writing a test for `trimInput` because you want to make sure that the method is working as expected. However, it is entirely possible that `ParseLogLine` manipulates `sanitizedInput` in such a way that you do not expect, rendering a test against `trimInput` useless.

The real test should be done against the public facing method `ParseLogLine` because that is what you should ultimately care about.

```

public void ParseLogLine_ByDefault_ReturnsTrimmedResult()
{
    var parser = new Parser();

    var result = parser.ParseLogLine(" a ");

    Assert.Equals("a", result);
}

```

With this viewpoint, if you see a private method, find the public method and write your tests against that method. Just because a private method returns the expected result, does not mean the system that eventually calls the private method uses the result correctly.

Stub static references

One of the principles of a unit test is that it must have full control of the system under test. This can be problematic when production code includes calls to static references (e.g. `DateTime.Now`). Consider the following code

```

public int GetDiscountedPrice(int price)
{
    if(DateTime.Now == DayOfWeek.Tuesday)
    {
        return price / 2;
    }
    else
    {
        return price;
    }
}

```

How can this code possibly be unit tested? You may try an approach such as

```

public void GetDiscountedPrice_ByDefault_ReturnsFullPrice()
{
    var priceCalculator = new PriceCalculator();

    var actual = priceCalculator.GetDiscountedPrice(2);

    Assert.Equals(2, actual)
}

public void GetDiscountedPrice_OnTuesday_ReturnsHalfPrice()
{
    var priceCalculator = new PriceCalculator();

    var actual = priceCalculator.GetDiscountedPrice(2);

    Assert.Equals(1, actual);
}

```

Unfortunately, you will quickly realize that there are a couple problems with your tests.

- If the test suite is run on a Tuesday, the second test will pass, but the first test will fail.
- If the test suite is run on any other day, the first test will pass, but the second test will fail.

To solve these problems, you'll need to introduce a *seam* into your production code. One approach is to wrap the code that you need to control in an interface and have the production code depend on that interface.

```

public interface IDateTimeProvider
{
    DayOfWeek DayOfWeek();
}

public int GetDiscountedPrice(int price, IDateTimeProvider dateTimeProvider)
{
    if(dateTimeProvider.DayOfWeek() == DayOfWeek.Tuesday)
    {
        return price / 2;
    }
    else
    {
        return price;
    }
}

```

Your test suite now becomes

```
public void GetDiscountedPrice_ByDefault_ReturnsFullPrice()
{
    var priceCalculator = new PriceCalculator();
    var dateTimeProviderStub = new Mock<IDateTimeProvider>();
    dateTimeProviderStub.Setup(dtp => dtp.DayOfWeek()).Returns(DayOfWeek.Monday);

    var actual = priceCalculator.GetDiscountedPrice(2, dateTimeProviderStub);

    Assert.Equals(2, actual);
}

public void GetDiscountedPrice_OnTuesday_ReturnsHalfPrice()
{
    var priceCalculator = new PriceCalculator();
    var dateTimeProviderStub = new Mock<IDateTimeProvider>();
    dateTimeProviderStub.Setup(dtp => dtp.DayOfWeek()).Returns(DayOfWeek.Tuesday);

    var actual = priceCalculator.GetDiscountedPrice(2, dateTimeProviderStub);

    Assert.Equals(1, actual);
}
```

Now the test suite has full control over `DateTime.Now` and can stub any value when calling into the method.

Unit testing C# in .NET Core using dotnet test and xUnit

3/27/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Creating the source project

Open a shell window. Create a directory called *unit-testing-using-dotnet-test* to hold the solution. Inside this new directory, run `dotnet new sln` to create a new solution. Having a solution makes it easier to manage both the class library and the unit test project. Inside the solution directory, create a *PrimeService* directory. The directory and file structure thus far should be as follows:

```
/unit-testing-using-dotnet-test
  unit-testing-using-dotnet-test.sln
    /PrimeService
```

Make *PrimeService* the current directory and run `dotnet new classlib` to create the source project. Rename *Class1.cs* to *PrimeService.cs*. You first create a failing implementation of the `PrimeService` class:

```
using System;

namespace Prime.Services
{
    public class PrimeService
    {
        public bool IsPrime(int candidate)
        {
            throw new NotImplementedException("Please create a test first");
        }
    }
}
```

Change the directory back to the *unit-testing-using-dotnet-test* directory.

Run the `dotnet sln` command to add the class library project to the solution:

```
dotnet sln add ./PrimeService/PrimeService.csproj
```

Creating the test project

Next, create the *PrimeService.Tests* directory. The following outline shows the directory structure:

```
/unit-testing-using-dotnet-test
  unit-testing-using-dotnet-test.sln
  /PrimeService
    Source Files
      PrimeService.csproj
  /PrimeService.Tests
```

Make the `PrimeService.Tests` directory the current directory and create a new project using `dotnet new xunit`. This command creates a test project that uses `xUnit` as the test library. The generated template configures the test runner in the `PrimeServiceTests.csproj` file similar to the following code:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.3.0" />
  <PackageReference Include="xunit" Version="2.2.0" />
  <PackageReference Include="xunit.runner.visualstudio" Version="2.2.0" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added `xUnit` and the `xUnit` runner. Now, add the `PrimeService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../PrimeService/PrimeService.csproj
```

You can see the entire file in the [samples repository](#) on GitHub.

The following shows the final solution layout:

```
/unit-testing-using-dotnet-test
  unit-testing-using-dotnet-test.sln
  /PrimeService
    Source Files
      PrimeService.csproj
  /PrimeService.Tests
    Test Source Files
      PrimeServiceTests.csproj
```

To add the test project to the solution, run the `dotnet sln` command in the `unit-testing-using-dotnet-test` directory:

```
dotnet sln add ./PrimeService.Tests/PrimeService.Tests.csproj
```

Creating the first test

You write one failing test, make it pass, then repeat the process. Remove `UnitTest1.cs` from the `PrimeService.Tests` directory and create a new C# file named `PrimeService_IsPrimeShould.cs`. Add the following code:

```

using Xunit;
using Prime.Services;

namespace Prime.UnitTests.Services
{
    public class PrimeService_IsPrimeShould
    {
        private readonly PrimeService _primeService;

        public PrimeService_IsPrimeShould()
        {
            _primeService = new PrimeService();
        }

        [Fact]
        public void ReturnFalseGivenValueOf1()
        {
            var result = _primeService.IsPrime(1);

            Assert.False(result, "1 should not be prime");
        }
    }
}

```

The `[Fact]` attribute indicates a test method that is run by the test runner. From the `PrimeService.Tests` folder, execute `dotnet test` to build the tests and the class library and then run the tests. The xUnit test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

Your test fails. You haven't created the implementation yet. Make this test pass by writing the simplest code in the `PrimeService` class that works. Replace the existing `IsPrime` method implementation with the following code:

```

public bool IsPrime(int candidate)
{
    if (candidate == 1)
    {
        return false;
    }
    throw new NotImplementedException("Please create a test first");
}

```

In the `PrimeService.Tests` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `PrimeService` project and then for the `PrimeService.Tests` project. After building both projects, it runs this single test. It passes.

Adding more features

Now that you've made one test pass, it's time to write more. There are a few other simple cases for prime numbers: 0, -1. You could add those cases as new tests with the `[Fact]` attribute, but that quickly becomes tedious. There are other xUnit attributes that enable you to write a suite of similar tests:

- `[Theory]` represents a suite of tests that execute the same code but have different input arguments.
- `[InlineData]` attribute specifies values for those inputs.

Instead of creating new tests, apply these two attributes, `[Theory]` and `[InlineData]`, to create a single theory in the `PrimeService_IsPrimeShould.cs` file. The theory is a method that tests several values less than two, which is the lowest prime number:

```
[Theory]
[InlineData(-1)]
[InlineData(0)]
[InlineData(1)]
public void ReturnFalseGivenValuesLessThan2(int value)
{
    var result = _primeService.IsPrime(value);

    Assert.False(result, $"{value} should not be prime");
}
```

Run `dotnet test` again, and two of these tests should fail. To make all of the tests pass, change the `if` clause at the beginning of the `IsPrime` method in the `PrimeService.cs` file:

```
if (candidate < 2)
```

Continue to iterate by adding more tests, more theories, and more code in the main library. You have the [finished version of the tests](#) and the [complete implementation of the library](#).

Unit testing C# with NUnit and .NET Core

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Prerequisites

- [.NET Core 2.1 SDK](#) or later versions.
- A text editor or code editor of your choice.

Creating the source project

Open a shell window. Create a directory called *unit-testing-using-nunit* to hold the solution. Inside this new directory, run the following command to create a new solution file for the class library and the test project:

```
dotnet new sln
```

Next, create a *PrimeService* directory. The following outline shows the directory and file structure so far:

```
/unit-testing-using-nunit
  unit-testing-using-nunit.sln
  /PrimeService
```

Make *PrimeService* the current directory and run the following command to create the source project:

```
dotnet new classlib
```

Rename *Class1.cs* to *PrimeService.cs*. You create a failing implementation of the `PrimeService` class:

```
using System;

namespace Prime.Services
{
    public class PrimeService
    {
        public bool IsPrime(int candidate)
        {
            throw new NotImplementedException("Please create a test first");
        }
    }
}
```

Change the directory back to the *unit-testing-using-nunit* directory. Run the following command to add the class library project to the solution:

```
dotnet sln add PrimeService/PrimeService.csproj
```

Creating the test project

Next, create the `PrimeService.Tests` directory. The following outline shows the directory structure:

```
/unit-testing-using-nunit
  unit-testing-using-nunit.sln
  /PrimeService
    Source Files
    PrimeService.csproj
  /PrimeService.Tests
```

Make the `PrimeService.Tests` directory the current directory and create a new project using the following command:

```
dotnet new nunit
```

The `dotnet new` command creates a test project that uses NUnit as the test library. The generated template configures the test runner in the `PrimeService.Tests.csproj` file:

```
<ItemGroup>
  <PackageReference Include="nunit" Version="3.10.1" />
  <PackageReference Include="NUnit3TestAdapter" Version="3.10.0" />
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.8.0" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added the Microsoft test SDK, the NUnit test framework, and the NUnit test adapter. Now, add the `PrimeService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../PrimeService/PrimeService.csproj
```

You can see the entire file in the [samples repository](#) on GitHub.

The following outline shows the final solution layout:

```
/unit-testing-using-nunit
  unit-testing-using-nunit.sln
  /PrimeService
    Source Files
    PrimeService.csproj
  /PrimeService.Tests
    Test Source Files
    PrimeService.Tests.csproj
```

Execute the following command in the `unit-testing-using-nunit` directory:

```
dotnet sln add ./PrimeService.Tests/PrimeService.Tests.csproj
```

Creating the first test

You write one failing test, make it pass, then repeat the process. In the `PrimeService.Tests` directory, rename the `UnitTest1.cs` file to `PrimeService_IsPrimeShould.cs` and replace its entire contents with the following code:

```

using NUnit.Framework;
using Prime.Services;

namespace Prime.UnitTests.Services
{
    [TestFixture]
    public class PrimeService_IsPrimeShould
    {
        private readonly PrimeService _primeService;

        public PrimeService_IsPrimeShould()
        {
            _primeService = new PrimeService();
        }

        [Test]
        public void ReturnFalseGivenValueOf1()
        {
            var result = _primeService.IsPrime(1);

            Assert.IsFalse(result, "1 should not be prime");
        }
    }
}

```

The `[TestFixture]` attribute denotes a class that contains unit tests. The `[Test]` attribute indicates a method is a test method.

Save this file and execute `dotnet test` to build the tests and the class library and then run the tests. The NUnit test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

Your test fails. You haven't created the implementation yet. Make this test pass by writing the simplest code in the `PrimeService` class that works:

```

public bool IsPrime(int candidate)
{
    if (candidate == 1)
    {
        return false;
    }
    throw new NotImplementedException("Please create a test first");
}

```

In the `unit-testing-using-nunit` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `PrimeService` project and then for the `PrimeService.Tests` project. After building both projects, it runs this single test. It passes.

Adding more features

Now that you've made one test pass, it's time to write more. There are a few other simple cases for prime numbers: 0, -1. You could add new tests with the `[Test]` attribute, but that quickly becomes tedious. There are other NUnit attributes that enable you to write a suite of similar tests. A `[TestCase]` attribute is used to create a suite of tests that execute the same code but have different input arguments. You can use the `[TestCase]` attribute to specify values for those inputs.

Instead of creating new tests, apply this attribute to create a single data driven test. The data driven test is a method that tests several values less than two, which is the lowest prime number:

```
[TestCase(-1)]
[TestCase(0)]
[TestCase(1)]
public void ReturnFalseGivenValuesLessThan2(int value)
{
    var result = _primeService.IsPrime(value);

    Assert.IsFalse(result, $"{value} should not be prime");
}
```

Run `dotnet test`, and two of these tests fail. To make all of the tests pass, change the `if` clause at the beginning of the `Main` method in the `PrimeService.cs` file:

```
if (candidate < 2)
```

Continue to iterate by adding more tests, more theories, and more code in the main library. You have the [finished version of the tests](#) and the [complete implementation of the library](#).

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing C# with MSTest and .NET Core

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Creating the source project

Open a shell window. Create a directory called *unit-testing-using-mstest* to hold the solution. Inside this new directory, run `dotnet new sln` to create a new solution file for the class library and the test project. Next, create a *PrimeService* directory. The following outline shows the directory and file structure thus far:

```
/unit-testing-using-mstest
  unit-testing-using-mstest.sln
  /PrimeService
```

Make *PrimeService* the current directory and run `dotnet new classlib` to create the source project. Rename *Class1.cs* to *PrimeService.cs*. You create a failing implementation of the `PrimeService` class:

```
using System;

namespace Prime.Services
{
    public class PrimeService
    {
        public bool IsPrime(int candidate)
        {
            throw new NotImplementedException("Please create a test first");
        }
    }
}
```

Change the directory back to the *unit-testing-using-mstest* directory. Run

```
dotnet sln add PrimeService/PrimeService.csproj
```

Creating the test project

Next, create the *PrimeService.Tests* directory. The following outline shows the directory structure:

```
/unit-testing-using-mstest
  unit-testing-using-mstest.sln
  /PrimeService
    Source Files
    PrimeService.csproj
  /PrimeService.Tests
```

Make the *PrimeService.Tests* directory the current directory and create a new project using `dotnet new mstest`. The dotnet new command creates a test project that uses MSTest as the test library. The generated template configures the test runner in the *PrimeServiceTests.csproj* file:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.3.0" />
  <PackageReference Include="MSTest.TestAdapter" Version="1.1.18" />
  <PackageReference Include="MSTest.TestFramework" Version="1.1.18" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added the MSTest SDK, the MSTest test framework, and the MSTest runner. Now, add the `PrimeService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../PrimeService/PrimeService.csproj
```

You can see the entire file in the [samples repository](#) on GitHub.

The following outline shows the final solution layout:

```
/unit-testing-using-mstest
  unit-testing-using-mstest.sln
  /PrimeService
    Source Files
    PrimeService.csproj
  /PrimeService.Tests
    Test Source Files
    PrimeServiceTests.csproj
```

Execute `dotnet sln add .\PrimeService.Tests\PrimeService.Tests.csproj` in the `unit-testing-using-mstest` directory.

Creating the first test

You write one failing test, make it pass, then repeat the process. Remove `UnitTest1.cs` from the `PrimeService.Tests` directory and create a new C# file named `PrimeService_IsPrimeShould.cs` with the following content:

```
using Microsoft.VisualStudio.TestTools.UnitTesting;
using Prime.Services;

namespace Prime.UnitTests.Services
{
    [TestClass]
    public class PrimeService_IsPrimeShould
    {
        private readonly PrimeService _primeService;

        public PrimeService_IsPrimeShould()
        {
            _primeService = new PrimeService();
        }

        [TestMethod]
        public void ReturnFalseGivenValueOf1()
        {
            var result = _primeService.IsPrime(1);

            Assert.IsFalse(result, "1 should not be prime");
        }
    }
}
```

The `[TestClass]` attribute denotes a class that contains unit tests. The `[TestMethod]` attribute indicates a method

is a test method.

Save this file and execute `dotnet test` to build the tests and the class library and then run the tests. The MSTest test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

Your test fails. You haven't created the implementation yet. Make this test pass by writing the simplest code in the `PrimeService` class that works:

```
public bool IsPrime(int candidate)
{
    if (candidate == 1)
    {
        return false;
    }
    throw new NotImplementedException("Please create a test first");
}
```

In the `unit-testing-using-mstest` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `PrimeService` project and then for the `PrimeService.Tests` project. After building both projects, it runs this single test. It passes.

Adding more features

Now that you've made one test pass, it's time to write more. There are a few other simple cases for prime numbers: 0, -1. You could add new tests with the `[TestMethod]` attribute, but that quickly becomes tedious. There are other MSTest attributes that enable you to write a suite of similar tests. A `[DataTestMethod]` attribute represents a suite of tests that execute the same code but have different input arguments. You can use the `[DataRow]` attribute to specify values for those inputs.

Instead of creating new tests, apply these two attributes to create a single data driven test. The data driven test is a method that tests several values less than two, which is the lowest prime number:

```
[DataTestMethod]
[DataRow(-1)]
[DataRow(0)]
[DataRow(1)]
public void ReturnFalseGivenValuesLessThan2(int value)
{
    var result = _primeService.IsPrime(value);

    Assert.IsFalse(result, $"{value} should not be prime");
}
```

Run `dotnet test`, and two of these tests fail. To make all of the tests pass, change the `if` clause at the beginning of the method:

```
if (candidate < 2)
```

Continue to iterate by adding more tests, more theories, and more code in the main library. You have the [finished version of the tests](#) and the [complete implementation of the library](#).

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing F# libraries in .NET Core using dotnet test and xUnit

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Creating the source project

Open a shell window. Create a directory called *unit-testing-with-fsharp* to hold the solution. Inside this new directory, run `dotnet new sln` to create a new solution. This makes it easier to manage both the class library and the unit test project. Inside the solution directory, create a *MathService* directory. The directory and file structure thus far is shown below:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
    /MathService
```

Make *MathService* the current directory and run `dotnet new classlib -lang F#` to create the source project. You'll create a failing implementation of the math service:

```
module MyMath =
    let squaresOfOdds xs = raise (System.NotImplementedException("You haven't written a test yet!"))
```

Change the directory back to the *unit-testing-with-fsharp* directory. Run

`dotnet sln add .\MathService\MathService.fsproj` to add the class library project to the solution.

Creating the test project

Next, create the *MathService.Tests* directory. The following outline shows the directory structure:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
    /MathService
      Source Files
        MathService.fsproj
    /MathService.Tests
```

Make the *MathService.Tests* directory the current directory and create a new project using

`dotnet new xunit -lang F#`. This creates a test project that uses xUnit as the test library. The generated template configures the test runner in the *MathServiceTests.fsproj*:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.3.0-preview-20170628-02" />
  <PackageReference Include="xunit" Version="2.2.0" />
  <PackageReference Include="xunit.runner.visualstudio" Version="2.2.0" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added xUnit and the xUnit runner. Now, add the `MathService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../MathService/MathService.fsproj
```

You can see the entire file in the [samples repository](#) on GitHub.

You have the following final solution layout:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
  /MathService
    Source Files
      MathService.fsproj
  /MathService.Tests
    Test Source Files
      MathServiceTests.fsproj
```

Execute `dotnet sln add .\MathService.Tests\MathService.Tests.fsproj` in the *unit-testing-with-fsharp* directory.

Creating the first test

You write one failing test, make it pass, then repeat the process. Open *Tests.fs* and add the following code:

```
[<Fact>]
let ``My test`` () =
    Assert.True(true)

[<Fact>]
let ``Fail every time`` () = Assert.True(false)
```

The `[<Fact>]` attribute denotes a test method that is run by the test runner. From the *unit-testing-with-fsharp*, execute `dotnet test` to build the tests and the class library and then run the tests. The xUnit test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

These two tests show the most basic passing and failing tests. `My test` passes, and `Fail every time` fails. Now, create a test for the `squaresOfOdds` method. The `squaresOfOdds` method returns a sequence of the squares of all odd integer values that are part of the input sequence. Rather than trying to write all of those functions at once, you can iteratively create tests that validate the functionality. Making each test pass means creating the necessary functionality for the method.

The simplest test we can write is to call `squaresOfOdds` with all even numbers, where the result should be an empty sequence of integers. Here's that test:

```
[<Fact>]
let ``Sequence of Evens returns empty collection`` () =
    let expected = Seq.empty<int>
    let actual = MyMath.squaresOfOdds [2; 4; 6; 8; 10]
    Assert.Equal<Collections.Generic.IEnumerable<int>>(expected, actual)
```

Your test fails. You haven't created the implementation yet. Make this test by writing the simplest code in the `MathService` class that works:

```
let squaresOfOdds xs =
    Seq.empty<int>
```

In the `unit-testing-with-fsharp` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `MathService` project and then for the `MathService.Tests` project. After building both projects, it runs this single test. It passes.

Completing the requirements

Now that you've made one test pass, it's time to write more. The next simple case works with a sequence whose only odd number is `1`. The number 1 is easier because the square of 1 is 1. Here's that next test:

```
[<Fact>]
let ``Sequences of Ones and Evens returns Ones`` () =
    let expected = [1; 1; 1; 1]
    let actual = MyMath.squaresOfOdds [2; 1; 4; 1; 6; 1; 8; 1; 10]
    Assert.Equal<Collections.Generic.IEnumerable<int>>(expected, actual)
```

Executing `dotnet test` runs your tests and shows you that the new test fails. Now, update the `squaresOfOdds` method to handle this new test. You filter all the even numbers out of the sequence to make this test pass. You can do that by writing a small filter function and using `Seq.filter`:

```
let private isOdd x = x % 2 <> 0

let squaresOfOdds xs =
    xs
    |> Seq.filter isOdd
```

There's one more step to go: square each of the odd numbers. Start by writing a new test:

```
[<Fact>]
let ``SquaresOfOdds works`` () =
    let expected = [1; 9; 25; 49; 81]
    let actual = MyMath.squaresOfOdds [1; 2; 3; 4; 5; 6; 7; 8; 9; 10]
    Assert.Equal(expected, actual)
```

You can fix the test by piping the filtered sequence through a map operation to compute the square of each odd number:

```
let private square x = x * x
let private isOdd x = x % 2 <> 0

let squaresOfOdds xs =
    xs
    |> Seq.filter isOdd
    |> Seq.map square
```

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing F# libraries in .NET Core using dotnet test and NUnit

2/23/2019 • 5 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Prerequisites

- [.NET Core 2.1 SDK](#) or later versions.
- A text editor or code editor of your choice.

Creating the source project

Open a shell window. Create a directory called *unit-testing-with-fsharp* to hold the solution. Inside this new directory, run the following command to create a new solution file for the class library and the test project:

```
dotnet new sln
```

Next, create a *MathService* directory. The following outline shows the directory and file structure so far:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
  /MathService
```

Make *MathService* the current directory and run the following command to create the source project:

```
dotnet new classlib -lang F#
```

You create a failing implementation of the math service:

```
module MyMath =
    let squaresOfOdds xs = raise (System.NotImplementedException("You haven't written a test yet!"))
```

Change the directory back to the *unit-testing-with-fsharp* directory. Run the following command to add the class library project to the solution:

```
dotnet sln add .\MathService\MathService.fsproj
```

Creating the test project

Next, create the *MathService.Tests* directory. The following outline shows the directory structure:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
  /MathService
    Source Files
      MathService.fsproj
  /MathService.Tests
```

Make the *MathService.Tests* directory the current directory and create a new project using the following command:

```
dotnet new nunit -lang F#
```

This creates a test project that uses NUnit as the test framework. The generated template configures the test runner in the *MathServiceTests.fsproj*:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.5.0" />
  <PackageReference Include="NUnit" Version="3.9.0" />
  <PackageReference Include="NUnit3TestAdapter" Version="3.9.0" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added NUnit and the NUnit test adapter. Now, add the `MathService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../MathService/MathService.fsproj
```

You can see the entire file in the [samples repository](#) on GitHub.

You have the following final solution layout:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
  /MathService
    Source Files
      MathService.fsproj
  /MathService.Tests
    Test Source Files
      MathService.Tests.fsproj
```

Execute the following command in the *unit-testing-with-fsharp* directory:

```
dotnet sln add .\MathService.Tests\MathService.Tests.fsproj
```

Creating the first test

You write one failing test, make it pass, then repeat the process. Open *UnitTest1.fs* and add the following code:

```

namespace MathService.Tests

open System
open NUnit.Framework
open MathService

[<TestFixture>]
type TestClass () =

    [<Test>]
    member this.TestMethodPassing() =
        Assert.True(true)

    [<Test>]
    member this.FailEveryTime() = Assert.True(false)

```

The `[<TestFixture>]` attribute denotes a class that contains tests. The `[<Test>]` attribute denotes a test method that is run by the test runner. From the *unit-testing-with-fsharp* directory, execute `dotnet test` to build the tests and the class library and then run the tests. The NUnit test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

These two tests show the most basic passing and failing tests. `My test` passes, and `Fail every time` fails. Now, create a test for the `squaresOfOdds` method. The `squaresOfOdds` method returns a sequence of the squares of all odd integer values that are part of the input sequence. Rather than trying to write all of those functions at once, you can iteratively create tests that validate the functionality. Making each test pass means creating the necessary functionality for the method.

The simplest test we can write is to call `squaresOfOdds` with all even numbers, where the result should be an empty sequence of integers. Here's that test:

```

[<Test>]
member this.TestEvenSequence() =
    let expected = Seq.empty<int>
    let actual = MyMath.squaresOfOdds [2; 4; 6; 8; 10]
    Assert.That(actual, Is.EqualTo(expected))

```

Notice that the `expected` sequence has been converted to a list. The NUnit framework relies on many standard .NET types. That dependency means that your public interface and expected results support `ICollection` rather than `IEnumerable`.

When you run the test, you see that your test fails. You haven't created the implementation yet. Make this test pass by writing the simplest code in the *Library.fs* class in your MathService project that works:

```

let squaresOfOdds xs =
    Seq.empty<int>

```

In the *unit-testing-with-fsharp* directory, run `dotnet test` again. The `dotnet test` command runs a build for the `MathService` project and then for the `MathService.Tests` project. After building both projects, it runs your tests. Two tests pass now.

Completing the requirements

Now that you've made one test pass, it's time to write more. The next simple case works with a sequence whose only odd number is `1`. The number 1 is easier because the square of 1 is 1. Here's that next test:

```
[<Test>]
member public this.TestOnesAndEvens() =
    let expected = [1; 1; 1; 1]
    let actual = MyMath.squaresOfOdds [2; 1; 4; 1; 6; 1; 8; 1; 10]
    Assert.That(actual, Is.EqualTo(expected))
```

Executing `dotnet test` fails the new test. You must update the `squaresOfOdds` method to handle this new test. You must filter all the even numbers out of the sequence to make this test pass. You can do that by writing a small filter function and using `Seq.filter`:

```
let private isOdd x = x % 2 >> 0

let squaresOfOdds xs =
    xs
    |> Seq.filter isOdd
```

Notice the call to `Seq.toList`. That creates a list, which implements the [ICollection](#) interface.

There's one more step to go: square each of the odd numbers. Start by writing a new test:

```
[<Test>]
member public this.TestSquaresOfOdds() =
    let expected = [1; 9; 25; 49; 81]
    let actual = MyMath.squaresOfOdds [1; 2; 3; 4; 5; 6; 7; 8; 9; 10]
    Assert.That(actual, Is.EqualTo(expected))
```

You can fix the test by piping the filtered sequence through a map operation to compute the square of each odd number:

```
let private square x = x * x
let private isOdd x = x % 2 >> 0

let squaresOfOdds xs =
    xs
    |> Seq.filter isOdd
    |> Seq.map square
```

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing F# libraries in .NET Core using dotnet test and MSTest

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Creating the source project

Open a shell window. Create a directory called *unit-testing-with-fsharp* to hold the solution. Inside this new directory, run `dotnet new sln` to create a new solution. This makes it easier to manage both the class library and the unit test project. Inside the solution directory, create a *MathService* directory. The directory and file structure thus far is shown below:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
    /MathService
```

Make *MathService* the current directory and run `dotnet new classlib -lang F#` to create the source project. You'll create a failing implementation of the math service:

```
module MyMath =
    let squaresOfOdds xs = raise (System.NotImplementedException("You haven't written a test yet!"))
```

Change the directory back to the *unit-testing-with-fsharp* directory. Run

`dotnet sln add .\MathService\MathService.fsproj` to add the class library project to the solution.

Creating the test project

Next, create the *MathService.Tests* directory. The following outline shows the directory structure:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
    /MathService
      Source Files
        MathService.fsproj
    /MathService.Tests
```

Make the *MathService.Tests* directory the current directory and create a new project using

`dotnet new mstest -lang F#`. This creates a test project that uses MSTest as the test framework. The generated template configures the test runner in the *MathServiceTests.fsproj*:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.3.0-preview-20170628-02" />
  <PackageReference Include="MSTest.TestAdapter" Version="1.1.18" />
  <PackageReference Include="MSTest.TestFramework" Version="1.1.18" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added MSTest and the MSTest runner. Now, add the `MathService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../MathService/MathService.fsproj
```

You can see the entire file in the [samples repository](#) on GitHub.

You have the following final solution layout:

```
/unit-testing-with-fsharp
  unit-testing-with-fsharp.sln
  /MathService
    Source Files
    MathService.fsproj
  /MathService.Tests
    Test Source Files
    MathServiceTests.fsproj
```

Execute `dotnet sln add .\MathService.Tests\MathService.Tests.fsproj` in the *unit-testing-with-fsharp* directory.

Creating the first test

You write one failing test, make it pass, then repeat the process. Open *Tests.fs* and add the following code:

```
namespace MathService.Tests

open System
open Microsoft.VisualStudio.TestTools.UnitTesting
open MathService

[<TestClass>]
type TestClass () =

    [<TestMethod>]
    member this.TestMethodPassing() =
        Assert.IsTrue(true)

    [<TestMethod>]
    member this.FailEveryTime() = Assert.IsTrue(false)
```

The `[<TestClass>]` attribute denotes a class that contains tests. The `[<TestMethod>]` attribute denotes a test method that is run by the test runner. From the *unit-testing-with-fsharp* directory, execute `dotnet test` to build the tests and the class library and then run the tests. The MSTest test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

These two tests show the most basic passing and failing tests. `My test` passes, and `Fail every time` fails. Now, create a test for the `squaresOfOdds` method. The `squaresOfOdds` method returns a list of the squares of all odd integer values that are part of the input sequence. Rather than trying to write all of those functions at once, you can iteratively create tests that validate the functionality. Making each test pass means creating the necessary functionality for the method.

The simplest test we can write is to call `squaresOfOdds` with all even numbers, where the result should be an empty sequence of integers. Here's that test:

```
[<TestMethod>]
member this.TestEvenSequence() =
    let expected = Seq.empty<int> |> Seq.toList
    let actual = MyMath.squaresOfOdds [2; 4; 6; 8; 10]
    Assert.AreEqual(expected, actual)
```

Notice that the `expected` sequence has been converted to a list. The MSTest library relies on many standard .NET types. That dependency means that your public interface and expected results support [ICollection](#) rather than [IEnumerable](#).

When you run the test, you see that your test fails. You haven't created the implementation yet. Make this test by writing the simplest code in the `Mathservice` class that works:

```
let squaresOfOdds xs =
    Seq.empty<int> |> Seq.toList
```

In the `unit-testing-with-fsharp` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `MathService` project and then for the `MathService.Tests` project. After building both projects, it runs this single test. It passes.

Completing the requirements

Now that you've made one test pass, it's time to write more. The next simple case works with a sequence whose only odd number is `1`. The number 1 is easier because the square of 1 is 1. Here's that next test:

```
[<TestMethod>]
member public this.TestOnesAndEvens() =
    let expected = [1; 1; 1; 1]
    let actual = MyMath.squaresOfOdds [2; 1; 4; 1; 6; 1; 8; 1; 10]
    Assert.AreEqual(expected, actual)
```

Executing `dotnet test` fails the new test. You must update the `squaresOfOdds` method to handle this new test. You must filter all the even numbers out of the sequence to make this test pass. You can do that by writing a small filter function and using `Seq.filter`:

```
let private isOdd x = x % 2 <> 0

let squaresOfOdds xs =
    xs
    |> Seq.filter isOdd |> Seq.toList
```

Notice the call to `Seq.toList`. That creates a list, which implements the [ICollection](#) interface.

There's one more step to go: square each of the odd numbers. Start by writing a new test:

```
[<TestMethod>]
member public this.TestSquaresOfOdds() =
    let expected = [1; 9; 25; 49; 81]
    let actual = MyMath.squaresOfOdds [1; 2; 3; 4; 5; 6; 7; 8; 9; 10]
    Assert.AreEqual(expected, actual)
```

You can fix the test by piping the filtered sequence through a map operation to compute the square of each odd number:

```
let private square x = x * x
let private isOdd x = x % 2 <> 0

let squaresOfOdds xs =
    xs
    |> Seq.filter isOdd
    |> Seq.map square
    |> Seq.toList
```

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing Visual Basic .NET Core libraries using dotnet test and xUnit

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Creating the source project

Open a shell window. Create a directory called `unit-testing-vb-using-dotnet-test` to hold the solution. Inside this new directory, run `dotnet new sln` to create a new solution. This practice makes it easier to manage both the class library and the unit test project. Inside the solution directory, create a `PrimeService` directory. You have the following directory and file structure thus far:

```
/unit-testing-using-dotnet-test
  unit-testing-using-dotnet-test.sln
    /PrimeService
```

Make `PrimeService` the current directory and run `dotnet new classlib -lang VB` to create the source project.

Rename `Class1.VB` to `PrimeService.VB`. You create a failing implementation of the `PrimeService` class:

```
Namespace Prime.Services
  Public Class PrimeService
    Public Function IsPrime(candidate As Integer) As Boolean
      Throw New NotImplementedException("Please create a test first")
    End Function
  End Class
End Namespace
```

Change the directory back to the `unit-testing-vb-using-dotnet-test` directory. Run

`dotnet sln add .\PrimeService\PrimeService.vbproj` to add the class library project to the solution.

Creating the test project

Next, create the `PrimeService.Tests` directory. The following outline shows the directory structure:

```
/unit-testing-vb-using-dotnet-test
  unit-testing-vb-using-dotnet-test.sln
  /PrimeService
    Source Files
    PrimeService.vbproj
  /PrimeService.Tests
```

Make the `PrimeService.Tests` directory the current directory and create a new project using

`dotnet new xunit -lang VB`. This command creates a test project that uses xUnit as the test library. The generated template configures the test runner in the `PrimeServiceTests.vbproj`:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.3.0-preview-20170628-02" />
  <PackageReference Include="xunit" Version="2.2.0" />
  <PackageReference Include="xunit.runner.visualstudio" Version="2.2.0" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added xUnit and the xUnit runner. Now, add the `PrimeService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../PrimeService/PrimeService.vbproj
```

You can see the entire file in the [samples repository](#) on GitHub.

You have the following final folder layout:

```
/unit-testing-using-dotnet-test
  unit-testing-using-dotnet-test.sln
  /PrimeService
    Source Files
    PrimeService.vbproj
  /PrimeService.Tests
    Test Source Files
    PrimeServiceTests.vbproj
```

Execute `dotnet sln add .\PrimeService.Tests\PrimeService.Tests.vbproj` in the *unit-testing-vb-using-dotnet-test* directory.

Creating the first test

You write one failing test, make it pass, then repeat the process. Remove *UnitTest1.vb* from the *PrimeService.Tests* directory and create a new Visual Basic file named *PrimeService_IsPrimeShould.VB*. Add the following code:

```
Imports Xunit

Namespace PrimeService.Tests
  Public Class PrimeService_IsPrimeShould
    Private _primeService As Prime.Services.PrimeService = New Prime.Services.PrimeService()

    <Fact>
    Sub ReturnFalseGivenValueOf1()
      Dim result As Boolean = _primeService.IsPrime(1)

      Assert.False(result, "1 should not be prime")
    End Sub

  End Class
End Namespace
```

The `<Fact>` attribute denotes a test method that is run by the test runner. From the *unit-testing-using-dotnet-test*, execute `dotnet test` to build the tests and the class library and then run the tests. The xUnit test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

Your test fails. You haven't created the implementation yet. Make this test by writing the simplest code in the `PrimeService` class that works:

```

Public Function IsPrime(candidate As Integer) As Boolean
    If candidate = 1 Then
        Return False
    End If
    Throw New NotImplementedException("Please create a test first")
End Function

```

In the `unit-testing-vb-using-dotnet-test` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `PrimeService` project and then for the `PrimeService.Tests` project. After building both projects, it runs this single test. It passes.

Adding more features

Now that you've made one test pass, it's time to write more. There are a few other simple cases for prime numbers: 0, -1. You could add those cases as new tests with the `<Fact>` attribute, but that quickly becomes tedious. There are other xUnit attributes that enable you to write a suite of similar tests. A `<Theory>` attribute represents a suite of tests that execute the same code but have different input arguments. You can use the `<InlineData>` attribute to specify values for those inputs.

Instead of creating new tests, apply these two attributes to create a single theory. The theory is a method that tests several values less than two, which is the lowest prime number:

```

Public Class PrimeService_IsPrimeShould
    Private _primeService As Prime.Services.PrimeService = New Prime.Services.PrimeService()

    <Theory>
    <InlineData(-1)>
    <InlineData(0)>
    <InlineData(1)>
    Sub ReturnFalseGivenValuesLessThan2(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.False(result, $"{value} should not be prime")
    End Sub

    <Theory>
    <InlineData(2)>
    <InlineData(3)>
    <InlineData(5)>
    <InlineData(7)>
    Public Sub ReturnTrueGivenPrimesLessThan10(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.True(result, $"{value} should be prime")
    End Sub

    <Theory>
    <InlineData(4)>
    <InlineData(6)>
    <InlineData(8)>
    <InlineData(9)>
    Public Sub ReturnFalseGivenNonPrimesLessThan10(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.False(result, $"{value} should not be prime")
    End Sub
End Class

```

Run `dotnet test`, and two of these tests fail. To make all of the tests pass, change the `if` clause at the beginning of the method:

```
if candidate < 2
```

Continue to iterate by adding more tests, more theories, and more code in the main library. You have the [finished version of the tests](#) and the [complete implementation of the library](#).

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing Visual Basic .NET Core libraries using dotnet test and NUnit

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Prerequisites

- [.NET Core 2.1 SDK](#) or later versions.
- A text editor or code editor of your choice.

Creating the source project

Open a shell window. Create a directory called *unit-testing-vb-nunit* to hold the solution. Inside this new directory, run the following command to create a new solution file for the class library and the test project:

```
dotnet new sln
```

Next, create a *PrimeService* directory. The following outline shows the file structure so far:

```
/unit-testing-vb-nunit
    unit-testing-vb-nunit.sln
    /PrimeService
```

Make *PrimeService* the current directory and run the following command to create the source project:

```
dotnet new classlib -lang VB
```

Rename *Class1.VB* to *PrimeService.VB*. You create a failing implementation of the `PrimeService` class:

```
Imports System

Namespace Prime.Services
    Public Class PrimeService
        Public Function IsPrime(candidate As Integer) As Boolean
            Throw New NotImplementedException("Please create a test first")
        End Function
    End Class
End Namespace
```

Change the directory back to the *unit-testing-vb-using-stest* directory. Run the following command to add the class library project to the solution:

```
dotnet sln add .\PrimeService\PrimeService.vbproj
```

Creating the test project

Next, create the `PrimeService.Tests` directory. The following outline shows the directory structure:

```
/unit-testing-vb-nunit
  unit-testing-vb-nunit.sln
  /PrimeService
    Source Files
    PrimeService.vbproj
  /PrimeService.Tests
```

Make the `PrimeService.Tests` directory the current directory and create a new project using the following command:

```
dotnet new nunit -lang VB
```

The `dotnet new` command creates a test project that uses NUnit as the test library. The generated template configures the test runner in the `PrimeServiceTests.vbproj` file:

```
<ItemGroup>
  <PackageReference Include="nunit" Version="3.10.1" />
  <PackageReference Include="NUnit3TestAdapter" Version="3.10.0" />
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.8.0" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added NUnit and the NUnit test adapter. Now, add the `PrimeService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../PrimeService/PrimeService.vbproj
```

You can see the entire file in the [samples repository](#) on GitHub.

You have the following final solution layout:

```
/unit-testing-vb-nunit
  unit-testing-vb-nunit.sln
  /PrimeService
    Source Files
    PrimeService.vbproj
  /PrimeService.Tests
    Test Source Files
    PrimeService.Tests.vbproj
```

Execute the following command in the `unit-testing-vb-nunit` directory:

```
dotnet sln add .\PrimeService.Tests\PrimeService.Tests.vbproj
```

Creating the first test

You write one failing test, make it pass, then repeat the process. In the `PrimeService.Tests` directory, rename the `UnitTest1.vb` file to `PrimeService_IsPrimeShould.VB` and replace its entire contents with the following code:

```

Imports NUnit.Framework

Namespace PrimeService.Tests
    <TestFixture>
    Public Class PrimeService_IsPrimeShould
        Private _primeService As Prime.Services.PrimeService = New Prime.Services.PrimeService()

        <Test>
        Sub ReturnFalseGivenValueOf1()
            Dim result As Boolean = _primeService.IsPrime(1)

            Assert.False(result, "1 should not be prime")
        End Sub

    End Class
End Namespace

```

The `<TestFixture>` attribute indicates a class that contains tests. The `<Test>` attribute denotes a method that is run by the test runner. From the `unit-testing-vb-nunit`, execute `dotnet test` to build the tests and the class library and then run the tests. The NUnit test runner contains the program entry point to run your tests. `dotnet test` starts the test runner using the unit test project you've created.

Your test fails. You haven't created the implementation yet. Make this test by writing the simplest code in the `PrimeService` class that works:

```

Public Function IsPrime(candidate As Integer) As Boolean
    If candidate = 1 Then
        Return False
    End If
    Throw New NotImplementedException("Please create a test first")
End Function

```

In the `unit-testing-vb-nunit` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `PrimeService` project and then for the `PrimeService.Tests` project. After building both projects, it runs this single test. It passes.

Adding more features

Now that you've made one test pass, it's time to write more. There are a few other simple cases for prime numbers: 0, -1. You could add those cases as new tests with the `<Test>` attribute, but that quickly becomes tedious. There are other xUnit attributes that enable you to write a suite of similar tests. A `<TestCase>` attribute represents a suite of tests that execute the same code but have different input arguments. You can use the `<TestCase>` attribute to specify values for those inputs.

Instead of creating new tests, apply these two attributes to create a series of tests that test several values less than two, which is the lowest prime number:

```

<TestFixture>
Public Class PrimeService_IsPrimeShould
    Private _primeService As Prime.Services.PrimeService = New Prime.Services.PrimeService()

    <TestCase(-1)>
    <TestCase(0)>
    <TestCase(1)>
    Sub ReturnFalseGivenValuesLessThan2(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.IsFalse(result, $"{value} should not be prime")
    End Sub

    <TestCase(2)>
    <TestCase(3)>
    <TestCase(5)>
    <TestCase(7)>
    Public Sub ReturnTrueGivenPrimesLessThan10(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.IsTrue(result, $"{value} should be prime")
    End Sub

    <TestCase(4)>
    <TestCase(6)>
    <TestCase(8)>
    <TestCase(9)>
    Public Sub ReturnFalseGivenNonPrimesLessThan10(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.IsFalse(result, $"{value} should not be prime")
    End Sub
End Class

```

Run `dotnet test`, and two of these tests fail. To make all of the tests pass, change the `if` clause at the beginning of the `Main` method in the `PrimeServices.cs` file:

```
if candidate < 2
```

Continue to iterate by adding more tests, more theories, and more code in the main library. You have the [finished version of the tests](#) and the [complete implementation of the library](#).

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Unit testing Visual Basic .NET Core libraries using dotnet test and MStest

2/23/2019 • 4 minutes to read • [Edit Online](#)

This tutorial takes you through an interactive experience building a sample solution step-by-step to learn unit testing concepts. If you prefer to follow the tutorial using a pre-built solution, [view or download the sample code](#) before you begin. For download instructions, see [Samples and Tutorials](#).

Creating the source project

Open a shell window. Create a directory called *unit-testing-vb-mstest* to hold the solution. Inside this new directory, run `dotnet new sln` to create a new solution. This practice makes it easier to manage both the class library and the unit test project. Inside the solution directory, create a *PrimeService* directory. You have the following directory and file structure thus far:

```
/unit-testing-vb-mstest
  unit-testing-vb-mstest.sln
  /PrimeService
```

Make *PrimeService* the current directory and run `dotnet new classlib -lang VB` to create the source project. Rename *Class1.VB* to *PrimeService.VB*. You create a failing implementation of the `PrimeService` class:

```
Imports System

Namespace Prime.Services
    Public Class PrimeService
        Public Function IsPrime(candidate As Integer) As Boolean
            Throw New NotImplementedException("Please create a test first")
        End Function
    End Class
End Namespace
```

Change the directory back to the *unit-testing-vb-using-stest* directory. Run `dotnet sln add .\PrimeService\PrimeService.vbproj` to add the class library project to the solution.

Creating the test project

Next, create the *PrimeService.Tests* directory. The following outline shows the directory structure:

```
/unit-testing-vb-mstest
  unit-testing-vb-mstest.sln
  /PrimeService
    Source Files
    PrimeService.vbproj
  /PrimeService.Tests
```

Make the *PrimeService.Tests* directory the current directory and create a new project using `dotnet new mstest -lang VB`. This command creates a test project that uses MSTest as the test library. The generated template configures the test runner in the *PrimeServiceTests.vbproj*:

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.5.0" />
  <PackageReference Include="MSTest.TestAdapter" Version="1.1.18" />
  <PackageReference Include="MSTest.TestFramework" Version="1.1.18" />
</ItemGroup>
```

The test project requires other packages to create and run unit tests. `dotnet new` in the previous step added MSTest and the MSTest runner. Now, add the `PrimeService` class library as another dependency to the project. Use the `dotnet add reference` command:

```
dotnet add reference ../PrimeService/PrimeService.vbproj
```

You can see the entire file in the [samples repository](#) on GitHub.

You have the following final solution layout:

```
/unit-testing-vb-mstest
  unit-testing-vb-mstest.sln
  /PrimeService
    Source Files
    PrimeService.vbproj
  /PrimeService.Tests
    Test Source Files
    PrimeServiceTests.vbproj
```

Execute `dotnet sln add .\PrimeService.Tests\PrimeService.Tests.vbproj` in the `unit-testing-vb-mstest` directory.

Creating the first test

You write one failing test, make it pass, then repeat the process. Remove `UnitTest1.vb` from the `PrimeService.Tests` directory and create a new Visual Basic file named `PrimeService_IsPrimeShould.VB`. Add the following code:

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting

Namespace PrimeService.Tests
  <TestClass>
  Public Class PrimeService_IsPrimeShould
    Private _primeService As Prime.Services.PrimeService = New Prime.Services.PrimeService()

    <TestMethod>
    Sub ReturnFalseGivenValueOf1()
      Dim result As Boolean = _primeService.IsPrime(1)

      Assert.False(result, "1 should not be prime")
    End Sub

  End Class
End Namespace
```

The `<TestClass>` attribute indicates a class that contains tests. The `<TestMethod>` attribute denotes a method that is run by the test runner. From the `unit-testing-vb-mstest`, execute `dotnet test` to build the tests and the class library and then run the tests. The MSTest test runner contains the program entry point to run your tests.

`dotnet test` starts the test runner using the unit test project you've created.

Your test fails. You haven't created the implementation yet. Make this test by writing the simplest code in the `PrimeService` class that works:

```

Public Function IsPrime(candidate As Integer) As Boolean
    If candidate = 1 Then
        Return False
    End If
    Throw New NotImplementedException("Please create a test first")
End Function

```

In the `unit-testing-vb-mstest` directory, run `dotnet test` again. The `dotnet test` command runs a build for the `PrimeService` project and then for the `PrimeService.Tests` project. After building both projects, it runs this single test. It passes.

Adding more features

Now that you've made one test pass, it's time to write more. There are a few other simple cases for prime numbers: 0, -1. You could add those cases as new tests with the `<TestMethod>` attribute, but that quickly becomes tedious. There are other MSTest attributes that enable you to write a suite of similar tests. A `<DataTestMethod>` attribute represents a suite of tests that execute the same code but have different input arguments. You can use the `<DataRow>` attribute to specify values for those inputs.

Instead of creating new tests, apply these two attributes to create a single theory. The theory is a method that tests several values less than two, which is the lowest prime number:

```

<TestClass>
Public Class PrimeService_IsPrimeShould
    Private _primeService As Prime.Services.PrimeService = New Prime.Services.PrimeService()

    <DataTestMethod>
    <DataRow(-1)>
    <DataRow(0)>
    <DataRow(1)>
    Sub ReturnFalseGivenValuesLessThan2(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.IsFalse(result, $"{value} should not be prime")
    End Sub

    <DataTestMethod>
    <DataRow(2)>
    <DataRow(3)>
    <DataRow(5)>
    <DataRow(7)>
    Public Sub ReturnTrueGivenPrimesLessThan10(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.IsTrue(result, $"{value} should be prime")
    End Sub

    <DataTestMethod>
    <DataRow(4)>
    <DataRow(6)>
    <DataRow(8)>
    <DataRow(9)>
    Public Sub ReturnFalseGivenNonPrimesLessThan10(value As Integer)
        Dim result As Boolean = _primeService.IsPrime(value)

        Assert.IsFalse(result, $"{value} should not be prime")
    End Sub
End Class

```

Run `dotnet test`, and two of these tests fail. To make all of the tests pass, change the `if` clause at the beginning of the method:

```
if candidate < 2
```

Continue to iterate by adding more tests, more theories, and more code in the main library. You have the [finished version of the tests](#) and the [complete implementation of the library](#).

You've built a small library and a set of unit tests for that library. You've structured the solution so that adding new packages and tests is part of the normal workflow. You've concentrated most of your time and effort on solving the goals of the application.

Running selective unit tests

3/1/2019 • 2 minutes to read • [Edit Online](#)

With the `dotnet test` command in .NET Core, you can use a filter expression to run selective tests. This article demonstrates how to filter which tests are run. The following examples use `dotnet test`. If you're using `vstest.console.exe`, replace `--filter` with `--testcasefilter:`.

MSTest

```
using Microsoft.VisualStudio.TestTools.UnitTesting;

namespace MSTestNamespace
{
    [TestClass]
    public class UnitTest1
    {
        [TestCategory("CategoryA")]
        [Priority(1)]
        [TestMethod]
        public void TestMethod1()
        {
        }

        [Priority(2)]
        [TestMethod]
        public void TestMethod2()
        {
        }
    }
}
```

EXPRESSION	RESULT
<code>dotnet test --filter Method</code>	Runs tests whose <code>FullyQualifiedName</code> contains <code>Method</code> . Available in <code>vstest 15.1+</code> .
<code>dotnet test --filter Name~TestMethod1</code>	Runs tests whose name contains <code>TestMethod1</code> .
<code>dotnet test --filter ClassName=MSTestNamespace.UnitTest1</code>	Runs tests which are in class <code>MSTestNamespace.UnitTest1</code> . Note: The <code>ClassName</code> value should have a namespace, so <code>ClassName=UnitTest1</code> won't work.
<code>dotnet test --filter FullyQualifiedName!=MSTestNamespace.UnitTest1.TestMethod1</code>	Runs all tests except <code>MSTestNamespace.UnitTest1.TestMethod1</code> .
<code>dotnet test --filter TestCategory=CategoryA</code>	Runs tests which are annotated with <code>[TestCategory("CategoryA")]</code> .
<code>dotnet test --filter Priority=2</code>	Runs tests which are annotated with <code>[Priority(2)]</code> .

Using conditional operators | and &

EXPRESSION	RESULT
<code>dotnet test --filter "FullyQualifiedName~UnitTest1 TestCategory=CategoryA"</code>	Runs tests which have <code>UnitTest1</code> in <code>FullyQualifiedName</code> or <code>TestCategory</code> is <code>CategoryA</code> .
<code>dotnet test --filter "FullyQualifiedName~UnitTest1&TestCategory=CategoryA"</code>	Runs tests which have <code>UnitTest1</code> in <code>FullyQualifiedName</code> and <code>TestCategory</code> is <code>CategoryA</code> .
<code>dotnet test --filter "(FullyQualifiedName~UnitTest1&TestCategory=CategoryA) Priority=1"</code>	Runs tests which have either <code>FullyQualifiedName</code> containing <code>UnitTest1</code> and <code>TestCategory</code> is <code>CategoryA</code> or <code>Priority</code> is 1.

xUnit

```
using Xunit;

namespace XUnitNamespace
{
    public class TestClass1
    {
        [Trait("Category", "CategoryA")]
        [Trait("Priority", "1")]
        [Fact]
        public void Test1()
        {
        }

        [Trait("Priority", "2")]
        [Fact]
        public void Test2()
        {
        }
    }
}
```

EXPRESSION	RESULT
<code>dotnet test --filter DisplayName=XUnitNamespace.TestClass1.Test1</code>	Runs only one test, <code>XUnitNamespace.TestClass1.Test1</code> .
<code>dotnet test --filter FullyQualifiedName!=XUnitNamespace.TestClass1.Test1</code>	Runs all tests except <code>XUnitNamespace.TestClass1.Test1</code> .
<code>dotnet test --filter DisplayName~TestClass1</code>	Runs tests whose display name contains <code>TestClass1</code> .

In the code example, the defined traits with keys `Category` and `Priority` can be used for filtering.

EXPRESSION	RESULT
<code>dotnet test --filter XUnit</code>	Runs tests whose <code>FullyQualifiedName</code> contains <code>XUnit</code> . Available in <code>vstest 15.1+</code> .
<code>dotnet test --filter Category=CategoryA</code>	Runs tests which have <code>[Trait("Category", "CategoryA")]</code> .

Using conditional operators | and &

EXPRESSION	RESULT
<code>dotnet test --filter "FullyQualifiedName~TestClass1 Category=CategoryA"</code>	Runs tests which has <code>TestClass1</code> in <code>FullyQualifiedName</code> or <code>Category</code> is <code>CategoryA</code> .
<code>dotnet test --filter "FullyQualifiedName~TestClass1&Category=CategoryA"</code>	Runs tests which has <code>TestClass1</code> in <code>FullyQualifiedName</code> and <code>Category</code> is <code>CategoryA</code> .
<code>dotnet test --filter "(FullyQualifiedName~TestClass1&Category=CategoryA) Priority=1"</code>	Runs tests which have either <code>FullyQualifiedName</code> containing <code>TestClass1</code> and <code>Category</code> is <code>CategoryA</code> or <code>Priority</code> is 1.

NUnit

```
using NUnit.Framework;

namespace NUnitNamespace
{
    public class UnitTest1
    {
        [Category("CategoryA")]
        [Property("Priority", 1)]
        [Test]
        public void TestMethod1()
        {

        }

        [Property("Priority", 2)]
        [Test]
        public void TestMethod2()
        {
        }
    }
}
```

EXPRESSION	RESULT
<code>dotnet test --filter Method</code>	Runs tests whose <code>FullyQualifiedName</code> contains <code>Method</code> . Available in <code>vstest 15.1+</code> .
<code>dotnet test --filter Name~TestMethod1</code>	Runs tests whose name contains <code>TestMethod1</code> .
<code>dotnet test --filter FullyQualifiedName~NUnitNamespace.UnitTest1</code>	Runs tests which are in class <code>NUnitNamespace.UnitTest1</code> .
<code>dotnet test --filter FullyQualifiedName!=NUnitNamespace.UnitTest1.TestMethod1</code>	Runs all tests except <code>NUnitNamespace.UnitTest1.TestMethod1</code> .
<code>dotnet test --filterTestCategory=CategoryA</code>	Runs tests which are annotated with <code>[Category("CategoryA")]</code> .
<code>dotnet test --filter Priority=2</code>	Runs tests which are annotated with <code>[Priority(2)]</code> .

Using conditional operators | and &

EXPRESSION	RESULT
<code>dotnet test --filter "FullyQualifiedName~UnitTest1 TestCategory=CategoryA"</code>	Runs tests which have <code>UnitTest1</code> in <code>FullyQualifiedName</code> or <code>TestCategory</code> is <code>CategoryA</code> .
<code>dotnet test --filter "FullyQualifiedName~UnitTest1&TestCategory=CategoryA"</code>	Runs tests which have <code>UnitTest1</code> in <code>FullyQualifiedName</code> and <code>TestCategory</code> is <code>CategoryA</code> .
<code>dotnet test --filter "(FullyQualifiedName~UnitTest1&TestCategory=CategoryA) Priority=1"</code>	Runs tests which have either <code>FullyQualifiedName</code> containing <code>UnitTest1</code> and <code>TestCategory</code> is <code>CategoryA</code> or <code>Priority</code> is 1.

Test published output with dotnet vstest

12/11/2018 • 2 minutes to read • [Edit Online](#)

You can run tests on already published output by using the `dotnet vstest` command. This will work on xUnit, MSTest, and NUnit tests. Simply locate the DLL file that was part of your published output and run:

```
dotnet vstest <MyPublishedTests>.dll
```

Where `<MyPublishedTests>` is the name of your published test project.

Example

The commands below demonstrate running tests on a published DLL.

```
dotnet new mstest -o MyProject.Tests
cd MyProject.Tests
dotnet publish -o out
dotnet vstest out/MyProject.Tests.dll
```

NOTE

Note: If your app is targeting a framework other than `netcoreapp` you can still run the `dotnet vstest` command by passing in the targeted framework with a framework flag. For example,

```
dotnet vstest <MyPublishedTests>.dll --Framework:".NETFramework,Version=v4.6" . In Visual Studio 2017 Update 5  
the desired framework is automatically detected.
```

Overview of how .NET Core is versioned

1/23/2019 • 4 minutes to read • [Edit Online](#)

.NET Core refers to the .NET Core Runtime and the .NET Core SDK, which contains the tools you need to develop applications. .NET Core SDKs are designed to work with any previous version of the .NET Core Runtime. This article explains the runtime and the SDK version strategy. An explanation of version numbers for .NET Standard can be found in the article introducing [.NET Standard](#).

The .NET Core Runtime and .NET Core SDK add new features at a different rate - in general the .NET Core SDK provides updated tools more quickly than the .NET Core Runtime changes the runtime you use in production.

Versioning details

".NET Core 2.1" refers to the .NET Core Runtime version number. The .NET Core Runtime has a major/minor/patch approach to versioning that follows [semantic versioning](#).

The .NET Core SDK doesn't follow semantic versioning. The .NET Core SDK releases faster and its versions must communicate both the aligned runtime and the SDK's own minor and patch releases. The first two positions of the .NET Core SDK version are locked to the .NET Core Runtime it released with. Each version of the SDK can create applications for this runtime or any lower version.

The third position of the SDK version number communicates both the minor and patch number. The minor version is multiplied by 100. Minor version 1, patch version 2 would be represented as 102. The final two digits represent the patch number. For example, the release of .NET Core 2.2 may create releases like the following table:

CHANGE	.NET CORE RUNTIME	.NET CORE SDK (*)
Initial release	2.2.0	2.2.100
SDK Patch	2.2.0	2.2.101
Runtime and SDK Patch	2.2.1	2.2.102
SDK Feature change	2.2.1	2.2.200

(*) This chart uses a future 2.2 .NET Core Runtime as the example because a historic artifact meant the first SDK for .NET Core 2.1 is 2.1.300. For more information, See the [.NET Core version selection](#).

NOTES:

- If the SDK has 10 feature updates before a runtime feature update, version numbers roll into the 1000 series with numbers like 2.2.1000 as the feature release following 2.2.900. This situation isn't expected to occur.
- 99 patch releases without a feature release won't occur. If a release approaches this number, it forces a feature release.

You can see more details in the initial proposal at the [dotnet/designs](#) repository.

Semantic versioning

The .NET Core Runtime roughly adheres to [Semantic Versioning \(SemVer\)](#), adopting the use of `MAJOR.MINOR.PATCH` versioning, using the various parts of the version number to describe the degree and type of change.

`MAJOR.MINOR.PATCH[-PRERELEASE-BUILDSNUMBER]`

The optional `PRERELEASE` and `BUILDSNUMBER` parts are never part of supported releases and only exist on nightly builds, local builds from source targets, and unsupported preview releases.

Understand runtime version number changes

`MAJOR` is incremented when:

- Significant changes occur to the product, or a new product direction.
- Breaking changes were taken. There's a high bar to accepting breaking changes.
- An old version is no longer supported.
- A newer `MAJOR` version of an existing dependency is adopted.

`MINOR` is incremented when:

- Public API surface area is added.
- A new behavior is added.
- A newer `MINOR` version of an existing dependency is adopted.
- A new dependency is introduced.

`PATCH` is incremented when:

- Bug fixes are made.
- Support for a newer platform is added.
- A newer `PATCH` version of an existing dependency is adopted.
- Any other change doesn't fit one of the previous cases.

When there are multiple changes, the highest element affected by individual changes is incremented, and the following ones are reset to zero. For example, when `MAJOR` is incremented, `MINOR` and `PATCH` are reset to zero. When `MINOR` is incremented, `PATCH` is reset to zero while `MAJOR` is left untouched.

Version numbers in file names

The files downloaded for .NET Core carry the version, for example, `dotnet-sdk-2.1.300-win10-x64.exe`.

Preview versions

Preview versions have a `-preview[number]-([build]|"final")` appended to the version. For example, `2.0.0-preview1-final`.

Servicing versions

After a release goes out, the release branches generally stop producing daily builds and instead start producing servicing builds. Servicing versions have a `-servicing-[number]` appended to the version. For example, `2.0.1-servicing-006924`.

Relationship to .NET Standard versions

.NET Standard consists of a .NET reference assembly. There are multiple implementations specific to each platform. The reference assembly contains the definition of .NET APIs which are part of a given .NET Standard version. Each implementation fulfills the .NET Standard contract on the specific platform. You can learn more about .NET Standard in the article on [.NET Standard](#) in the .NET Guide.

The .NET Standard reference assembly uses a `MAJOR.MINOR` versioning scheme. `PATCH` level isn't useful for .NET Standard because it exposes only an API specification (no implementation) and by definition any change to the

API would represent a change in the feature set, and thus a new **MINOR** version.

The implementations on each platform may be updated, typically as part of the platform release, and thus not evident to the programmers using .NET Standard on that platform.

Each version of .NET Core implements a version of .NET Standard. Implementing a version of .NET Standard implies support for previous versions of .NET Standard. .NET Standard and .NET Core version independently. It's a coincidence that .NET Core 2.0 implements .NET Standard 2.0. .NET Core 2.1 also implements .NET Standard 2.0. .NET Core will support future versions of .NET Standard as they become available.

.NET CORE	.NET STANDARD
1.0	up to 1.6
2.0	up to 2.0
2.1	up to 2.0

Select the .NET Core version to use

12/7/2018 • 5 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.0 SDK and later versions

This article explains the policies used by the .NET Core tools, SDK, and runtime for selecting versions. These policies provide a balance between running applications using the specified versions and enabling ease of upgrading both developer and end-user machines. These policies perform the following actions:

- Easy and efficient deployment of .NET Core, including security and reliability updates.
- Use the latest tools and commands independent of target runtime.

Version selection occurs:

- When you run an SDK command, [the SDK uses the latest installed version](#).
- When you build an assembly, [target framework monikers define build time APIs](#).
- When you run a .NET Core application, [target framework dependent apps roll forward](#).
- When you publish a self-contained application, [self-contained deployments include the selected runtime](#).

The rest of this document examines those four scenarios.

The SDK uses the latest installed version

SDK commands include `dotnet new` and `dotnet run`. The .NET Core CLI must choose an SDK version for every `dotnet` command. It uses the latest SDK installed on the machine by default, even if:

- The project targets an earlier version of the .NET Core runtime.
- The latest version of the .NET Core SDK is a preview version.

You can take advantage of the latest SDK features and improvements while targeting earlier .NET Core runtime versions. You can target multiple runtime versions of .NET Core on different projects, using the same SDK tools for all projects.

On rare occasions, you may need to use an earlier version of the SDK. You specify that version in a [*global.json* file](#). The "use latest" policy means you only use *global.json* to specify a .NET Core SDK version earlier than the latest installed version.

global.json can be placed anywhere in the file hierarchy. The CLI searches upward from the project directory for the first *global.json* it finds. You control which projects a given *global.json* applies to by its place in the file system. The .NET CLI searches for a *global.json* file iteratively navigating the path upward from the current working directory. The first *global.json* file found specifies the version used. If that version is installed, that version is used. If the SDK specified in the *global.json* is not found, the .NET CLI rolls forward to the latest SDK installed. Roll-forward is the same as the default behavior, when no *global.json* file is found.

The following example shows the *global.json* syntax:

```
{  
  "sdk": {  
    "version": "2.0.0"  
  }  
}
```

The process for selecting an SDK version is:

1. `dotnet` searches for a *global.json* file iteratively reverse-navigating the path upward from the current working directory.
2. `dotnet` uses the SDK specified in the first *global.json* found.
3. `dotnet` uses the latest installed SDK if no *global.json* is found.

You can learn more about selecting an SDK version in the [Matching rules](#) section of the article on *global.json*.

Target Framework Monikers define build time APIs

You build your project against APIs defined in a **Target Framework Moniker** (TFM). You specify the [target framework](#) in the project file. Set the `TargetFramework` element in your project file as shown in the following example:

```
<TargetFramework>netcoreapp2.0</TargetFramework>
```

You may build your project against multiple TFMs. Setting multiple target frameworks is more common for libraries but can be done with applications as well. You specify a `TargetFrameworks` property (plural of `TargetFramework`). The target frameworks are semicolon-delimited as shown in the following example:

```
<TargetFrameworks>netcoreapp2.0;net47</TargetFrameworks>
```

A given SDK supports a fixed set of frameworks, capped to the target framework of the runtime it ships with. For example, the .NET Core 2.0 SDK includes the .NET Core 2.0 runtime, which is an implementation of the `netcoreapp2.0` target framework. The .NET Core 2.0 SDK supports `netcoreapp1.0`, `netcoreapp1.1`, and `netcoreapp2.0` but not `netcoreapp2.1` (or higher). You install the .NET Core 2.1 SDK to build for `netcoreapp2.1`.

.NET Standard target frameworks are also capped to the target framework of the runtime the SDK ships with. The .NET Core 2.0 SDK is capped to `netstandard2.0`.

Framework-dependent apps roll forward

When you run an application from source with `dotnet run`, from a **framework-dependent deployment** with `dotnet myapp.dll`, or from a **framework-dependent executable** with `myapp.exe`, the `dotnet` executable is the **host** for the application.

The host chooses the latest patch version installed on the machine. For example, if you specified `netcoreapp2.0` in your project file, and `2.0.4` is the latest .NET runtime installed, the `2.0.4` runtime is used.

If no acceptable `2.0.*` version is found, a new `2.*` version is used. For example, if you specified `netcoreapp2.0` and only `2.1.0` is installed, the application runs using the `2.1.0` runtime. This behavior is referred to as "minor version roll-forward." Lower versions also won't be considered. When no acceptable runtime is installed, the application won't run.

A few usage examples demonstrate the behavior:

- 2.0.4 is required. 2.0.5 is the highest patch version installed. 2.0.5 is used.
- 2.0.4 is required. No 2.0.* versions are installed. 1.1.1 is the highest runtime installed. An error message is displayed.
- 2.0.4 is required. 2.0.0 is the highest version installed. An error message is displayed.
- 2.0.4 is required. No 2.0.* versions are installed. 2.2.2 is the highest 2.x runtime version installed. 2.2.2 is used.
- 2.0.4 is required. No 2.x versions are installed. 3.0.0 (not a currently available version) is installed. An error message is displayed.

Minor version roll-forward has one side-effect that may affect end users. Consider the following scenario:

- 2.0.4 is required. No 2.0.* versions are installed. 2.2.2 is installed. 2.2.2 is used.
- 2.0.5 is later installed. 2.0.5 will be used for subsequent application launches, not 2.2.2. The latest patch of the required minor version is preferred over a higher minor version.
- It's possible that 2.0.5 and 2.2.2 behave differently, particularly for scenarios like serializing binary data.

Self-contained deployments include the selected runtime

You can publish an application as a [self-contained distribution](#). This approach bundles the .NET Core runtime and libraries with your application. Self-contained deployments don't have a dependency on runtime environments. Runtime version selection occurs at publishing time, not run time.

The publishing process selects the latest patch version of the given runtime family. For example, `dotnet publish` will select .NET Core 2.0.4 if it is the latest patch version in the .NET Core 2.0 runtime family. The target framework (including the latest installed security patches) is packaged with the application.

It's an error if the minimum version specified for an application isn't satisfied. `dotnet publish` binds to the latest runtime patch version (within a given major.minor version family). `dotnet publish` doesn't support the roll-forward semantics of `dotnet run`. For more information about patches and self-contained deployments, see the article on [runtime patch selection](#) in deploying .NET Core applications.

Self-contained deployments may require a specific patch version. You can override the minimum runtime patch version (to higher or lower versions) in the project file, as shown in the following example:

```
<RuntimeFrameworkVersion>2.0.4</RuntimeFrameworkVersion>
```

The `RuntimeFrameworkVersion` element overrides the default version policy. For self-contained deployments, the `RuntimeFrameworkVersion` specifies the *exact* runtime framework version. For framework-dependent applications, the `RuntimeFrameworkVersion` specifies the *minimum* required runtime framework version.

How to remove the .NET Core Runtime and SDK

2/28/2019 • 5 minutes to read • [Edit Online](#)

Over time, as you install updated versions of the .NET Core runtime and SDK, you may want to remove outdated versions of .NET Core from your machine. Removing older versions of the runtime may change the runtime chosen to run shared framework applications, as detailed in the article on [.NET Core version selection](#).

Should I remove a version?

The [.NET Core version selection](#) behaviors and the runtime compatibility of .NET Core across updates enables safe removal of previous versions. .NET Core runtime updates are compatible within a major version 'band' such as 1.x and 2.x. Additionally, newer releases of the .NET Core SDK generally maintain the ability to build applications that target previous versions of the runtime in a compatible manner.

In general, you only need the latest SDK and latest patch version of the runtimes required for your application. Instances where retaining older SDK or Runtime versions include maintaining **project.json**-based applications. Unless your application has specific reasons for earlier SDKs or runtimes, you may safely remove older versions.

Determine what is installed

Starting with .NET Core 2.1, the .NET CLI has options you can use to list the versions of the SDK and runtime that are installed on your machine. Use `dotnet --list-sdks` to see the list of SDKs installed on your machine. Use `dotnet --list-runtimes` to see the list of runtimes installed on your machine. The following text shows typical output for Windows, macOS, or Linux:

- [Windows](#)
- [Linux](#)
- [macOS](#)

```
C:\> dotnet --list-sdks
2.1.200-preview-007474 [C:\Program Files\dotnet\sdk]
2.1.200-preview-007480 [C:\Program Files\dotnet\sdk]
2.1.200-preview-007509 [C:\Program Files\dotnet\sdk]
2.1.200-preview-007570 [C:\Program Files\dotnet\sdk]
2.1.200-preview-007576 [C:\Program Files\dotnet\sdk]
2.1.200-preview-007587 [C:\Program Files\dotnet\sdk]
2.1.200-preview-007589 [C:\Program Files\dotnet\sdk]
2.1.200 [C:\Program Files\dotnet\sdk]
2.1.201 [C:\Program Files\dotnet\sdk]
2.1.202 [C:\Program Files\dotnet\sdk]
2.1.300-preview2-008533 [C:\Program Files\dotnet\sdk]
2.1.300 [C:\Program Files\dotnet\sdk]
2.1.400-preview-009063 [C:\Program Files\dotnet\sdk]
2.1.400-preview-009088 [C:\Program Files\dotnet\sdk]
2.1.400-preview-009171 [C:\Program Files\dotnet\sdk]

C:\> dotnet --list-runtimes

.NET Core RID Catalog

2/23/2019 • 4 minutes to read • [Edit Online](#)

RID is short for *Runtime Identifier*. RID values are used to identify target platforms where the application runs. They're used by .NET packages to represent platform-specific assets in NuGet packages. The following values are examples of RIDs: `linux-x64`, `ubuntu.14.04-x64`, `win7-x64`, or `osx.10.12-x64`. For the packages with native dependencies, the RID designates on which platforms the package can be restored.

A single RID can be set in the `<RuntimeIdentifier>` element of your project file. Multiple RIDs can be defined as a semicolon-delimited list in the project file's `<RuntimeIdentifiers>` element. They're also used via the `--runtime` option with the following [.NET Core CLI commands](#):

- [dotnet build](#)
- [dotnet clean](#)
- [dotnet pack](#)
- [dotnet publish](#)
- [dotnet restore](#)
- [dotnet run](#)
- [dotnet store](#)

RIDs that represent concrete operating systems usually follow this pattern:

`[os].[version]-[architecture]-[additional qualifiers]` where:

- `[os]` is the operating/platform system moniker. For example, `ubuntu`.
- `[version]` is the operating system version in the form of a dot-separated (`.`) version number. For example, `15.10`.
 - The version **shouldn't** be marketing versions, as they often represent multiple discrete versions of the operating system with varying platform API surface area.
- `[architecture]` is the processor architecture. For example: `x86`, `x64`, `arm`, or `arm64`.
- `[additional qualifiers]` further differentiate different platforms. For example: `aot`.

RID graph

The RID graph or runtime fallback graph is a list of RIDs that are compatible with each other. The RIDs are defined in the [Microsoft.NETCore.Platforms](#) package. You can see the list of supported RIDs and the RID graph in the `runtime.json` file, which is located at the CoreFX repo. In this file, you can see that all RIDs, except for the base one, contain an `"#import"` statement. These statements indicate compatible RIDs.

When NuGet restores packages, it tries to find an exact match for the specified runtime. If an exact match is not found, NuGet walks back the graph until it finds the closest compatible system according to the RID graph.

The following example is the actual entry for the `osx.10.12-x64` RID:

```
"osx.10.12-x64": {
  "#import": [ "osx.10.12", "osx.10.11-x64" ]
}
```

The above RID specifies that `osx.10.12-x64` imports `osx.10.11-x64`. So, when NuGet restores packages, it tries to find an exact match for `osx.10.12-x64` in the package. If NuGet cannot find the specific runtime, it can restore packages that specify `osx.10.11-x64` runtimes, for example.

The following example shows a slightly bigger RID graph also defined in the `runtime.json` file:

```
win7-x64      win7-x86
|   \ /   |
|   win7   |
|   |   |
win-x64 |  win-x86
\ | /
  win
  |
any
```

All RIDs eventually map back to the root `any` RID.

There are some considerations about RIDs that you have to keep in mind when working with them:

- RIDs are **opaque strings** and should be treated as black boxes.
- Don't build RIDs programmatically.
- Use RIDs that are already defined for the platform.
- The RIDs need to be specific, so don't assume anything from the actual RID value.

Using RIDs

To be able to use RIDs, you have to know which RIDs exist. New values are added regularly to the platform. For the latest and complete version, see the [runtime.json](#) file on CoreFX repo.

.NET Core 2.0 SDK introduces the concept of portable RIDs. They are new values added to the RID graph that aren't tied to a specific version or OS distribution and are the preferred choice when using .NET Core 2.0 and higher. They're particularly useful when dealing with multiple Linux distros since most distribution RIDs are mapped to the portable RIDs.

The following list shows a small subset of the most common RIDs used for each OS.

Windows RIDs

Only common values are listed. For the latest and complete version, see the [runtime.json](#) file on CoreFX repo.

- Portable (.NET Core 2.0 or later versions)
 - `win-x64`
 - `win-x86`
 - `win-arm`
 - `win-arm64`
- Windows 7 / Windows Server 2008 R2
 - `win7-x64`
 - `win7-x86`
- Windows 8.1 / Windows Server 2012 R2
 - `win81-x64`
 - `win81-x86`
 - `win81-arm`
- Windows 10 / Windows Server 2016

- `win10-x64`
- `win10-x86`
- `win10-arm`
- `win10-arm64`

See [Prerequisites for .NET Core on Windows](#) for more information.

Linux RIDs

Only common values are listed. For the latest and complete version, see the [runtime.json](#) file on CoreFX repo. Devices running a distribution not listed below may work with one of the Portable RIDs. For example, Raspberry Pi devices running a Linux distribution not listed can be targeted with `linux-arm`.

- Portable (.NET Core 2.0 or later versions)
 - `linux-x64` (Most desktop distributions like CentOS, Debian, Fedora, Ubuntu and derivatives)
 - `linux-musl-x64` (Lightweight distributions using [musl](#) like Alpine Linux)
 - `linux-arm` (Linux distributions running on ARM like Raspberry Pi)
- Red Hat Enterprise Linux
 - `rhel-x64` (Superseded by `linux-x64` for RHEL above version 6)
 - `rhel.6-x64` (.NET Core 2.0 or later versions)
- Tizen (.NET Core 2.0 or later versions)
 - `tizen`
 - `tizen.4.0.0`
 - `tizen.5.0.0`

See [Prerequisites for .NET Core on Linux](#) for more information.

macOS RIDs

macOS RIDs use the older "OSX" branding. Only common values are listed. For the latest and complete version, see the [runtime.json](#) file on CoreFX repo.

- Portable (.NET Core 2.0 or later versions)
 - `osx-x64` (Minimum OS version is macOS 10.12 Sierra)
- macOS 10.10 Yosemite
 - `osx.10.10-x64`
- macOS 10.11 El Capitan
 - `osx.10.11-x64`
- macOS 10.12 Sierra (.NET Core 1.1 or later versions)
 - `osx.10.12-x64`
- macOS 10.13 High Sierra (.NET Core 1.1 or later versions)
 - `osx.10.13-x64`
- macOS 10.14 Mojave (.NET Core 1.1 or later versions)
 - `osx.10.14-x64`

See [Prerequisites for .NET Core on macOS](#) for more information.

.NET Core SDK Overview

12/10/2018 • 2 minutes to read • [Edit Online](#)

.NET Core Software Development Kit (SDK) is a set of libraries and tools that allow developers to create .NET Core applications and libraries. This is the package that developers will most likely acquire.

It contains the following components:

1. The .NET Core Command Line Tools that are used to build applications
2. .NET Core (libraries and runtime) that allow applications to both be built and run
3. The `dotnet` driver for running the [CLI commands](#) as well as running applications

Acquiring the .NET Core SDK

As with any tooling, the first thing is to get the tools to your machine. Depending on your scenario, you can either use the native installers to install the SDK or use the installation shell script.

The native installers are primarily meant for developer's machines. The SDK is distributed using each supported platform's native install mechanism, for instance DEB packages on Ubuntu or MSI bundles on Windows. These installers will install and set up the environment as needed for the user to use the SDK immediately after the install. However, they also require administrative privileges on the machine. You can view the installation instructions on the [.NET Core installation guide](#).

Install scripts, on the other hand, do not require administrative privileges. However, they will also not install any prerequisites on the machine; you need to install all of the prerequisites manually. The scripts are meant mostly for setting up build servers or when you wish to install the tools without admin privileges (do note the prerequisites caveat above). You can find more information on the [install script reference topic](#). If you are interested in how to set up SDK on your CI build server you can take a look at the [SDK with CI servers](#) document.

By default, the SDK will install in a "side-by-side" (SxS) manner. This means that multiple versions of the CLI tools can coexist at any given time on a single machine. How the correct version gets used is explained in more detail in the [driver section](#) of .NET Core Command Line Tools topic.

.NET Core command-line interface (CLI) tools

1/23/2019 • 3 minutes to read • [Edit Online](#)

The .NET Core command-line interface (CLI) is a new cross-platform toolchain for developing .NET applications. The CLI is a foundation upon which higher-level tools, such as Integrated Development Environments (IDEs), editors, and build orchestrators, can rest.

Installation

Either use the native installers or use the installation shell scripts:

- The native installers are primarily used on developer's machines and use each supported platform's native install mechanism, for instance, DEB packages on Ubuntu or MSI bundles on Windows. These installers install and configure the environment for immediate use by the developer but require administrative privileges on the machine. You can view the installation instructions in the [.NET Core installation guide](#).
- Shell scripts are primarily used for setting up build servers or when you wish to install the tools without administrative privileges. Install scripts don't install prerequisites on the machine, which must be installed manually. For more information, see the [install script reference topic](#). For information on how to set up CLI on your continuous integration (CI) build server, see [Using .NET Core SDK and tools in Continuous Integration \(CI\)](#).

By default, the CLI installs in a side-by-side (SxS) manner, so multiple versions of the CLI tools can coexist on a single machine. Determining which version is used on a machine where multiple versions are installed is explained in more detail in the [Driver](#) section.

CLI commands

The following commands are installed by default:

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

Basic commands

- [new](#)
- [restore](#)
- [build](#)
- [publish](#)
- [run](#)
- [test](#)
- [vstest](#)
- [pack](#)
- [migrate](#)
- [clean](#)
- [sln](#)
- [help](#)
- [store](#)

Project modification commands

- [add package](#)
- [add reference](#)
- [remove package](#)
- [remove reference](#)
- [list reference](#)

Advanced commands

- [nuget delete](#)
- [nuget locals](#)
- [nuget push](#)
- [msbuild](#)
- [dotnet install script](#)

The CLI adopts an extensibility model that allows you to specify additional tools for your projects. For more information, see the [.NET Core CLI extensibility model](#) topic.

Command structure

CLI command structure consists of [the driver \("dotnet"\)](#), [the command \(or "verb"\)](#), and possibly command [arguments](#) and [options](#). You see this pattern in most CLI operations, such as creating a new console app and running it from the command line as the following commands show when executed from a directory named *my_app*:

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

```
dotnet new console  
dotnet build --output /build_output  
dotnet /build_output/my_app.dll
```

Driver

The driver is named [dotnet](#) and has two responsibilities, either running a [framework-dependent app](#) or executing a command. The only time `dotnet` is used without a command is when it's used to start an application.

To run a framework-dependent app, specify the app after the driver, for example, `dotnet /path/to/my_app.dll`. When executing the command from the folder where the app's DLL resides, simply execute `dotnet my_app.dll`.

When you supply a command to the driver, `dotnet.exe` starts the CLI command execution process. First, the driver determines the version of the SDK to use. If the version isn't specified in the command options, the driver uses the latest version available. To specify a version other than the latest installed version, use the `--fx-version <VERSION>` option (see the [dotnet command](#) reference). Once the SDK version is determined, the driver executes the command.

Command ("verb")

The command (or "verb") is simply a command that performs an action. For example, `dotnet build` builds your code. `dotnet publish` publishes your code. The commands are implemented as a console application using a `dotnet {verb}` convention.

Arguments

The arguments you pass on the command line are the arguments to the command invoked. For example when you execute `dotnet publish my_app.csproj`, the `my_app.csproj` argument indicates the project to publish and is

passed to the `publish` command.

Options

The options you pass on the command line are the options to the command invoked. For example when you execute `dotnet publish --output /build_output`, the `--output` option and its value are passed to the `publish` command.

Migration from project.json

If you used Preview 2 tooling to produce *project.json*-based projects, consult the [dotnet migrate](#) topic for information on migrating your project to MSBuild/.*cspoj* for use with release tooling. For .NET Core projects created prior to the release of Preview 2 tooling, either manually update the project following the guidance in [Migrating from DNX to .NET Core CLI \(project.json\)](#) and then use `dotnet migrate` or directly upgrade your projects.

.NET Core SDK telemetry

3/9/2019 • 4 minutes to read • [Edit Online](#)

The .NET Core SDK includes a [telemetry feature](#) that collects usage information. It's important that the .NET Team understands how the tools are used so they can be improved. For more information, see [What we've learned from .NET Core SDK Telemetry](#).

The collected data is anonymous and published in an aggregated form for use by both Microsoft and the community under the [Creative Commons Attribution License](#).

Scope

The `dotnet` command is used to launch both apps and the .NET Core CLI. The `dotnet` command itself doesn't collect telemetry. The .NET Core CLI commands run by the `dotnet` command collect the telemetry.

Telemetry *isn't enabled* when using the `dotnet` command itself, with no command attached:

- `dotnet`
- `dotnet [path-to-app]`

Telemetry *is enabled* when using the [.NET Core CLI commands](#), such as:

- `dotnet build`
- `dotnet pack`
- `dotnet restore`
- `dotnet run`

How to opt out

The .NET Core SDK telemetry feature is enabled by default. Opt out of the telemetry feature by setting the `DOTNET_CLI_TELEMETRY_OPTOUT` environment variable to `1` or `true`.

Data points

The feature collects the following data:

- Timestamp of invocation†
- Command invoked (for example, "build")†
- Three octet IP address used to determine geographical location†
- `ExitCode` of the command
- Test runner (for test projects)
- Operating system and version†
- Whether runtime IDs are present in the runtimes node
- .NET Core SDK version†

†This metric is published.

Starting with .NET Core 2.0 SDK, new data points are collected:

- `dotnet` command arguments and options: only known arguments and options are collected (not arbitrary strings).

- Whether the SDK is running in a container.
- Target frameworks.
- Hashed MAC address: a cryptographically (SHA256) anonymous and unique ID for a machine. This metric isn't published.
- Hashed current working directory.

The feature doesn't collect personal data, such as usernames or email addresses. It doesn't scan your code and doesn't extract sensitive project-level data, such as name, repo, or author. The data is sent securely to Microsoft servers using [Microsoft Azure Application Insights](#) technology, held under restricted access, and published under strict security controls from secure [Azure Storage](#) systems.

The .NET team wants to know how the tools are used and if they're working well, not what you're building with the tools. If you suspect that the telemetry is collecting sensitive data or that the data is being insecurely or inappropriately handled, file an issue in the [dotnet/cli](#) repository for investigation.

Published data

Published data is available quarterly and are listed at [.NET Core SDK Usage Data](#). The columns of a data file are:

- Timestamp
- Occurrences[†]
- Command
- Geography[‡]
- OSFamily
- RuntimeID
- OSVersion
- SDKVersion

[†]The *Occurrences* column displays the aggregate count of that command's use for that row's metrics that day.

[‡]Typically, the *Geography* column displays the name of a country. In some cases, the continent of Antarctica appears in this column, either due to researchers using .NET Core in Antarctica or incorrect location data.

Example

TIMESTAMP	OCCURRENCES	COMMAND	GEOGRAPHY	OSFAMILY	RUNTIMEID	OSVERSION	SDKVERSION
4/16/2017 0:00	8	run	Uganda	Darwin	osx.10.12-x64	10.12	1.0.1

Datasets

- [2016 - Q3](#)
[2016 - Q4](#)
[2017 - Q1](#)
[2017 - Q2](#)
[2017 - Q3](#)
[2017 - Q4](#)

Additional datasets are posted using a standard URL format. Replace <YEAR> with the year and replace <QUARTER> with the quarter of the year (use 1, 2, 3, or 4). The files are in tab-separated values (TSV) format.

<https://dotnetcli.blob.core.windows.net/usagedata/dotnet-cli-usage-<YEAR>-q<QUARTER>.tsv>

License

The Microsoft distribution of .NET Core is licensed with the [MICROSOFT .NET LIBRARY EULA](#). This license includes the "DATA" section to enable telemetry (shown below).

.NET NuGet packages use the same license but don't enable telemetry (see [Scope](#)).

2. DATA. The software may collect information about you and your use of the software, and send that to Microsoft. Microsoft may use this information to improve our products and services. You can learn more about data collection and use in the help documentation and the privacy statement at <http://go.microsoft.com/fwlink/?LinkId=528096>. Your use of the software operates as your consent to these practices.

Disclosure

The .NET Core SDK displays the following text when you first run one of the [NET Core CLI commands](#) (for example, `dotnet restore`). Text may vary slightly depending on the version of the SDK you're running. This "first run" experience is how Microsoft notifies you about data collection.

```
Welcome to .NET Core!
-----
Learn more about .NET Core: https://aka.ms/dotnet-docs
Use 'dotnet --help' to see available commands or visit: https://aka.ms/dotnet-cli-docs

Telemetry
-----
The .NET Core tools collect usage data in order to help us improve your experience.
The data is anonymous and doesn't include command-line arguments.
The data is collected by Microsoft and shared with the community.
You can opt-out of telemetry by setting the DOTNET_CLI_TELEMETRY_OPTOUT environment variable to '1' or 'true'
using your favorite shell.

Read more about .NET Core CLI Tools telemetry: https://aka.ms/dotnet-cli-telemetry
```

.NET Core Global Tools overview

12/10/2018 • 5 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

A .NET Core Global Tool is a special NuGet package that contains a console application. A Global Tool can be installed on your machine on a default location that is included in the PATH environment variable or on a custom location.

If you want to use a .NET Core Global Tool:

- Find information about the tool (usually a website or GitHub page).
- Check the author and statistics in the home for the feed (usually NuGet.org).
- Install the tool.
- Call the tool.
- Update the tool.
- Uninstall the tool.

IMPORTANT

.NET Core Global Tools appear on your path and run in full trust. Do not install .NET Core Global Tools unless you trust the author.

Find a .NET Core Global Tool

Currently, there isn't a Global Tool search feature in the .NET Core Command-line Interface (CLI).

You can find .NET Core Global Tools on [NuGet](#). However, NuGet doesn't yet allow you to search specifically for .NET Core Global Tools.

You may also find tool recommendations in blog posts or in the [natemcmaster/dotnet-tools](#) GitHub repository.

You can also see the source code for the Global Tools created by the ASP.NET team at the [aspnet/DotNetTools](#) GitHub repository.

Check the author and statistics

Since .NET Core Global Tools run in full trust and are generally installed on your path, they can be very powerful. Don't download tools from people you don't trust.

If the tool is hosted on NuGet, you can check the author and statistics by searching for the tool.

Install a Global Tool

To install a Global Tool, you use the `dotnet tool install` .NET Core CLI command. The following example shows how to install a Global Tool in the default location:

```
dotnet tool install -g dotnetsay
```

If the tool can't be installed, error messages are displayed. Check that the feeds you expected are being checked.

If you're trying to install a pre-release version or a specific version of the tool, you can specify the version number using the following format:

```
dotnet tool install -g <package-name> --version <version-number>
```

If installation is successful, a message is displayed showing the command used to call the tool and the version installed, similar to the following example:

```
You can invoke the tool using the following command: dotnetsay  
Tool 'dotnetsay' (version '2.0.0') was successfully installed.
```

Global Tools can be installed in the default directory or in a specific location. The default directories are:

os	PATH
Linux/macOS	\$HOME/.dotnet/tools
Windows	%USERPROFILE%\.dotnet\tools

These locations are added to the user's path when the SDK is first run, so Global Tools installed there can be called directly.

Note that the Global Tools are user-specific, not machine global. Being user-specific means you cannot install a Global Tool that is available to all users of the machine. The tool is only available for each user profile where the tool was installed.

Global Tools can also be installed in a specific directory. When installed in a specific directory, the user must ensure the command is available, by including that directory in the path, by calling the command with the directory specified, or calling the tool from within the specified directory. In this case, the .NET Core CLI doesn't add this location automatically to the PATH environment variable.

Use the tool

Once the tool is installed, you can call it by using its command. Note that the command may not be the same as the package name.

If the command is `dotnetsay`, you call it with:

```
dotnetsay
```

If the tool author wanted the tool to appear in the context of the `dotnet` prompt, they may have written it in a way that you call it as `dotnet <command>`, such as:

```
dotnet doc
```

You can find which tools are included in an installed Global Tool package by listing the installed packages using the [dotnet tool list](#) command.

You can also look for usage instructions at the tool's website or by typing one of the following commands:

```
<command> --help  
dotnet <command> --help
```

What could go wrong

Global Tools are [framework-dependent applications](#), which means they rely on a .NET Core runtime installed on your machine. If the expected runtime is not found, they follow normal .NET Core runtime roll-forward rules such as:

- An application rolls forward to the highest patch release of the specified major and minor version.
- If there is no matching runtime with a matching major and minor version number, the next higher minor version is used.
- Roll forward doesn't occur between preview versions of the runtime or between preview versions and release versions. Thus, Global Tools created using preview versions must be rebuilt and republished by the author and reinstalled.
- Additional issues can occur with Global Tools created in .NET Core 2.1 Preview 1. For more information, see [.NET Core 2.1 Preview 2 Known Issues](#).

If an application cannot find an appropriate runtime, it fails to run and reports an error.

Another issue that might happen is that a Global Tool that was created during an earlier preview may not run with your currently installed .NET Core runtimes. You can see which runtimes are installed on your machine using the following command:

```
dotnet --list-runtimes
```

Contact the author of the Global Tool and see if they can recompile and republish their tool package to NuGet with an updated version number. Once they have updated the package on NuGet, you can update your copy.

The .NET Core CLI tries to add the default locations to the PATH environment variable on its first usage. However, there are a couple of scenarios where the location might not be added to PATH automatically, such as:

- If you've set the `DOTNET_SKIP_FIRST_TIME_EXPERIENCE` environment variable.
- On macOS, if you've installed the .NET Core SDK using `.tar.gz` files and not `.pkg`.
- On Linux, you need to edit the shell environment file to configure the PATH.

Other CLI commands

The .NET Core SDK contains other commands that support .NET Core Global Tools. Use any of the `dotnet tool` commands with one of the following options:

- `--global` or `-g` specifies that the command is applicable to user-wide Global Tools.
- `--tool-path` specifies a custom location for Global Tools.

To find out which commands are available for Global Tools:

```
dotnet tool --help
```

Updating a Global Tool involves uninstalling and reinstalling it with the latest stable version. To update a Global Tool, use the [dotnet tool update](#) command:

```
dotnet tool update -g <packagename>
```

Remove a Global Tool using the [dotnet tool uninstall](#):

```
dotnet tool uninstall -g <packagename>
```

To display all of the Global Tools currently installed on the machine, along with their version and commands, use the [dotnet tool list](#) command:

```
dotnet tool list -g
```

Create a .NET Core Global Tool using the .NET Core CLI

3/8/2019 • 3 minutes to read • [Edit Online](#)

This article teaches you how to create and package a .NET Core Global Tool. The .NET Core CLI allows you to create a console application as a Global Tool, which others can easily install and run. .NET Core Global Tools are NuGet packages that are installed from the .NET Core CLI. For more information about Global Tools, see [.NET Core Global Tools overview](#).

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

Create a project

This article uses the .NET Core CLI to create and manage a project.

Our example tool will be a console application that generates an ASCII bot and prints a message. First, create a new .NET Core Console Application.

```
dotnet new console -o botsay
```

Navigate to the `botsay` directory created by the previous command.

Add the code

Open the `Program.cs` file with your favorite text editor, such as `vim` or [Visual Studio Code](#).

Add the following `using` directive to the top of the file, this helps shorten the code to display the version information of the application.

```
using System.Reflection;
```

Next, move down to the `Main` method. Replace the method with the following code to process the command-line arguments for your application. If no arguments were passed, a short help message is displayed. Otherwise, all of those arguments are transformed into a string and printed with the bot.

```
static void Main(string[] args)
{
    if (args.Length == 0)
    {
        var versionString = Assembly.GetEntryAssembly()
            .GetCustomAttribute<AssemblyInformationalVersionAttribute>()
            .InformationalVersion
            .ToString();

        Console.WriteLine($"botsay v{versionString}");
        Console.WriteLine("-----");
        Console.WriteLine("\nUsage:");
        Console.WriteLine("  botsay <message>");
        return;
    }

    ShowBot(string.Join(' ', args));
}
```

Create the bot

Next, add a new method named `ShowBot` that takes a string parameter. This method prints out the message and the ASCII bot. The ASCII bot code was taken from the [dotnetbot](#) sample.

Test the tool

Run the project and see the output. Try these variations of the command-line to see different results:

```
dotnet run  
dotnet run -- "Hello from the bot"  
dotnet run -- hello from the bot
```

All arguments after the `--` delimiter are passed to your application.

Setup the global tool

Before you can pack and distribute the application as a Global Tool, you need to modify the project file. Open the `botsay.csproj` file and add three new XML nodes to the `<Project><PropertyGroup>` node:

- <PackAsTool>

[REQUIRED] Indicates that the application will be packaged for install as a Global Tool.

- <ToolCommandName>

[OPTIONAL] An alternative name for the tool, otherwise the command name for the tool will be named after the project file. You can have multiple tools in a package, choosing a unique and friendly name helps differentiate from other tools in the same package.

- <PackageOutputPath>

[OPTIONAL] Where the NuGet package will be produced. The NuGet package is what the .NET Core CLI Global Tools uses to install your tool.

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>
  <OutputType>Exe</OutputType>
  <TargetFramework>netcoreapp2.1</TargetFramework>

  <PackAsTool>true</PackAsTool>
  <ToolCommandName>botsay</ToolCommandName>
  <PackageOutputPath>./nupkg</PackageOutputPath>

</PropertyGroup>

</Project>
```

Even though <PackageOutputPath> is optional, use it in this example. Make sure you set it:

```
<PackageOutputPath>./nupkg</PackageOutputPath> .
```

Next, create a NuGet package for your application.

```
dotnet pack
```

The `botsay.1.0.0.nupkg` file is created in the folder identified by the <PackageOutputPath> XML value from the `botsay.csproj` file, which in this example is the `./nupkg` folder. This makes it easy to install and test. When you want to release a tool publicly, upload it to <https://www.nuget.org>. Once the tool is available on NuGet, developers can perform a user-wide installation of the tool using the `--global` option of the `dotnet tool install` command.

Now that you have a package, install the tool from that package:

```
dotnet tool install --global --add-source ./nupkg botsay
```

The `--add-source` parameter tells the .NET Core CLI to temporarily use the `./nupkg` folder (our <PackageOutputPath> folder) as an additional source feed for NuGet packages. For more information about installing Global Tools, see [.NET Core Global Tools overview](#).

If installation is successful, a message is displayed showing the command used to call the tool and the version installed, similar to the following example:

```
You can invoke the tool using the following command: botsay
Tool 'botsay' (version '1.0.0') was successfully installed.
```

You should now be able to type `botsay` and get a response from the tool.

NOTE

If the install was successful, but you cannot use the `botsay` command, you may need to open a new terminal to refresh the PATH.

Remove the tool

Once you're done experimenting with the tool, you can remove it with the following command:

```
dotnet tool uninstall -g botsay
```

.NET Core CLI tools extensibility model

3/8/2019 • 8 minutes to read • [Edit Online](#)

This document covers the different ways you can extend the .NET Core Command-line Interface (CLI) tools and explain the scenarios that drive each one of them. You'll see how to consume the tools as well as how to build the different types of tools.

How to extend CLI tools

The CLI tools can be extended in three main ways:

1. [Via NuGet packages on a per-project basis](#)

Per-project tools are contained within the project's context, but they allow easy installation through restoration.

2. [Via NuGet packages with custom targets](#)

Custom targets allow you to easily extend the build process with custom tasks.

3. [Via the system's PATH](#)

PATH-based tools are good for general, cross-project tools that are usable on a single machine.

The three extensibility mechanisms outlined above are not exclusive. You can use one, or all, or a combination of them. Which one to pick depends largely on the goal you are trying to achieve with your extension.

Per-project based extensibility

Per-project tools are [framework-dependent deployments](#) that are distributed as NuGet packages. Tools are only available in the context of the project that references them and for which they are restored. Invocation outside of the context of the project (for example, outside of the directory that contains the project) will fail because the command cannot be found.

These tools are perfect for build servers, since nothing outside of the project file is needed. The build process runs restore for the project it builds and tools will be available. Language projects, such as F#, are also in this category since each project can only be written in one specific language.

Finally, this extensibility model provides support for creation of tools that need access to the built output of the project. For instance, various Razor view tools in [ASP.NET](#) MVC applications fall into this category.

Consuming per-project tools

Consuming these tools requires you to add a `<DotNetCliToolReference>` element to your project file for each tool you want to use. Inside the `<DotNetCliToolReference>` element, you reference the package in which the tool resides and specify the version you need. After running `dotnet restore`, the tool and its dependencies are restored.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

For tools that need to load the build output of the project for execution, there is usually another dependency which is listed under the regular dependencies in the project file. Since CLI uses MSBuild as its build engine, we recommend that these parts of the tool be written as custom MSBuild [targets](#) and [tasks](#), since they can then take part in the overall build process. Also, they can get any and all data easily that is produced via the build, such as the location of the output files, the current configuration being built, etc. All this information becomes a set of MSBuild properties that can be read from any target. You can see how to add a custom target using NuGet later in this document.

Let's review an example of adding a simple tools-only tool to a simple project. Given an example command called `dotnet-api-search` that allows you to search through the NuGet packages for the specified API, here is a console application's project file that uses that tool:

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>netcoreapp2.1</TargetFramework>
  </PropertyGroup>

  <!-- The tools reference -->
  <ItemGroup>
    <DotNetCliToolReference Include="dotnet-api-search" Version="1.0.0" />
  </ItemGroup>
</Project>
```

The `<DotNetCliToolReference>` element is structured in a similar way as the `<PackageReference>` element. It needs the package ID of the package containing the tool and its version to be able to restore.

Building tools

As mentioned, tools are just portable console applications. You build tools as you would build any other console application. After you build it, you use the `dotnet pack` command to create a NuGet package (.nupkg file) that contains your code, information about its dependencies, and so on. You can give any name to the package, but the application inside, the actual tool binary, has to conform to the convention of `dotnet-<command>` in order for `dotnet` to be able to invoke it.

NOTE

In pre-RC3 versions of the .NET Core command-line tools, the `dotnet pack` command had a bug that caused the `runtime.config.json` to not be packed with the tool. Lacking that file results in errors at runtime. If you encounter this behavior, be sure to update to the latest tooling and try the `dotnet pack` again.

Since tools are portable applications, the user consuming the tool must have the version of the .NET Core libraries that the tool was built against in order to run the tool. Any other dependency that the tool uses and that is not contained within the .NET Core libraries is restored and placed in the NuGet cache. The entire tool is, therefore, run using the assemblies from the .NET Core libraries as well as assemblies from the NuGet cache.

These kinds of tools have a dependency graph that is completely separate from the dependency graph of the project that uses them. The restore process first restores the project's dependencies and then restores each of the tools and their dependencies.

You can find richer examples and different combinations of this in the [.NET Core CLI repo](#). You can also see the [implementation of tools used](#) in the same repo.

Custom targets

NuGet has the capability to [package custom MSBuild targets and props files](#). With the move of the .NET Core CLI

tools to use MSBuild, the same mechanism of extensibility now applies to .NET Core projects. You would use this type of extensibility when you want to extend the build process, or when you want to access any of the artifacts in the build process, such as generated files, or you want to inspect the configuration under which the build is invoked, etc.

In the following example, you can see the target's project file using the `csproj` syntax. This instructs the `dotnet pack` command what to package, placing the targets files as well as the assemblies into the *build* folder inside the package. Notice the `<ItemGroup>` element that has the `Label` property set to `dotnet pack instructions`, and the Target defined beneath it.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <Description>Sample Packer</Description>
    <VersionPrefix>0.1.0-preview</VersionPrefix>
    <TargetFramework>netstandard1.3</TargetFramework>
    <DebugType>portable</DebugType>
    <AssemblyName>SampleTargets.PackerTarget</AssemblyName>
  </PropertyGroup>
  <ItemGroup>
    <EmbeddedResource Include="Resources\Pkg\dist-template.xml;compiler\resources\**\**"
      Exclude="bin\**;obj\**;**\*.xproj;packages\**" />
    <None Include="build\SampleTargets.PackerTarget.targets" />
  </ItemGroup>
  <ItemGroup Label="dotnet pack instructions">
    <Content Include="build\*.targets">
      <Pack>true</Pack>
      <PackagePath>build\</PackagePath>
    </Content>
  </ItemGroup>
  <Target Name="CollectRuntimeOutputs" BeforeTargets="_GetPackageFiles">
    <!-- Collect these items inside a target that runs after build but before packaging. -->
    <ItemGroup>
      <Content Include="$(OutputPath)\*.dll;$(OutputPath)\*.json">
        <Pack>true</Pack>
        <PackagePath>build\</PackagePath>
      </Content>
    </ItemGroup>
  </Target>
  <ItemGroup>
    <PackageReference Include="Microsoft.Extensions.DependencyModel" Version="1.0.1-beta-000933"/>
    <PackageReference Include="Microsoft.Build.Framework" Version="0.1.0-preview-00028-160627" />
    <PackageReference Include="Microsoft.Build.Utilities.Core" Version="0.1.0-preview-00028-160627" />
    <PackageReference Include="Newtonsoft.Json" Version="9.0.1" />
  </ItemGroup>
  <ItemGroup />
  <PropertyGroup Label="Globals">
    <ProjectGuid>463c66f0-921d-4d34-8bde-7c9d0bffaf7b</ProjectGuid>
  </PropertyGroup>
  <PropertyGroup Condition=" '$(TargetFramework)' == 'netstandard1.3' ">
    <DefineConstants>$(DefineConstants);NETSTANDARD1_3</DefineConstants>
  </PropertyGroup>
  <PropertyGroup Condition=" '$(Configuration)' == 'Release' ">
    <DefineConstants>$(DefineConstants);RELEASE</DefineConstants>
  </PropertyGroup>
</Project>
```

Consuming custom targets is done by providing a `<PackageReference>` that points to the package and its version inside the project that is being extended. Unlike the tools, the custom targets package does get included into the consuming project's dependency closure.

Using the custom target depends solely on how you configure it. Since it's an MSBuild target, it can depend on a given target, run after another target and can also be manually invoked using the `dotnet msbuild -t:<target-name>` command.

However, if you want to provide a better user experience to your users, you can combine per-project tools and custom targets. In this scenario, the per-project tool would essentially just accept whatever needed parameters and would translate that into the required `dotnet msbuild` invocation that would execute the target. You can see a sample of this kind of synergy on the [MVP Summit 2016 Hackathon samples](#) repo in the `dotnet-packer` project.

PATH-based extensibility

PATH-based extensibility is usually used for development machines where you need a tool that conceptually covers more than a single project. The main drawback of this extension mechanism is that it's tied to the machine where the tool exists. If you need it on another machine, you would have to deploy it.

This pattern of CLI toolset extensibility is very simple. As covered in the [.NET Core CLI overview](#), `dotnet` driver can run any command that is named after the `dotnet-<command>` convention. The default resolution logic first probes several locations and finally falls back to the system PATH. If the requested command exists in the system PATH and is a binary that can be invoked, `dotnet` driver will invoke it.

The file must be executable. On Unix systems, this means anything that has the execute bit set via `chmod +x`. On Windows, you can use *cmd* files.

Let's take a look at the very simple implementation of a "Hello World" tool. We will use both `bash` and `cmd` on Windows. The following command will simply echo "Hello World" to the console.

```
#!/bin/bash  
  
echo "Hello World!"
```

```
echo "Hello World"
```

On macOS, we can save this script as `dotnet-hello` and set its executable bit with `chmod +x dotnet-hello`. We can then create a symbolic link to it in `/usr/local/bin` using the command

```
ln -s <full_path>/dotnet-hello /usr/local/bin/. This will make it possible to invoke the command using the  
dotnet hello syntax.
```

On Windows, we can save this script as `dotnet-hello.cmd` and put it in a location that is in a system path (or you can add it to a folder that is already in the path). After this, you can just use `dotnet hello` to run this example.

Using .NET Core SDK and tools in Continuous Integration (CI)

1/23/2019 • 8 minutes to read • [Edit Online](#)

This document outlines using the .NET Core SDK and its tools on a build server. The .NET Core toolset works both interactively, where a developer types commands at a command prompt, and automatically, where a Continuous Integration (CI) server runs a build script. The commands, options, inputs, and outputs are the same, and the only things you supply are a way to acquire the tooling and a system to build your app. This document focuses on scenarios of tool acquisition for CI with recommendations on how to design and structure your build scripts.

Installation options for CI build servers

Using the native installers

Native installers are available for macOS, Linux, and Windows. The installers require admin (sudo) access to the build server. The advantage of using a native installer is that it installs all of the native dependencies required for the tooling to run. Native installers also provide a system-wide installation of the SDK.

macOS users should use the PKG installers. On Linux, there's a choice of using a feed-based package manager, such as apt-get for Ubuntu or yum for CentOS, or using the packages themselves, DEB or RPM. On Windows, use the MSI installer.

The latest stable binaries are found at [.NET downloads](#). If you wish to use the latest (and potentially unstable) pre-release tooling, use the links provided at the [dotnet/core-sdk GitHub repository](#). For Linux distributions, `tar.gz` archives (also known as `tarballs`) are available; use the installation scripts within the archives to install .NET Core.

Using the installer script

Using the installer script allows for non-administrative installation on your build server and easy automation for obtaining the tooling. The script takes care of downloading the tooling and extracting it into a default or specified location for use. You can also specify a version of the tooling that you wish to install and whether you want to install the entire SDK or only the shared runtime.

The installer script is automated to run at the start of the build to fetch and install the desired version of the SDK. The *desired version* is whatever version of the SDK your projects require to build. The script allows you to install the SDK in a local directory on the server, run the tools from the installed location, and then clean up (or let the CI service clean up) after the build. This provides encapsulation and isolation to your entire build process. The installation script reference is found in the [dotnet-install](#) article.

NOTE

Azure DevOps Services

When using the installer script, native dependencies aren't installed automatically. You must install the native dependencies if the operating system doesn't have them. For more information, see [Prerequisites for .NET Core on Linux](#).

CI setup examples

This section describes a manual setup using a PowerShell or bash script, along with a description of several software as a service (SaaS) CI solutions. The SaaS CI solutions covered are [Travis CI](#), [AppVeyor](#), and [Azure](#).

Manual setup

Each SaaS service has its own methods for creating and configuring a build process. If you use different SaaS solution than those listed or require customization beyond the pre-packaged support, you must perform at least some manual configuration.

In general, a manual setup requires you to acquire a version of the tools (or the latest nightly builds of the tools) and run your build script. You can use a PowerShell or bash script to orchestrate the .NET Core commands or use a project file that outlines the build process. The [orchestration section](#) provides more detail on these options.

After you create a script that performs a manual CI build server setup, use it on your dev machine to build your code locally for testing purposes. Once you confirm that the script is running well locally, deploy it to your CI build server. A relatively simple PowerShell script demonstrates how to obtain the .NET Core SDK and install it on a Windows build server:

```
$ErrorActionPreference="Stop"
$ProgressPreference="SilentlyContinue"

# $LocalDotnet is the path to the locally-installed SDK to ensure the
#   correct version of the tools are executed.
$LocalDotnet=""
# $InstallDir and $CliVersion variables can come from options to the
#   script.
$InstallDir = "./cli-tools"
$CliVersion = "1.0.1"

# Test the path provided by $InstallDir to confirm it exists. If it
#   does, it's removed. This is not strictly required, but it's a
#   good way to reset the environment.
if (Test-Path $InstallDir)
{
    rm -Recurse $InstallDir
}
New-Item -Type "directory" -Path $InstallDir

Write-Host "Downloading the CLI installer..."

# Use the Invoke-WebRequest PowerShell cmdlet to obtain the
#   installation script and save it into the installation directory.
Invoke-WebRequest `

    -Uri "https://dot.net/v1/dotnet-install.ps1" `

    -OutFile "$InstallDir/dotnet-install.ps1"

Write-Host "Installing the CLI requested version ($CliVersion) ..."

# Install the SDK of the version specified in $CliVersion into the
#   specified location ($InstallDir).
& $InstallDir/dotnet-install.ps1 -Version $CliVersion `

    -InstallDir $InstallDir

Write-Host "Downloading and installation of the SDK is complete."

# $LocalDotnet holds the path to dotnet.exe for future use by the
#   script.
$LocalDotnet = "$InstallDir/dotnet"

# Run the build process now. Implement your build script here.
```

You provide the implementation for your build process at the end of the script. The script acquires the tools and then executes your build process. For UNIX machines, the following bash script performs the actions described in the PowerShell script in a similar manner:

```

#!/bin/bash
INSTALLDIR="cli-tools"
CLI_VERSION=1.0.1
DOWNLOADER=$(which curl)
if [ -d "$INSTALLDIR" ]
then
    rm -rf "$INSTALLDIR"
fi
mkdir -p "$INSTALLDIR"
echo Downloading the CLI installer.
$DOWNLOADER https://dot.net/v1/dotnet-install.sh > "$INSTALLDIR/dotnet-install.sh"
chmod +x "$INSTALLDIR/dotnet-install.sh"
echo Installing the CLI requested version $CLI_VERSION. Please wait, installation may take a few minutes.
"$INSTALLDIR/dotnet-install.sh" --install-dir "$INSTALLDIR" --version $CLI_VERSION
if [ $? -ne 0 ]
then
    echo Download of $CLI_VERSION version of the CLI failed. Exiting now.
    exit 0
fi
echo The CLI has been installed.
LOCALDOTNET="$INSTALLDIR/dotnet"
# Run the build process now. Implement your build script here.

```

Travis CI

You can configure [Travis CI](#) to install the .NET Core SDK using the `csharp` language and the `dotnet` key. For more information, see the official Travis CI docs on [Building a C#, F#, or Visual Basic Project](#). Note as you access the Travis CI information that the community-maintained `language: csharp` language identifier works for all .NET languages, including F#, and Mono.

Travis CI runs both macOS and Linux jobs in a *build matrix*, where you specify a combination of runtime, environment, and exclusions/inclusions to cover your build combinations for your app. For more information, see the [Customizing the Build](#) article in the Travis CI documentation. The MSBuild-based tools include the LTS (1.0.x) and Current (1.1.x) runtimes in the package; so by installing the SDK, you receive everything you need to build.

AppVeyor

[AppVeyor](#) installs the .NET Core 1.0.1 SDK with the `Visual Studio 2017` build worker image. Other build images with different versions of the .NET Core SDK are available. For more information, see the [appveyor.yml example](#) and the [Build worker images](#) article in the AppVeyor docs.

The .NET Core SDK binaries are downloaded and unzipped in a subdirectory using the install script, and then they're added to the `PATH` environment variable. Add a build matrix to run integration tests with multiple versions of the .NET Core SDK:

```

environment:
matrix:
- CLI_VERSION: 1.0.1
- CLI_VERSION: Latest

install:
# See appveyor.yml example for install script

```

Azure DevOps Services

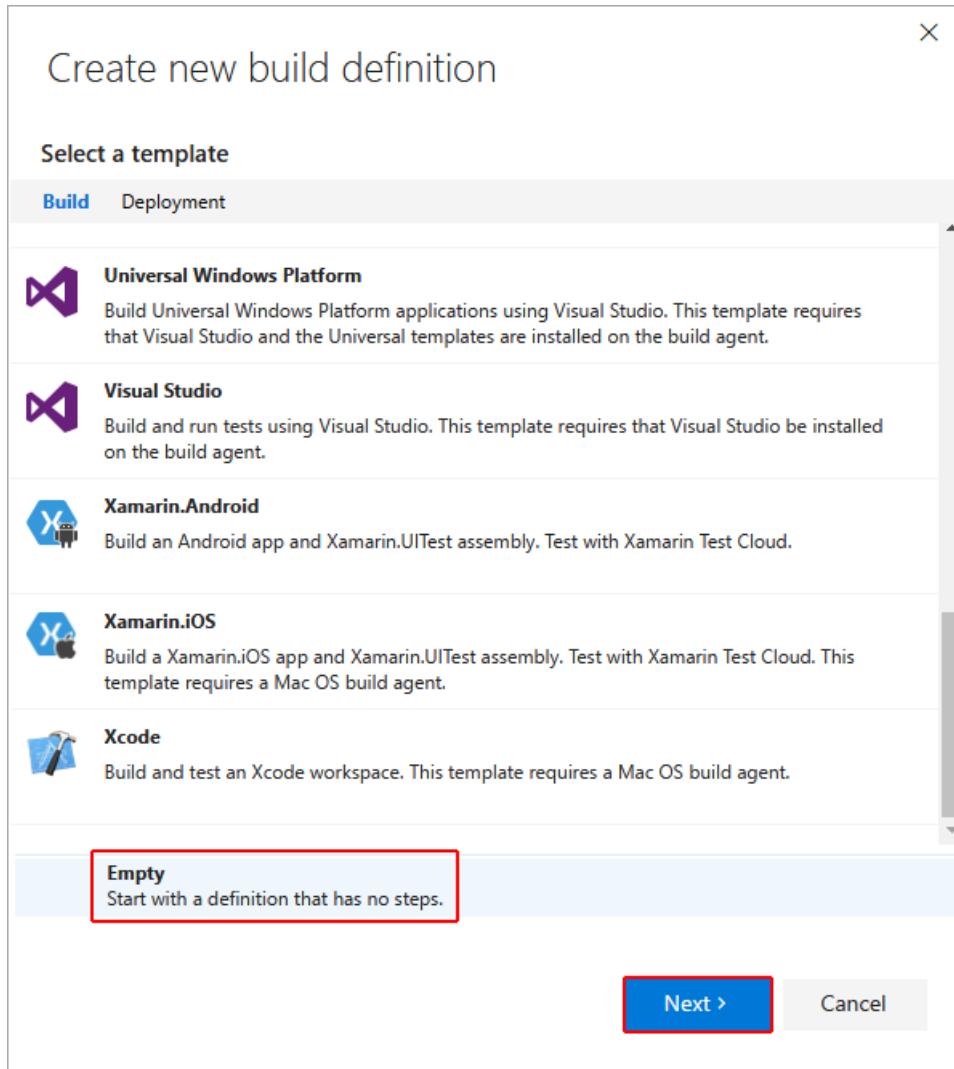

Configure Azure DevOps Services to build .NET Core projects using one of these approaches:

1. Run the script from the [manual setup step](#) using your commands.
2. Create a build composed of several Azure DevOps Services built-in build tasks that are configured to use .NET Core tools.

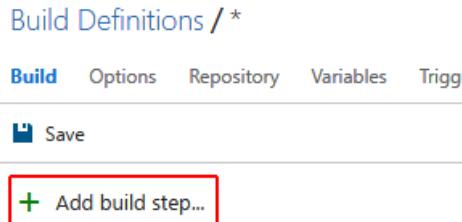

Both solutions are valid. Using a manual setup script, you control the version of the tools that you receive, since you download them as part of the build. The build is run from a script that you must create. This article only covers the manual option. For more information on composing a build with Azure DevOps Services build tasks, see the [Azure Pipelines documentation](#).

To use a manual setup script in Azure DevOps Services, create a new build definition and specify the script to run for the build step. This is accomplished using the Azure DevOps Services user interface:

1. Start by creating a new build definition. Once you reach the screen that provides you an option to define what kind of a build you wish to create, select the **Empty** option.

2. After configuring the repository to build, you're directed to the build definitions. Select **Add build step**:

3. You're presented with the **Task catalog**. The catalog contains tasks that you use in the build. Since you have a script, select the **Add** button for **PowerShell: Run a PowerShell script**.

The screenshot shows the 'Task catalog' window in Azure Pipelines. On the left, a sidebar lists categories: All, Build, Utility (which is selected), Test, Package, and Deploy. The main area displays a list of tasks with their icons and descriptions. The 'PowerShell' task is highlighted with a red border around its 'Add' button. Other tasks shown include Extract archive, FTP Upload, Jenkins Download Artifacts, Publish Build Artifacts, Shell Script, Update Service Fabric App Versions, and Xamarin License. A note at the bottom says 'Don't see what you need? Check out our Marketplace.' and a 'Close' button is at the bottom right.

4. Configure the build step. Add the script from the repository that you're building:

The screenshot shows the configuration for a 'PowerShell Script' build step. The 'File Path' field is highlighted with a red box. The 'Arguments' field is below it. Under 'Control Options', there are checkboxes for 'Enabled', 'Continue on error', 'Always run', and a 'Timeout' field set to 0. A 'Save' button is at the top left, and a 'Close' button is at the bottom right.

Orchestrating the build

Most of this document describes how to acquire the .NET Core tools and configure various CI services without providing information on how to orchestrate, or *actually build*, your code with .NET Core. The choices on how to structure the build process depend on many factors that can't be covered in a general way here. For more information on orchestrating your builds with each technology, explore the resources and samples provided in the documentation sets of [Travis CI](#), [AppVeyor](#), and [Azure Pipelines](#).

Two general approaches that you take in structuring the build process for .NET Core code using the .NET Core tools are using MSBuild directly or using the .NET Core command-line commands. Which approach you should take is determined by your comfort level with the approaches and trade-offs in complexity. MSBuild provides you the ability to express your build process as tasks and targets, but it comes with the added complexity of learning

MSBuild project file syntax. Using the .NET Core command-line tools is perhaps simpler, but it requires you to write orchestration logic in a scripting language like `bash` or PowerShell.

Custom templates for dotnet new

3/8/2019 • 7 minutes to read • [Edit Online](#)

The [.NET Core SDK](#) comes with many templates pre-installed to use with the `dotnet new` command. Starting with .NET Core 2.0, you can create your own custom templates for any type of project, such as an app, service, tool, or class library. You can even create a template that outputs one or more independent files, such as a configuration file.

You can install custom templates from a NuGet package on any NuGet feed, by referencing a NuGet *nupkg* file directly, or by specifying a file system directory that contains the template. The template engine offers features that allow you to replace values, include and exclude files and regions of files, and execute custom processing operations when your template is used.

The template engine is open source, and the online code repository is at [dotnettemplating](#) on GitHub. Visit the [dotnet/dotnet-template-samples](#) repo for samples of templates. More templates, including templates from third parties, are found at [Available templates for dotnet new](#) on GitHub. For more information about creating and using custom templates, see [How to create your own templates for dotnet new](#) and the [dotnettemplating GitHub repo Wiki](#).

To follow a walkthrough and create a template, see the [Create a custom template for dotnet new](#) tutorial.

Configuration

A template is composed of the following components:

- Source files and folders
- A configuration file (*template.json*)

Source files and folders

The source files and folders include whatever files and folders you want the template engine to use when the `dotnet new <TEMPLATE>` command is executed. The template engine is designed to use *runnable projects* as source code to produce projects. This has several benefits:

- The template engine doesn't require you to inject special tokens into your project's source code.
- The code files aren't special files or modified in any way to work with the template engine. So, the tools you normally use when working with projects also work with template content.
- You build, run, and debug your template projects just like you do for any of your other projects.
- You can quickly create a template from an existing project just by adding a *template.json* configuration file to the project.

Files and folders stored in the template aren't limited to formal .NET project types, such as .NET Core or .NET Framework solutions. Source files and folders may consist of any content that you wish to create when the template is used, even if the template engine produces just one file for its output, such as a configuration file or a solution file. For example, you can create a template that contains a *web.config* source file and creates a modified *web.config* file for projects where the template is used. The modifications to source files are based on logic and settings you've provided in the *template.json* configuration file along with values provided by the user passed as options to the `dotnet new <TEMPLATE>` command.

template.json

The *template.json* file is placed in a *.template.config* folder in the root directory of the template. The file provides configuration information to the template engine. The minimum configuration requires the members shown in the

following table, which is sufficient to create a functional template.

MEMBER	TYPE	DESCRIPTION
<code>\$schema</code>	URI	The JSON schema for the <i>template.json</i> file. Editors that support JSON schemas enable JSON-editing features when the schema is specified. For example, Visual Studio Code requires this member to enable IntelliSense. Use a value of http://json.schemastore.org/template .
<code>author</code>	string	The author of the template.
<code>classifications</code>	array(string)	Zero or more characteristics of the template that a user might use to find the template when searching for it. The classifications also appear in the <i>Tags</i> column when it appears in a list of templates produced by using the <code>dotnet new -1 --list</code> command.
<code>identity</code>	string	A unique name for this template.
<code>name</code>	string	The name for the template that users should see.
<code>shortName</code>	string	A default shorthand for selecting the template that applies to environments where the template name is specified by the user, not selected via a GUI. For example, the short name is useful when using templates from a command prompt with CLI commands.

Example:

```
{  
  "$schema": "http://json.schemastore.org/template",  
  "author": "Catalina Garcia",  
  "classifications": [ "Common", "Console" ],  
  "identity": "GarciaSoftware.ConsoleTemplate.CSharp",  
  "name": "Garcia Software Console Application",  
  "shortName": "garciaconsole"  
}
```

The full schema for the *template.json* file is found at the [JSON Schema Store](#).

.NET default templates

When you install the [.NET Core SDK](#), you receive over a dozen built-in templates for creating projects and files, including console apps, class libraries, unit test projects, ASP.NET Core apps (including [Angular](#) and [React](#) projects), and configuration files. To list the built-in templates, execute the `dotnet new` command with the `-1|--list` option:

```
dotnet new -1
```

Packing a template into a NuGet package (nupkg file)

Currently, a custom template is packed on Windows with [nuget.exe](#) (not [dotnet pack](#)). For cross-platform packaging, consider using [NuGetizer 3000](#).

The contents of the project folder, together with its `.template.config/template.json` file, are placed into a folder named `content`. Next to the `content` folder, add a [nuspec file](#), which is an XML manifest file that describes a package's contents and drives the process of creating the NuGet package. Inside of a `<packageTypes>` element in the `nuspec` file, include a `<packageType>` element with a `name` attribute value of `Template`. Both the `content` folder and the `nuspec` file should reside in the same directory. The table shows the minimum `nuspec` file elements required to produce a template as a NuGet package.

ELEMENT	TYPE	DESCRIPTION
<code><authors></code>	string	A comma-separated list of packages authors, matching the profile names on nuget.org. Authors are displayed in the NuGet Gallery on nuget.org and are used to cross-reference packages by the same authors.
<code><description></code>	string	A long description of the package for UI display.
<code><id></code>	string	The case-insensitive package identifier, which must be unique across nuget.org or whatever gallery the package will reside in. IDs may not contain spaces or characters that are not valid for a URL and generally follow .NET namespace rules. See Choosing a unique package identifier and setting the version number for guidance.
<code><packageType></code>	string	Place this element inside a <code><packageTypes></code> element among the <code><metadata></code> elements. Set the <code>name</code> attribute of the <code><packageType></code> element to <code>Template</code> .
<code><version></code>	string	The version of the package, following the major.minor.patch pattern. Version numbers may include a pre-release suffix as described in the Pre-release versions topic.

See the [.nuspec reference](#) for the complete `nuspec` file schema. An example `nuspec` file for a template appears in the [Create a custom template for dotnet new](#) tutorial.

Create a package using the `nuget pack <PATH_TO_NUSPEC_FILE>` command.

Installing a template

Install a custom template from a NuGet package on any NuGet feed by referencing a `nupkg` file directly or by specifying a file system directory that contains a templating configuration. Use the `-i|--install` option with the [dotnet new](#) command.

To install a template from a NuGet package stored at nuget.org

```
dotnet new -i <NUGET_PACKAGE_ID>
```

To install a template from a local nupkg file

```
dotnet new -i <PATH_TO_NUPKG_FILE>
```

To install a template from a file system directory

The `FILE_SYSTEM_DIRECTORY` is the project folder containing the project and the `.template.config` folder:

```
dotnet new -i <FILE_SYSTEM_DIRECTORY>
```

Uninstalling a template

Uninstall a custom template by referencing a NuGet package by its `id` or by specifying a file system directory that contains a templating configuration. Use the `-u|--uninstall` install option with the [dotnet new](#) command.

To uninstall a template from a NuGet package stored at nuget.org

```
dotnet new -u <NUGET_PACKAGE_ID>
```

To uninstall a template from a local nupkg file

To uninstall the template, don't attempt to use the path to the *nupkg* file. Attempting to uninstall a template using

```
dotnet new -u <PATH_TO_NUPKG_FILE>
```

fails. Reference the package by its `id`:

```
dotnet new -u <NUGET_PACKAGE_ID>
```

To uninstall a template from a file system directory

The `FILE_SYSTEM_DIRECTORY` is the project folder containing the project and the `.template.config` folder. The path provided needs to be the absolute path. Attempting to uninstall a template using a relative path fails. For more information, see the [dotnet new](#) article.

```
dotnet new -u <FILE_SYSTEM_DIRECTORY>
```

Create a project using a custom template

After a template is installed, use the template by executing the `dotnet new <TEMPLATE>` command as you would with any other pre-installed template. You can also specify [options](#) to the `dotnet new` command, including template specific options you configured in the template settings. Supply the template's short name directly to the command:

```
dotnet new <TEMPLATE>
```

How to enable TAB completion for .NET Core CLI

3/1/2019 • 2 minutes to read • [Edit Online](#)

Starting with .NET Core 2.0 SDK, the .NET Core CLI supports tab completion. This article describes how to configure tab completion for three shells, PowerShell, Bash, and zsh. Other shells may have support for auto completion. Refer to their documentation on how to configure auto completion, the steps should be similar to the steps described in this article.

This topic applies to: ✓ .NET Core 2.0 SDK and later versions

Once setup, tab completion for the .NET Core CLI is triggered by typing a `dotnet` command in the shell, and then pressing the TAB key. The current command line is sent to the `dotnet complete` command, and the results are processed by your shell. You can test the results without enabling tab completion by sending something directly to the `dotnet complete` command. For example:

```
> dotnet complete "dotnet a"
add
clean
--diagnostics
migrate
pack
```

If that command doesn't work, make sure that .NET Core 2.0 SDK or above is installed. If it's installed, but that command still doesn't work, make sure that the `dotnet` command resolves to a version of .NET Core 2.0 SDK and above. Use the `dotnet --version` command to see what version of `dotnet` your current path is resolving to. For more information, see [Select the .NET Core version to use](#).

Examples

Here are some examples of what tab completion provides:

INPUT	BECOMES	BECAUSE
<code>dotnet a*</code>	<code>dotnet add</code>	<code>add</code> is the first subcommand, alphabetically.
<code>dotnet add p*</code>	<code>dotnet add --help</code>	Tab completion matches substrings and <code>--help</code> comes first alphabetically.
<code>dotnet add p**</code>	<code>dotnet add package</code>	Pressing tab a second time brings up the next suggestion.
<code>dotnet add package Microsoft*</code>	<code>dotnet add package Microsoft.ApplicationInsights.Web</code>	Results are returned alphabetically.
<code>dotnet remove reference →</code>	<code>dotnet remove reference ...\\src\\OmniSharp.DotNet\\OmniSharp.DotNet.csproj</code>	Tab completion is project file aware.

PowerShell

To add tab completion to **PowerShell** for the .NET Core CLI, create or edit the profile stored in the variable `$PROFILE`. For more information, see [How to create your profile](#) and [Profiles and execution policy](#).

Add the following code to your profile:

```
# PowerShell parameter completion shim for the dotnet CLI
Register-ArgumentCompleter -Native -CommandName dotnet -ScriptBlock {
    param($commandName, $wordToComplete, $cursorPosition)
        dotnet complete --position $cursorPosition "$wordToComplete" | ForEach-Object {
            [System.Management.Automation.CompletionResult]::new($_, $_, 'ParameterValue', $_)
        }
}
```

Bash

To add tab completion to your **bash** shell for the .NET Core CLI, add the following code to your `.bashrc` file:

```
# bash parameter completion for the dotnet CLI

_dotnet_bash_complete()
{
    local word=${COMP_WORDS[COMP_CWORD]}

    local completions
    completions=$(dotnet complete --position "${COMP_POINT}" "${COMP_LINE}")

    COMPREPLY=( $(compgen -W "$completions" -- "$word") )
}

complete -f -F _dotnet_bash_complete dotnet
```

Zsh

To add tab completion to your **zsh** shell for the .NET Core CLI, add the following code to your `.zshrc` file:

```
# zsh parameter completion for the dotnet CLI

_dotnet_zsh_complete()
{
    local completions=$(dotnet complete "$words")

    reply=( "${(ps:\n:)completions}" )
}

compctl -K _dotnet_zsh_complete dotnet
```

dotnet command

3/19/2019 • 8 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet` - A tool for managing .NET source code and binaries.

Synopsis

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

```
dotnet [command] [arguments] [--additional-deps] [--additionalprobingpath] [-d|--diagnostics] [--fx-version]
      [-h|--help] [--info] [--list-runtimes] [--list-sdks] [--roll-forward-on-no-candidate-fx] [-v|--verbosity]
      [--version]
```

Description

`dotnet` is a tool for managing .NET source code and binaries. It exposes commands that perform specific tasks, such as `dotnet build` and `dotnet run`. Each command defines its own arguments. Type `--help` after each command to access brief help documentation.

`dotnet` can be used to run applications, by specifying an application DLL, such as `dotnet myapp.dll`. See [.NET Core application deployment](#) for to learn about deployment options.

Options

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

`--additional-deps <PATH>`

Path to additional *deps.json* file.

`--additionalprobingpath <PATH>`

Path containing probing policy and assemblies to probe.

`-d|--diagnostics`

Enables diagnostic output.

`--fx-version <VERSION>`

Version of the .NET Core runtime to use to run the application.

`-h|--help`

Prints out documentation for a given command, such as `dotnet build --help`. `dotnet --help` prints a list of available commands.

`--info`

Prints out detailed information about a .NET Core installation and the machine environment, such as the current operating system, and commit SHA of the .NET Core version.

`--list-runtimes`

Displays the installed .NET Core runtimes.

`--list-sdks`

Displays the installed .NET Core SDKs.

`--roll-forward-on-no-candidate-fx <N>`

Defines behavior when the required shared framework is not available. `N` can be:

- `0` - Disable even minor version roll forward.
- `1` - Roll forward on minor version, but not on major version. This is the default behavior.
- `2` - Roll forward on minor and major versions.

For more information, see [Roll forward](#).

`-v|--verbosity <LEVEL>`

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`. Not supported in every command; see specific command page to determine if this option is available.

`--version`

Prints out the version of the .NET Core SDK in use.

dotnet commands

General

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

COMMAND	FUNCTION
dotnet build	Builds a .NET Core application.
dotnet build-server	Interacts with servers started by a build.
dotnet clean	Clean build outputs.
dotnet help	Shows more detailed documentation online for the command.
dotnet migrate	Migrates a valid Preview 2 project to a .NET Core SDK 1.0 project.
dotnet msbuild	Provides access to the MSBuild command line.

COMMAND	FUNCTION
dotnet new	Initializes a C# or F# project for a given template.
dotnet pack	Creates a NuGet package of your code.
dotnet publish	Publishes a .NET framework-dependent or self-contained application.
dotnet restore	Restores the dependencies for a given application.
dotnet run	Runs the application from source.
dotnet sln	Options to add, remove, and list projects in a solution file.
dotnet store	Stores assemblies in the runtime package store.
dotnet test	Runs tests using a test runner.

Project references

COMMAND	FUNCTION
dotnet add reference	Adds a project reference.
dotnet list reference	Lists project references.
dotnet remove reference	Removes a project reference.

NuGet packages

COMMAND	FUNCTION
dotnet add package	Adds a NuGet package.
dotnet remove package	Removes a NuGet package.

NuGet commands

COMMAND	FUNCTION
dotnet nuget delete	Deletes or unlists a package from the server.
dotnet nuget locals	Clears or lists local NuGet resources such as http-request cache, temporary cache, or machine-wide global packages folder.
dotnet nuget push	Pushes a package to the server and publishes it.

Global Tools commands

.NET Core Global Tools are available starting with .NET Core SDK 2.1.300:

COMMAND	FUNCTION
<code>dotnet tool install</code>	Installs a Global Tool on your machine.
<code>dotnet tool list</code>	Lists all Global Tools currently installed in the default directory on your machine or in the specified path.
<code>dotnet tool uninstall</code>	Uninstalls a Global Tool from your machine.
<code>dotnet tool update</code>	Updates a Global Tool on your machine.

Additional tools

Starting with .NET Core SDK 2.1.300, a number of tools that were available only on a per project basis using `DotnetCliToolReference` are now available as part of the .NET Core SDK. These tools are listed in the following table:

TOOL	FUNCTION
<code>dev-certs</code>	Creates and manages development certificates.
<code>ef</code>	Entity Framework Core command-line tools.
<code>sql-cache</code>	SQL Server cache command-line tools.
<code>user-secrets</code>	Manages development user secrets.
<code>watch</code>	Starts a file watcher that runs a command when files change.

For more information about each tool, type `dotnet <tool-name> --help`.

Examples

Creates a new .NET Core console application:

```
dotnet new console
```

Restore dependencies for a given application:

```
dotnet restore
```

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

Build a project and its dependencies in a given directory:

```
dotnet build
```

Run an application DLL, such as `myapp.dll`:

```
dotnet myapp.dll
```

Environment variables

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

DOTNET_PACKAGES

The primary package cache. If not set, it defaults to `$HOME/.nuget/packages` on Unix or `%HOME%\NuGet\Packages` on Windows.

DOTNET_SERVICING

Specifies the location of the servicing index to use by the shared host when loading the runtime.

DOTNET_CLI_TELEMETRY_OPTOUT

Specifies whether data about the .NET Core tools usage is collected and sent to Microsoft. Set to `true` to opt-out of the telemetry feature (values `true`, `1`, or `yes` accepted). Otherwise, set to `false` to opt into the telemetry features (values `false`, `0`, or `no` accepted). If not set, the default is `false` and the telemetry feature is active.

DOTNET_MULTILEVEL_LOOKUP

Specifies whether .NET Core runtime, shared framework, or SDK are resolved from the global location. If not set, it defaults to `true`. Set to `false` to not resolve from the global location and have isolated .NET Core installations (values `0` or `false` are accepted). For more information about multi-level lookup, see [Multi-level SharedFX Lookup](#).

DOTNET_ROLL_FORWARD_ON_NO_CANDIDATE_FX

Disables minor version roll forward, if set to `0`. For more information, see [Roll forward](#).

dotnet build

12/10/2018 • 5 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet build` - Builds a project and all of its dependencies.

Synopsis

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

```
dotnet build [<PROJECT>|<SOLUTION>] [-c|--configuration] [-f|--framework] [--force] [--no-dependencies] [--no-incremental]
    [--no-restore] [-o|--output] [-r|--runtime] [-v|--verbosity] [--version-suffix]

dotnet build [-h|--help]
```

Description

The `dotnet build` command builds the project and its dependencies into a set of binaries. The binaries include the project's code in Intermediate Language (IL) files with a *.dll* extension and symbol files used for debugging with a *.pdb* extension. A dependencies JSON file (**.deps.json*) is produced that lists the dependencies of the application. A **.runtimeconfig.json* file is produced, which specifies the shared runtime and its version for the application.

If the project has third-party dependencies, such as libraries from NuGet, they're resolved from the NuGet cache and aren't available with the project's built output. With that in mind, the product of `dotnet build` isn't ready to be transferred to another machine to run. This is in contrast to the behavior of the .NET Framework in which building an executable project (an application) produces output that's runnable on any machine where the .NET Framework is installed. To have a similar experience with .NET Core, you need to use the [dotnet publish](#) command. For more information, see [.NET Core Application Deployment](#).

Building requires the *project.assets.json* file, which lists the dependencies of your application. The file is created when `dotnet restore` is executed. Without the assets file in place, the tooling cannot resolve reference assemblies, which results in errors. With .NET Core 1.x SDK, you needed to explicitly run the `dotnet restore` before running `dotnet build`. Starting with .NET Core 2.0 SDK, `dotnet restore` runs implicitly when you run `dotnet build`. If you want to disable implicit restore when running the build command, you can pass the `--no-restore` option.

NOTE

Starting with .NET Core 2.0, you don't have to run `dotnet restore` because it's run implicitly by all commands, such as `dotnet build` and `dotnet run`, that require a restore to occur. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

This command also supports the `dotnet restore` options when passed in the long form (for example, `--source`). Short form options, such as `-s`, are not supported.

Whether the project is executable or not is determined by the `<OutputType>` property in the project file. The following example shows a project that produces executable code:

```
<PropertyGroup>
  <OutputType>Exe</OutputType>
</PropertyGroup>
```

In order to produce a library, omit the `<outputType>` property. The main difference in built output is that the IL DLL for a library doesn't contain entry points and can't be executed.

MSBuild

`dotnet build` uses MSBuild to build the project, so it supports both parallel and incremental builds. For more information, see [Incremental Builds](#).

In addition to its options, the `dotnet build` command accepts MSBuild options, such as `-p` for setting properties or `-l` to define a logger. For more information about these options, see the [MSBuild Command-Line Reference](#). Or you can also use the `dotnet msbuild` command.

Running `dotnet build` is equivalent to `dotnet msbuild -restore -target:Build`.

Arguments

PROJECT | SOLUTION

The project or solution file to build. If a project or solution file is not specified, MSBuild searches the current working directory for a file that has a file extension that ends in either *proj* or *sln* and uses that file.

Options

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)
- `-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`.
- `-f|--framework <FRAMEWORK>`

Compiles for a specific [framework](#). The framework must be defined in the [project file](#).
- `--force`

Forces all dependencies to be resolved even if the last restore was successful. Specifying this flag is the same as deleting the `project.assets.json` file.
- `-h|--help`

Prints out a short help for the command.

- `--no-dependencies`

Ignores project-to-project (P2P) references and only builds the specified root project.

- `--no-incremental`

Marks the build as unsafe for incremental build. This flag turns off incremental compilation and forces a clean rebuild of the project's dependency graph.

- `--no-restore`

Doesn't execute an implicit restore during build.

- `-o| --output <OUTPUT_DIRECTORY>`

Directory in which to place the built binaries. You also need to define `--framework` when you specify this option. If not specified, the default path is `./bin/<configuration>/<framework>/`.

- `-r| --runtime <RUNTIME_IDENTIFIER>`

Specifies the target runtime. For a list of Runtime Identifiers (RIDs), see the [RID catalog](#).

- `-v| --verbosity <LEVEL>`

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

- `--version-suffix <VERSION_SUFFIX>`

Defines the version suffix for an asterisk (`*`) in the version field of the project file. The format follows NuGet's version guidelines.

Examples

- Build a project and its dependencies:

```
dotnet build
```

- Build a project and its dependencies using Release configuration:

```
dotnet build --configuration Release
```

- Build a project and its dependencies for a specific runtime (in this example, Ubuntu 16.04):

```
dotnet build --runtime ubuntu.16.04-x64
```

- Build the project and use the specified NuGet package source during the restore operation (.NET Core 2.0 SDK and later versions):

```
dotnet build --source c:\packages\mypackages
```

- Build the project and set 1.2.3.4 version as a build parameter:

```
dotnet build -p:Version=1.2.3.4
```

dotnet build-server

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

Name

`dotnet build-server` - Interacts with servers started by a build.

Synopsis

```
dotnet build-server shutdown [--msbuild] [--razor] [--vbcscompiler]
dotnet build-server shutdown [-h|--help]
dotnet build-server [-h|--help]
```

Commands

- `shutdown`

Shuts down build servers that are started from dotnet. By default, all servers are shut down.

Options

- `-h|--help`

Prints out a short help for the command.

- `--msbuild`

Shuts down the MSBuild build server.

- `--razor`

Shuts down the Razor build server.

- `--vbcscompiler`

Shuts down the VB/C# compiler build server.

dotnet clean

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet clean` - Cleans the output of a project.

Synopsis

```
dotnet clean [<PROJECT>] [-c|--configuration] [-f|--framework] [-o|--output] [-r|--runtime] [-v|--verbosity]
dotnet clean [-h|--help]
```

Description

The `dotnet clean` command cleans the output of the previous build. It's implemented as an [MSBuild target](#), so the project is evaluated when the command is run. Only the outputs created during the build are cleaned. Both intermediate (*obj*) and final output (*bin*) folders are cleaned.

Arguments

`PROJECT`

The MSBuild project to clean. If a project file is not specified, MSBuild searches the current working directory for a file that has a file extension that ends in *proj* and uses that file.

Options

- `-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`. This option is only required when cleaning if you specified it during build time.

- `-f|--framework <FRAMEWORK>`

The [framework](#) that was specified at build time. The framework must be defined in the [project file](#). If you specified the framework at build time, you must specify the framework when cleaning.

- `-h|--help`

Prints out a short help for the command.

- `-o|--output <OUTPUT_DIRECTORY>`

Directory in which the build outputs are placed. Specify the `-f|--framework <FRAMEWORK>` switch with the output directory switch if you specified the framework when the project was built.

- `-r|--runtime <RUNTIME_IDENTIFIER>`

Cleans the output folder of the specified runtime. This is used when a [self-contained deployment](#) was created. Option available since .NET Core 2.0 SDK.

- `-v|--verbosity <LEVEL>`

Sets the verbosity level of the command. Allowed levels are q[uiet], m[inimal], n[ormal], d[etailed], and diag[nostic].

Examples

- Clean a default build of the project:

```
dotnet clean
```

- Clean a project built using the Release configuration:

```
dotnet clean --configuration Release
```

dotnet help reference

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.0 SDK and later versions

Name

`dotnet help` - Shows more detailed documentation online for the specified command.

Synopsis

```
dotnet help <COMMAND_NAME> [-h|--help]
```

Description

The `dotnet help` command opens up the reference page for more detailed information about the specified command at docs.microsoft.com.

Arguments

- `COMMAND_NAME`

Name of the .NET Core CLI command. For a list of the valid CLI commands, see [CLI commands](#).

Options

- `-h|--help`

Prints out a short help for the command.

Examples

- Opens the documentation page for the `dotnet new` command:

```
dotnet help new
```

dotnet migrate

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet migrate` - Migrates a Preview 2 .NET Core project to a .NET Core SDK 1.0 project.

Synopsis

```
dotnet migrate [<SOLUTION_FILE|PROJECT_DIR>] [--format-report-file=json] [-r|--report-file] [-s|--skip-project-references] [--skip-backup] [-t|--template-file] [-v|--sdk-package-version] [-x|--xproj-file]
dotnet migrate [-h|--help]
```

Description

The `dotnet migrate` command migrates a valid Preview 2 *project.json*-based project to a valid .NET Core SDK 1.0 *csproj* project.

By default, the command migrates the root project and any project references that the root project contains. This behavior is disabled using the `--skip-project-references` option at runtime.

Migration can be performed on the following assets:

- A single project by specifying the *project.json* file to migrate.
- All of the directories specified in the *global.json* file by passing in a path to the *global.json* file.
- A *solution.sln* file, where it migrates the projects referenced in the solution.
- On all subdirectories of the given directory recursively.

The `dotnet migrate` command keeps the migrated *project.json* file inside a `backup` directory, which it creates if the directory doesn't exist. This behavior is overridden using the `--skip-backup` option.

By default, the migration operation outputs the state of the migration process to standard output (STDOUT). If you use the `--report-file <REPORT_FILE>` option, the output is saved to the file specify.

The `dotnet migrate` command only supports valid Preview 2 *project.json*-based projects. This means that you cannot use it to migrate DNX or Preview 1 *project.json*-based projects directly to MSBuild/csproj projects. You first need to manually migrate the project to a Preview 2 *project.json*-based project and then use the `dotnet migrate` command to migrate the project.

Arguments

`PROJECT_JSON/GLOBAL_JSON/SOLUTION_FILE/PROJECT_DIR`

The path to one of the following:

- a *project.json* file to migrate.
- a *global.json* file: the folders specified in *global.json* are migrated.
- a *solution.sln* file: the projects referenced in the solution are migrated.
- a directory to migrate: recursively searches for *project.json* files to migrate inside the specified directory.

Defaults to current directory if nothing is specified.

Options

```
--format-report-file-json <REPORT_FILE>
```

Output migration report file as JSON rather than user messages.

```
-h|--help
```

Prints out a short help for the command.

```
-r|--report-file <REPORT_FILE>
```

Output migration report to a file in addition to the console.

```
-s|--skip-project-references [Debug|Release]
```

Skip migrating project references. By default, project references are migrated recursively.

```
--skip-backup
```

Skip moving *project.json*, *global.json*, and **.xproj* to a `backup` directory after successful migration.

```
-t|--template-file <TEMPLATE_FILE>
```

Template csproj file to use for migration. By default, the same template as the one dropped by `dotnet new console` is used.

```
-v|--sdk-package-version <VERSION>
```

The version of the sdk package that's referenced in the migrated app. The default is the version of the SDK in `dotnet new`.

```
-x|--xproj-file <FILE>
```

The path to the xproj file to use. Required when there is more than one xproj in a project directory.

Examples

Migrate a project in the current directory and all of its project-to-project dependencies:

```
dotnet migrate
```

Migrate all projects that *global.json* file includes:

```
dotnet migrate path/to/global.json
```

Migrate only the current project and no project-to-project (P2P) dependencies. Also, use a specific SDK version:

```
dotnet migrate -s -v 1.0.0-preview4
```

dotnet msbuild

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet msbuild` - Builds a project and all of its dependencies.

Synopsis

`dotnet msbuild <msbuild_arguments> [-h]`

Description

The `dotnet msbuild` command allows access to a fully functional MSBuild.

The command has the exact same capabilities as the existing MSBuild command-line client for SDK-style project only. The options are all the same. For more information about the available options, see the [MSBuild Command-Line Reference](#).

The `dotnet build` command is equivalent to `dotnet msbuild -restore -target:Build`. `dotnet build` is more commonly used for building projects, but `dotnet msbuild` gives you more control. For example, if you have a specific target you want to run (without running the build target), you probably want to use `dotnet msbuild`.

Examples

- Build a project and its dependencies:

```
dotnet msbuild
```

- Build a project and its dependencies using Release configuration:

```
dotnet msbuild -p:Configuration=Release
```

- Run the publish target and publish for the `osx.10.11-x64` RID:

```
dotnet msbuild -t:Publish -p:RuntimeIdentifiers=osx.10.11-x64
```

- See the whole project with all targets included by the SDK:

```
dotnet msbuild -pp
```

dotnet new

1/23/2019 • 15 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet new` - Creates a new project, configuration file, or solution based on the specified template.

Synopsis

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

```
dotnet new <TEMPLATE> [--force] [-i|--install] [-lang|--language] [-n|--name] [--nuget-source] [-o|-  
-output]  
      [-u|--uninstall] [Template options]  
dotnet new <TEMPLATE> [-l|--list] [--type]  
dotnet new [-h|--help]
```

Description

The `dotnet new` command provides a convenient way to initialize a valid .NET Core project.

The command calls the [template engine](#) to create the artifacts on disk based on the specified template and options.

Arguments

`TEMPLATE`

The template to instantiate when the command is invoked. Each template might have specific options you can pass. For more information, see [Template options](#).

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

The command contains a default list of templates. Use `dotnet new -l` to obtain a list of the available templates. The following table shows the templates that come pre-installed with the .NET Core SDK 2.1.300. The default language for the template is shown inside the brackets.

TEMPLATE DESCRIPTION	TEMPLATE NAME	LANGUAGES
Console application	<code>console</code>	[C#], F#, VB
Class library	<code>classlib</code>	[C#], F#, VB
Unit test project	<code>mstest</code>	[C#], F#, VB

TEMPLATE DESCRIPTION	TEMPLATE NAME	LANGUAGES
xUnit test project	xunit	[C#], F#, VB
NUnit test project	nunit	[C#], F#, VB
Razor page	page	[C#]
MVC ViewImports	viewimports	[C#]
MVC ViewStart	viewstart	[C#]
ASP.NET Core empty	web	[C#], F#
ASP.NET Core Web App (Model-View-Controller)	mvc	[C#], F#
ASP.NET Core Web App	razor , webapp	[C#]
ASP.NET Core with Angular	angular	[C#]
ASP.NET Core with React.js	react	[C#]
ASP.NET Core with React.js and Redux	reactredux	[C#]
ASP.NET Core Web API	webapi	[C#], F#
Razor class library	razorclasslib	[C#]
global.json file	globaljson	
NuGet config	nugetconfig	
Web config	webconfig	
Solution file	sln	

Options

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

--force

Forces content to be generated even if it would change existing files. This is required when the output directory already contains a project.

-h|--help

Prints out help for the command. It can be invoked for the `dotnet new` command itself or for any

template, such as `dotnet new mvc --help`.

`-i|--install <PATH|NUGET_ID>`

Installs a source or template pack from the `PATH` or `NUGET_ID` provided. If you want to install a prerelease version of a template package, you need to specify the version in the format of `<package-name>::<package-version>`. By default, `dotnet new` passes * for the version, which represents the last stable package version. See an example at the [Examples](#) section.

For information on creating custom templates, see [Custom templates for dotnet new](#).

`-l|--list`

Lists templates containing the specified name. If invoked for the `dotnet new` command, it lists the possible templates available for the given directory. For example if the directory already contains a project, it doesn't list all project templates.

`-lang|--language {C#|F#|VB}`

The language of the template to create. The language accepted varies by the template (see defaults in the [arguments](#) section). Not valid for some templates.

NOTE

Some shells interpret # as a special character. In those cases, you need to enclose the language parameter value, such as `dotnet new console -lang "F#"`.

`-n|--name <OUTPUT_NAME>`

The name for the created output. If no name is specified, the name of the current directory is used.

`--nuget-source`

Specifies a NuGet source to use during install.

`-o|--output <OUTPUT_DIRECTORY>`

Location to place the generated output. The default is the current directory.

`--type`

Filters templates based on available types. Predefined values are "project", "item" or "other".

`-u|--uninstall <PATH|NUGET_ID>`

Uninstalls a source or template pack at the `PATH` or `NUGET_ID` provided.

NOTE

To uninstall a template using a `PATH`, you need to fully qualify the path. For example, `C:/Users/<USER>/Documents/Templates/GarciaSoftware.ConsoleTemplate.CSharp` will work, but `./GarciaSoftware.ConsoleTemplate.CSharp` from the containing folder will not. Additionally, do not include a final terminating directory slash on your template path.

Template options

Each project template may have additional options available. The core templates have the following additional options:

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

console, angular, react, reactredux, razorclasslib

`--no-restore` - Doesn't execute an implicit restore during project creation.

classlib

`-f| --framework <FRAMEWORK>` - Specifies the [framework](#) to target. Values: `netcoreapp2.0` to create a .NET Core Class Library or `netstandard2.0` to create a .NET Standard Class Library. The default value is `netstandard2.0`.

`--no-restore` - Doesn't execute an implicit restore during project creation.

mstest, xunit

`-p| --enable-pack` - Enables packaging for the project using [dotnet pack](#).

`--no-restore` - Doesn't execute an implicit restore during project creation.

globaljson

`--sdk-version <VERSION_NUMBER>` - Specifies the version of the .NET Core SDK to use in the *global.json* file.

web

`--exclude-launch-settings` - Exclude *launchSettings.json* from the generated template.

`--no-restore` - Doesn't execute an implicit restore during project creation.

`--no-https` - Project doesn't require HTTPS. This option only applies if `IndividualAuth` or `OrganizationalAuth` are not being used.

webapi

`-au| --auth <AUTHENTICATION_TYPE>` - The type of authentication to use. The possible values are:

- `None` - No authentication (Default).
- `IndividualB2C` - Individual authentication with Azure AD B2C.
- `SingleOrg` - Organizational authentication for a single tenant.
- `Windows` - Windows authentication.

`--aad-b2c-instance <INSTANCE>` - The Azure Active Directory B2C instance to connect to. Use with `IndividualB2C` authentication. The default value is `https://login.microsoftonline.com/tfp/`.

`-ssp| --sus-i-policy-id <ID>` - The sign-in and sign-up policy ID for this project. Use with `IndividualB2C` authentication.

`--aad-instance <INSTANCE>` - The Azure Active Directory instance to connect to. Use with `SingleOrg` authentication. The default value is `https://login.microsoftonline.com/`.

`--client-id <ID>` - The Client ID for this project. Use with `IndividualB2C` or `SingleOrg` authentication. The default value is `11111111-1111-1111-1111-111111111111`.

`--domain <DOMAIN>` - The domain for the directory tenant. Use with `SingleOrg` or `IndividualB2C` authentication. The default value is `qualified.domain.name`.

`--tenant-id <ID>` - The TenantId ID of the directory to connect to. Use with `SingleOrg` authentication. The default value is `22222222-2222-2222-2222-222222222222`.

`-r|--org-read-access` - Allows this application read-access to the directory. Only applies to `SingleOrg` or `MultiOrg` authentication.

`--exclude-launch-settings` - Exclude `launchSettings.json` from the generated template.

`-uld|--use-local-db` - Specifies LocalDB should be used instead of SQLite. Only applies to `Individual` or `IndividualB2C` authentication.

`--no-restore` - Doesn't execute an implicit restore during project creation.

`--no-https` - Project doesn't require HTTPS. `app.UseHsts` and `app.UseHttpsRedirection` aren't added to `Startup.Configure`. This option only applies if `Individual`, `IndividualB2C`, `SingleOrg`, or `MultiOrg` aren't being used.

mvc, razor

`-au|--auth <AUTHENTICATION_TYPE>` - The type of authentication to use. The possible values are:

- `None` - No authentication (Default).
- `Individual` - Individual authentication.
- `IndividualB2C` - Individual authentication with Azure AD B2C.
- `SingleOrg` - Organizational authentication for a single tenant.
- `MultiOrg` - Organizational authentication for multiple tenants.
- `Windows` - Windows authentication.

`--aad-b2c-instance <INSTANCE>` - The Azure Active Directory B2C instance to connect to. Use with `IndividualB2C` authentication. The default value is `https://login.microsoftonline.com/tfp/`.

`-ssp|--sus-i-policy-id <ID>` - The sign-in and sign-up policy ID for this project. Use with `IndividualB2C` authentication.

`-rp|--reset-password-policy-id <ID>` - The reset password policy ID for this project. Use with `IndividualB2C` authentication.

`-ep|--edit-profile-policy-id <ID>` - The edit profile policy ID for this project. Use with `IndividualB2C` authentication.

`--aad-instance <INSTANCE>` - The Azure Active Directory instance to connect to. Use with `SingleOrg` or `MultiOrg` authentication. The default value is `https://login.microsoftonline.com/`.

`--client-id <ID>` - The Client ID for this project. Use with `IndividualB2C`, `SingleOrg`, or `MultiOrg` authentication. The default value is `11111111-1111-1111-1111-111111111111`.

`--domain <DOMAIN>` - The domain for the directory tenant. Use with `SingleOrg` or `IndividualB2C` authentication. The default value is `qualified.domain.name`.

`--tenant-id <ID>` - The TenantId ID of the directory to connect to. Use with `SingleOrg` authentication. The default value is `22222222-2222-2222-2222-222222222222`.

`--callback-path <PATH>` - The request path within the application's base path of the redirect URI. Use with `SingleOrg` or `IndividualB2C` authentication. The default value is `/signin-oidc`.

`-r|--org-read-access` - Allows this application read-access to the directory. Only applies to `SingleOrg` or `MultiOrg` authentication.

--exclude-launch-settings - Exclude *launchSettings.json* from the generated template.

--use-browserlink - Includes BrowserLink in the project.

-uld|--use-local-db - Specifies LocalDB should be used instead of SQLite. Only applies to Individual or IndividualB2C authentication.

--no-restore - Doesn't execute an implicit restore during project creation.

--no-https - Project doesn't require HTTPS. `app.UseHsts` and `app.UseHttpsRedirection` aren't added to `Startup.Configure`. This option only applies if Individual, IndividualB2C, SingleOrg, or MultiOrg aren't being used.

page

-na|--namespace <NAMESPACE_NAME> - Namespace for the generated code. The default value is `MyApp.Namespace`.

-np|--no-pagemode - Creates the page without a PageModel.

viewimports

-na|--namespace <NAMESPACE_NAME> - Namespace for the generated code. The default value is `MyApp.Namespace`.

Examples

Create an F# console application project in the current directory:

```
dotnet new console -lang F#
```

Create a .NET Standard class library project in the specified directory (available only with .NET Core SDK 2.0 or later versions):

```
dotnet new classlib -lang VB -o MyLibrary
```

Create a new ASP.NET Core C# MVC application project in the current directory with no authentication:

```
dotnet new mvc -au None
```

Create a new xUnit application:

```
dotnet new xunit
```

List all templates available for MVC:

```
dotnet new mvc -l
```

Install version 2.0 of the Single Page Application templates for ASP.NET Core (command option available for .NET Core SDK 1.1 and later versions only):

```
dotnet new -i Microsoft.DotNet.Web.Spa.ProjectTemplates::2.0.0
```

Create a *global.json* in the current directory setting the SDK version to 2.0.0 (available only with .NET Core SDK 2.0 or later versions):

```
dotnet new globaljson --sdk-version 2.0.0
```

dotnet nuget delete

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet nuget delete` - Deletes or unlists a package from the server.

Synopsis

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

```
dotnet nuget delete [<PACKAGE_NAME> <PACKAGE_VERSION>] [--force-english-output] [--interactive] [-k|--api-key]
[--no-service-endpoint]
[--non-interactive] [-s|--source]
dotnet nuget delete [-h|--help]
```

Description

The `dotnet nuget delete` command deletes or unlists a package from the server. For [nuget.org](#), the action is to unlist the package.

Arguments

- `PACKAGE_NAME`

Name/ID of the package to delete.

- `PACKAGE_VERSION`

Version of the package to delete.

Options

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

- `--force-english-output`

Forces the application to run using an invariant, English-based culture.

- `-h|--help`

Prints out a short help for the command.

- `--interactive`

Allows the command to block and requires manual action for operations like authentication. Option available since .NET Core 2.2 SDK.

- `-k|--api-key <API_KEY>`

The API key for the server.

- `--no-service-endpoint`

Doesn't append "api/v2/package" to the source URL. Option available since .NET Core 2.1 SDK.

- `--non-interactive`

Doesn't prompt for user input or confirmations.

- `-s|--source <SOURCE>`

Specifies the server URL. Supported URLs for nuget.org include `https://www.nuget.org`, `https://www.nuget.org/api/v3`, and `https://www.nuget.org/api/v2/package`. For private feeds, replace the host name (for example, `%hostname%/api/v3`).

Examples

- Deletes version 1.0 of package `Microsoft.AspNetCore.Mvc`:

```
dotnet nuget delete Microsoft.AspNetCore.Mvc 1.0
```

- Deletes version 1.0 of package `Microsoft.AspNetCore.Mvc`, not prompting user for credentials or other input:

```
dotnet nuget delete Microsoft.AspNetCore.Mvc 1.0 --non-interactive
```

dotnet nuget locals

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet nuget locals` - Clears or lists local NuGet resources.

Synopsis

```
dotnet nuget locals <CACHE_LOCATION> [(-c|--clear)|(-l|--list)] [--force-english-output]
dotnet nuget locals [-h|--help]
```

Description

The `dotnet nuget locals` command clears or lists local NuGet resources in the http-request cache, temporary cache, or machine-wide global packages folder.

Arguments

- `CACHE_LOCATION`

The cache location to list or clear. It accepts one of the following values:

- `all` - Indicates that the specified operation is applied to all cache types: http-request cache, global packages cache, and the temporary cache.
- `http-cache` - Indicates that the specified operation is applied only to the http-request cache. The other cache locations aren't affected.
- `global-packages` - Indicates that the specified operation is applied only to the global packages cache. The other cache locations aren't affected.
- `temp` - Indicates that the specified operation is applied only to the temporary cache. The other cache locations aren't affected.

Options

- `--force-english-output`

Forces the application to run using an invariant, English-based culture.

- `-h|--help`

Prints out a short help for the command.

- `-c|--clear`

The clear option executes a clear operation on the specified cache type. The contents of the cache directories are deleted recursively. The executing user/group must have permission to the files in the cache directories. If not, an error is displayed indicating the files/folders that weren't cleared.

- `-l|--list`

The list option is used to display the location of the specified cache type.

Examples

- Displays the paths of all the local cache directories (http-cache directory, global-packages cache directory, and temporary cache directory):

```
dotnet nuget locals -l all
```

- Displays the path for the local http-cache directory:

```
dotnet nuget locals --list http-cache
```

- Clears all files from all local cache directories (http-cache directory, global-packages cache directory, and temporary cache directory):

```
dotnet nuget locals --clear all
```

- Clears all files in local global-packages cache directory:

```
dotnet nuget locals -c global-packages
```

- Clears all files in local temporary cache directory:

```
dotnet nuget locals -c temp
```

Troubleshooting

For information on common problems and errors while using the `dotnet nuget locals` command, see [Managing the NuGet cache](#).

dotnet nuget push

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet nuget push` - Pushes a package to the server and publishes it.

Synopsis

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

```
dotnet nuget push [<ROOT>] [-d|--disable-buffering] [--force-english-output] [--interactive] [-k|--api-key] [-n|--no-symbols]
    [--no-service-endpoint] [-s|--source] [-sk|--symbol-api-key] [-ss|--symbol-source] [-t|--timeout]
dotnet nuget push [-h|--help]
```

Description

The `dotnet nuget push` command pushes a package to the server and publishes it. The push command uses server and credential details found in the system's NuGet config file or chain of config files. For more information on config files, see [Configuring NuGet Behavior](#). NuGet's default configuration is obtained by loading `%AppData%\NuGet\NuGet.config` (Windows) or `$HOME/.local/share` (Linux/macOS), then loading any `nuget.config` or `.nuget\NuGet.config` starting from the root of drive and ending in the current directory.

Arguments

- `ROOT`

Specifies the file path to the package to be pushed.

Options

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

- `-d|--disable-buffering`

Disables buffering when pushing to an HTTP(S) server to reduce memory usage.

- `--force-english-output`

Forces the application to run using an invariant, English-based culture.

- `-h|--help`

Prints out a short help for the command.

- `--interactive`

Allows the command to block and requires manual action for operations like authentication. Option available since .NET Core 2.2 SDK.

- `-k|--api-key <API_KEY>`

The API key for the server.

- `-n|--no-symbols`

Doesn't push symbols (even if present).

- `--no-service-endpoint`

Doesn't append "api/v2/package" to the source URL. Option available since .NET Core 2.1 SDK.

- `-s|--source <SOURCE>`

Specifies the server URL. This option is required unless `DefaultPushSource` config value is set in the NuGet config file.

- `-sk|--symbol-api-key <API_KEY>`

The API key for the symbol server.

- `-ss|--symbol-source <SOURCE>`

Specifies the symbol server URL.

- `-t|--timeout <TIMEOUT>`

Specifies the timeout for pushing to a server in seconds. Defaults to 300 seconds (5 minutes). Specifying 0 (zero seconds) applies the default value.

Examples

- Pushes *foo.nupkg* to the default push source, specifying an API key:

```
dotnet nuget push foo.nupkg -k 4003d786-cc37-4004-bfdf-c4f3e8ef9b3a
```

- Pushes *foo.nupkg* to the custom push source `https://customsource`, specifying an API key:

```
dotnet nuget push foo.nupkg -k 4003d786-cc37-4004-bfdf-c4f3e8ef9b3a -s https://customsource/
```

- Pushes *foo.nupkg* to the default push source:

```
dotnet nuget push foo.nupkg
```

- Pushes *foo.symbols.nupkg* to the default symbols source:

```
dotnet nuget push foo.symbols.nupkg
```

- Pushes *foo.nupkg* to the default push source, specifying a 360-second timeout:

```
dotnet nuget push foo.nupkg --timeout 360
```

- Pushes all *.nupkg* files in the current directory to the default push source:

```
dotnet nuget push *.nupkg
```

dotnet pack

3/26/2019 • 4 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet pack` - Packs the code into a NuGet package.

Synopsis

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

```
dotnet pack [<PROJECT>] [-c|--configuration] [--force] [--include-source] [--include-symbols] [--no-build]
[--no-dependencies]
      [--no-restore] [-o|--output] [--runtime] [-s|--serviceable] [-v|--verbosity] [--version-suffix]
dotnet pack [-h|--help]
```

Description

The `dotnet pack` command builds the project and creates NuGet packages. The result of this command is a NuGet package. If the `--include-symbols` option is present, another package containing the debug symbols is created.

NuGet dependencies of the packed project are added to the `.nuspec` file, so they're properly resolved when the package is installed. Project-to-project references aren't packaged inside the project. Currently, you must have a package per project if you have project-to-project dependencies.

By default, `dotnet pack` builds the project first. If you wish to avoid this behavior, pass the `--no-build` option. This option is often useful in Continuous Integration (CI) build scenarios where you know the code was previously built.

You can provide MSBuild properties to the `dotnet pack` command for the packing process. For more information, see [NuGet metadata properties](#) and the [MSBuild Command-Line Reference](#). The [Examples](#) section shows how to use the MSBuild `-p` switch for a couple of different scenarios.

NOTE

Starting with .NET Core 2.0, you don't have to run `dotnet restore` because it's run implicitly by all commands, such as `dotnet build` and `dotnet run`, that require a restore to occur. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

This command also supports the `dotnet restore` options when passed in the long form (for example, `--source`). Short form options, such as `-s`, are not supported.

Arguments

- `PROJECT`

The project to pack. It's either a path to a [csproj](#) file or to a directory. If not specified, it defaults to the current directory.

Options

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

- `-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`.

- `--force`

Forces all dependencies to be resolved even if the last restore was successful. Specifying this flag is the same as deleting the *project.assets.json* file.

- `-h|--help`

Prints out a short help for the command.

- `--include-source`

Includes the source files in the NuGet package. The sources files are included in the `src` folder within the `nupkg`.

- `--include-symbols`

Generates the symbols `nupkg`.

- `--no-build`

Doesn't build the project before packing. It also implicitly sets the `--no-restore` flag.

- `--no-dependencies`

Ignores project-to-project references and only restores the root project.

- `--no-restore`

Doesn't execute an implicit restore when running the command.

- `-o|--output <OUTPUT_DIRECTORY>`

Places the built packages in the directory specified.

- `--runtime <RUNTIME_IDENTIFIER>`

Specifies the target runtime to restore packages for. For a list of Runtime Identifiers (RIDs), see the [RID catalog](#).

- `-s|--serviceable`

Sets the serviceable flag in the package. For more information, see [.NET Blog: .NET 4.5.1 Supports Microsoft Security Updates for .NET NuGet Libraries](#).

- `--version-suffix <VERSION_SUFFIX>`

Defines the value for the `$(VersionSuffix)` MSBuild property in the project.

- `-v|--verbosity <LEVEL>`

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

NOTE

Web projects aren't packable by default. To override the default behavior, add the following property to your `.csproj` file:

```
<PropertyGroup>
  <IsPackable>true</IsPackable>
</PropertyGroup>
```

Examples

- Pack the project in the current directory:

```
dotnet pack
```

- Pack the `app1` project:

```
dotnet pack ~/projects/app1/project.csproj
```

- Pack the project in the current directory and place the resulting packages into the `nupkgs` folder:

```
dotnet pack --output nupkgs
```

- Pack the project in the current directory into the `nupkgs` folder and skip the build step:

```
dotnet pack --no-build --output nupkgs
```

- With the project's version suffix configured as `<VersionSuffix>$(VersionSuffix)</VersionSuffix>` in the `.csproj` file, pack the current project and update the resulting package version with the given suffix:

```
dotnet pack --version-suffix "ci-1234"
```

- Set the package version to `2.1.0` with the `PackageVersion` MSBuild property:

```
dotnet pack -p:PackageVersion=2.1.0
```

- Pack the project for a specific [target framework](#):

```
dotnet pack -p:TargetFrameworks=net45
```

- Pack the project and use a specific runtime (Windows 10) for the restore operation (.NET Core SDK 2.0 and later versions):

```
dotnet pack --runtime win10-x64
```

- Pack the project using a [.nuspec file](#):

```
dotnet pack ~/projects/app1/project.csproj /p:NuspecFile=~/projects/app1/project.nuspec  
/p:NuspecBasePath=~/projects/app1/nuget
```

dotnet publish

1/23/2019 • 6 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet publish` - Packs the application and its dependencies into a folder for deployment to a hosting system.

Synopsis

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

```
dotnet publish [<PROJECT>] [-c|--configuration] [-f|--framework] [--force] [--manifest] [--no-build] [--no-dependencies]
    [--no-restore] [-o|--output] [-r|--runtime] [--self-contained] [-v|--verbosity] [--version-suffix]
dotnet publish [-h|--help]
```

Description

`dotnet publish` compiles the application, reads through its dependencies specified in the project file, and publishes the resulting set of files to a directory. The output includes the following assets:

- Intermediate Language (IL) code in an assembly with a *dll* extension.
- *.deps.json* file that includes all of the dependencies of the project.
- *.runtime.config.json* file that specifies the shared runtime that the application expects, as well as other configuration options for the runtime (for example, garbage collection type).
- The application's dependencies, which are copied from the NuGet cache into the output folder.

The `dotnet publish` command's output is ready for deployment to a hosting system (for example, a server, PC, Mac, laptop) for execution. It's the only officially supported way to prepare the application for deployment. Depending on the type of deployment that the project specifies, the hosting system may or may not have the .NET Core shared runtime installed on it. For more information, see [.NET Core Application Deployment](#). For the directory structure of a published application, see [Directory structure](#).

NOTE

Starting with .NET Core 2.0, you don't have to run `dotnet restore` because it's run implicitly by all commands, such as `dotnet build` and `dotnet run`, that require a restore to occur. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

This command also supports the `dotnet restore` options when passed in the long form (for example, `--source`). Short form options, such as `-s`, are not supported.

Arguments

PROJECT

The project to publish. It's either the path and filename of a [C#](#), [F#](#), or [Visual Basic](#) project file, or the path to a directory that contains a [C#](#), [F#](#), or [Visual Basic](#) project file. If not specified, it defaults to the current directory.

Options

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

`-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`.

`-f|--framework <FRAMEWORK>`

Publishes the application for the specified [target framework](#). You must specify the target framework in the project file.

`--force`

Forces all dependencies to be resolved even if the last restore was successful. Specifying this flag is the same as deleting the `project.assets.json` file.

`-h|--help`

Prints out a short help for the command.

`--manifest <PATH_TO_MANIFEST_FILE>`

Specifies one or several [target manifests](#) to use to trim the set of packages published with the app. The manifest file is part of the output of the `dotnet store` command. To specify multiple manifests, add a `--manifest` option for each manifest. This option is available starting with .NET Core 2.0 SDK.

`--no-build`

Doesn't build the project before publishing. It also implicitly sets the `--no-restore` flag.

`--no-dependencies`

Ignores project-to-project references and only restores the root project.

`--no-restore`

Doesn't execute an implicit restore when running the command.

`-o|--output <OUTPUT_DIRECTORY>`

Specifies the path for the output directory. If not specified, it defaults to `/bin/[configuration]/[framework]/publish/` for a framework-dependent deployment or `/bin/[configuration]/[framework]/[runtime]/publish/` for a self-contained deployment. If the path is relative, the output directory generated is relative to the project file location, not to the current working directory.

`--self-contained`

Publishes the .NET Core runtime with your application so the runtime doesn't need to be installed on the target machine. If a runtime identifier is specified, its default value is `true`. For more information about the different deployment types, see [.NET Core application deployment](#).

`-r|--runtime <RUNTIME_IDENTIFIER>`

Publishes the application for a given runtime. This is used when creating a [self-contained deployment \(SCD\)](#). For a list of Runtime Identifiers (RIDs), see the [RID catalog](#). Default is to publish a [framework-dependent deployment \(FDD\)](#).

```
-v|--verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

```
--version-suffix <VERSION_SUFFIX>
```

Defines the version suffix to replace the asterisk (*) in the version field of the project file.

Examples

Publish the project in the current directory:

```
dotnet publish
```

Publish the application using the specified project file:

```
dotnet publish ~/projects/app1/app1.csproj
```

Publish the project in the current directory using the `netcoreapp1.1` framework:

```
dotnet publish --framework netcoreapp1.1
```

Publish the current application using the `netcoreapp1.1` framework and the runtime for `os x 10.10` (you must list this RID in the project file):

```
dotnet publish --framework netcoreapp1.1 --runtime osx.10.11-x64
```

Publish the current application but don't restore project-to-project (P2P) references, just the root project during the restore operation (.NET Core SDK 2.0 and later versions):

```
dotnet publish --no-dependencies
```

dotnet restore

12/10/2018 • 5 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet restore` - Restores the dependencies and tools of a project.

Synopsis

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

```
dotnet restore [<ROOT>] [--configfile] [--disable-parallel] [--force] [--ignore-failed-sources] [--no-cache]
    [--no-dependencies] [--packages] [-r|--runtime] [-s|--source] [-v|--verbosity] [--interactive]
dotnet restore [-h|--help]
```

Description

The `dotnet restore` command uses NuGet to restore dependencies as well as project-specific tools that are specified in the project file. By default, the restoration of dependencies and tools are executed in parallel.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

To restore the dependencies, NuGet needs the feeds where the packages are located. Feeds are usually provided via the *NuGet.config* configuration file. A default configuration file is provided when the CLI tools are installed. You specify additional feeds by creating your own *NuGet.config* file in the project directory. You also specify additional feeds per invocation at a command prompt.

For dependencies, you specify where the restored packages are placed during the restore operation using the `--packages` argument. If not specified, the default NuGet package cache is used, which is found in the `.nuget/packages` directory in the user's home directory on all operating systems. For example, `/home/user1` on Linux or `C:\Users\user1` on Windows.

For project-specific tooling, `dotnet restore` first restores the package in which the tool is packed, and then proceeds to restore the tool's dependencies as specified in its project file.

The behavior of the `dotnet restore` command is affected by some of the settings in the *Nuget.Config* file, if present. For example, setting the `globalPackagesFolder` in *NuGet.Config* places the restored NuGet packages in the specified folder. This is an alternative to specifying the `--packages` option on the `dotnet restore` command. For more information, see the [NuGet.Config reference](#).

Implicit `dotnet restore`

Starting with .NET Core 2.0, `dotnet restore` is run implicitly if necessary when you issue the following commands:

- `dotnet new`
- `dotnet build`
- `dotnet build-server`
- `dotnet run`
- `dotnet test`
- `dotnet publish`
- `dotnet pack`

In most cases, you no longer need to explicitly use the `dotnet restore` command.

Sometimes, it might be inconvenient to run `dotnet restore` implicitly. For example, some automated systems, such as build systems, need to call `dotnet restore` explicitly to control when the restore occurs so that they can control network usage. To prevent `dotnet restore` from running implicitly, you can use the `--no-restore` flag with any of these commands to disable implicit restore.

Arguments

`ROOT`

Optional path to the project file to restore.

Options

- [.NET Core 2.x](#)
- [.NET Core 1.x](#)

`--configfile <FILE>`

The NuGet configuration file (*NuGet.config*) to use for the restore operation.

`--disable-parallel`

Disables restoring multiple projects in parallel.

`--force`

Forces all dependencies to be resolved even if the last restore was successful. Specifying this flag is the same as deleting the *project.assets.json* file.

`-h | --help`

Prints out a short help for the command.

`--ignore-failed-sources`

Only warn about failed sources if there are packages meeting the version requirement.

`--no-cache`

Specifies to not cache packages and HTTP requests.

`--no-dependencies`

When restoring a project with project-to-project (P2P) references, restores the root project and not the references.

```
--packages <PACKAGES_DIRECTORY>
```

Specifies the directory for restored packages.

```
-r|--runtime <RUNTIME_IDENTIFIER>
```

Specifies a runtime for the package restore. This is used to restore packages for runtimes not explicitly listed in the `<RuntimeIdentifiers>` tag in the `.csproj` file. For a list of Runtime Identifiers (RIDs), see the [RID catalog](#). Provide multiple RIDs by specifying this option multiple times.

```
-s|--source <SOURCE>
```

Specifies a NuGet package source to use during the restore operation. This setting overrides all of the sources specified in the `NuGet.config` files. Multiple sources can be provided by specifying this option multiple times.

```
--verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

```
--interactive
```

Allows the command to stop and wait for user input or action (for example to complete authentication). Since .NET Core 2.1.400.

Examples

Restore dependencies and tools for the project in the current directory:

```
dotnet restore
```

Restore dependencies and tools for the `app1` project found in the given path:

```
dotnet restore ~/projects/app1/app1.csproj
```

Restore the dependencies and tools for the project in the current directory using the file path provided as the source:

```
dotnet restore -s c:\packages\mypackages
```

Restore the dependencies and tools for the project in the current directory using the two file paths provided as sources:

```
dotnet restore -s c:\packages\mypackages -s c:\packages\myotherpackages
```

Restore dependencies and tools for the project in the current directory and shows only minimal output:

```
dotnet restore --verbosity minimal
```

dotnet run

12/10/2018 • 5 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet run` - Runs source code without any explicit compile or launch commands.

Synopsis

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

```
dotnet run [-c|--configuration] [-f|--framework] [--force] [--launch-profile] [--no-build] [--no-dependencies]
           [--no-launch-profile] [--no-restore] [-p|--project] [--runtime] [-v|--verbosity] [[--] [application
           arguments]]
dotnet run [-h|--help]
```

Description

The `dotnet run` command provides a convenient option to run your application from the source code with one command. It's useful for fast iterative development from the command line. The command depends on the `dotnet build` command to build the code. Any requirements for the build, such as that the project must be restored first, apply to `dotnet run` as well.

Output files are written into the default location, which is `bin/<configuration>/<target>`. For example if you have a `netcoreapp2.1` application and you run `dotnet run`, the output is placed in `bin/Debug/netcoreapp2.1`. Files are overwritten as needed. Temporary files are placed in the `obj` directory.

If the project specifies multiple frameworks, executing `dotnet run` results in an error unless the `-f|--framework <FRAMEWORK>` option is used to specify the framework.

The `dotnet run` command is used in the context of projects, not built assemblies. If you're trying to run a framework-dependent application DLL instead, you must use `dotnet` without a command. For example, to run `myapp.dll`, use:

```
dotnet myapp.dll
```

For more information on the `dotnet` driver, see the [.NET Core Command Line Tools \(CLI\)](#) topic.

To run the application, the `dotnet run` command resolves the dependencies of the application that are outside of the shared runtime from the NuGet cache. Because it uses cached dependencies, it's not recommended to use `dotnet run` to run applications in production. Instead, [create a deployment](#) using the `dotnet publish` command and deploy the published output.

NOTE

Starting with .NET Core 2.0, you don't have to run `dotnet restore` because it's run implicitly by all commands, such as `dotnet build` and `dotnet run`, that require a restore to occur. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

This command also supports the `dotnet restore` options when passed in the long form (for example, `--source`). Short form options, such as `-s`, are not supported.

Options

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

`--`

Delimits arguments to `dotnet run` from arguments for the application being run. All arguments after this delimiter are passed to the application run.

`-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`.

`-f|--framework <FRAMEWORK>`

Builds and runs the app using the specified [framework](#). The framework must be specified in the project file.

`--force`

Forces all dependencies to be resolved even if the last restore was successful. Specifying this flag is the same as deleting the `project.assets.json` file.

`-h|--help`

Prints out a short help for the command.

`--launch-profile <NAME>`

The name of the launch profile (if any) to use when launching the application. Launch profiles are defined in the `launchSettings.json` file and are typically called `Development`, `Staging`, and `Production`. For more information, see [Working with multiple environments](#).

`--no-build`

Doesn't build the project before running. It also implicit sets the `--no-restore` flag.

`--no-dependencies`

When restoring a project with project-to-project (P2P) references, restores the root project and not the references.

`--no-launch-profile`

Doesn't try to use `launchSettings.json` to configure the application.

`--no-restore`

Doesn't execute an implicit restore when running the command.

```
-p|--project <PATH>
```

Specifies the path of the project file to run (folder name or full path). If not specified, it defaults to the current directory.

```
--runtime <RUNTIME_IDENTIFIER>
```

Specifies the target runtime to restore packages for. For a list of Runtime Identifiers (RIDs), see the [RID catalog](#).

```
-v|--verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

Examples

Run the project in the current directory:

```
dotnet run
```

Run the specified project:

```
dotnet run --project ./projects/proj1/proj1.csproj
```

Run the project in the current directory (the `--help` argument in this example is passed to the application, since the blank `--` option is used):

```
dotnet run --configuration Release -- --help
```

Restore dependencies and tools for the project in the current directory only showing minimal output and then run the project (.NET Core SDK 2.0 and later versions):

```
dotnet run --verbosity m
```

dotnet sln

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet sln` - Modifies a .NET Core solution file.

Synopsis

```
dotnet sln [<SOLUTION_NAME>] add <PROJECT> <PROJECT> ...
dotnet sln [<SOLUTION_NAME>] add <GLOBBING_PATTERN>
dotnet sln [<SOLUTION_NAME>] remove <PROJECT> <PROJECT> ...
dotnet sln [<SOLUTION_NAME>] remove <GLOBBING_PATTERN>
dotnet sln [<SOLUTION_NAME>] list
dotnet sln [-h|--help]
```

Description

The `dotnet sln` command provides a convenient way to add, remove, and list projects in a solution file.

To use the `dotnet sln` command, the solution file must already exist. If you need to create one, use the `dotnet new` command, like in the following example:

```
dotnet new sln
```

Commands

`add <PROJECT> ...`

`add <GLOBBING_PATTERN>`

Adds a project or multiple projects to the solution file. [Globbing patterns](#) are supported on Unix/Linux based terminals.

`remove <PROJECT> ...`

`remove <GLOBBING_PATTERN>`

Removes a project or multiple projects from the solution file. [Globbing patterns](#) are supported on Unix/Linux based terminals.

`list`

Lists all projects in a solution file.

Arguments

`SOLUTION_NAME`

Solution file to use. If not specified, the command searches the current directory for one. If there are multiple

solution files in the directory, one must be specified.

Options

```
-h|--help
```

Prints out a short help for the command.

Examples

Add a C# project to a solution:

```
dotnet sln todo.sln add todo-app/todo-app.csproj
```

Remove a C# project from a solution:

```
dotnet sln todo.sln remove todo-app/todo-app.csproj
```

Add multiple C# projects to a solution:

```
dotnet sln todo.sln add todo-app/todo-app.csproj back-end/back-end.csproj
```

Remove multiple C# projects from a solution:

```
dotnet sln todo.sln remove todo-app/todo-app.csproj back-end/back-end.csproj
```

Add multiple C# projects to a solution using a globbing pattern:

```
dotnet sln todo.sln add **/*.csproj
```

Remove multiple C# projects from a solution using a globbing pattern:

```
dotnet sln todo.sln remove **/*.csproj
```

NOTE

Globbing is not a CLI feature but rather a feature of the command shell. To successfully expand the files, you must use a shell that supports globbing. For more information about globbing, see [Wikipedia](#).

dotnet store

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.0 SDK and later versions

Name

`dotnet store` - Stores the specified assemblies in the [runtime package store](#).

Synopsis

```
dotnet store -m|--manifest -f|--framework -r|--runtime [--framework-version] [-h|--help] [--output] [--skip-optimization] [--skip-symbols] [-v|--verbosity] [--working-dir]
```

Description

`dotnet store` stores the specified assemblies in the [runtime package store](#). By default, assemblies are optimized for the target runtime and framework. For more information, see the [runtime package store](#) topic.

Required options

`-f|--framework <FRAMEWORK>`

Specifies the [target framework](#).

`-m|--manifest <PATH_TO_MANIFEST_FILE>`

The *package store manifest file* is an XML file that contains the list of packages to store. The format of the manifest file is compatible with the SDK-style project format. So, a project file that references the desired packages can be used with the `-m|--manifest` option to store assemblies in the runtime package store. To specify multiple manifest files, repeat the option and path for each file. For example:

`--manifest packages1.csproj --manifest packages2.csproj .`

`-r|--runtime <RUNTIME_IDENTIFIER>`

The [runtime identifier](#) to target.

Optional options

`--framework-version <FRAMEWORK_VERSION>`

Specifies the .NET Core SDK version. This option enables you to select a specific framework version beyond the framework specified by the `-f|--framework` option.

`-h|--help`

Shows help information.

`-o|--output <OUTPUT_DIRECTORY>`

Specifies the path to the runtime package store. If not specified, it defaults to the *store* subdirectory of the user profile .NET Core installation directory.

`--skip-optimization`

Skips the optimization phase.

```
--skip-symbols
```

Skips symbol generation. Currently, you can only generate symbols on Windows and Linux.

```
-v|--verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

```
-w|--working-dir <INTERMEDIATE_WORKING_DIRECTORY>
```

The working directory used by the command. If not specified, it uses the `obj` subdirectory of the current directory.

Examples

Store the packages specified in the `packages.csproj` project file for .NET Core 2.0.0:

```
dotnet store --manifest packages.csproj --framework-version 2.0.0
```

Store the packages specified in the `packages.csproj` without optimization:

```
dotnet store --manifest packages.csproj --skip-optimization
```

- [Runtime package store](#)

dotnet test

1/23/2019 • 6 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet test` - .NET test driver used to execute unit tests.

Synopsis

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

```
dotnet test [<PROJECT>] [-a|--test-adapter-path] [--blame] [-c|--configuration] [--collect] [-d|--diag] [-f|--framework] [--filter]
    [-l|--logger] [--no-build] [--no-restore] [-o|--output] [-r|--results-directory] [-s|--settings] [-t|--list-tests]
    [-v|--verbosity] [-- <RunSettings arguments>]

dotnet test [-h|--help]
```

Description

The `dotnet test` command is used to execute unit tests in a given project. The `dotnet test` command launches the test runner console application specified for a project. The test runner executes the tests defined for a unit test framework (for example, MSTest, NUnit, or xUnit) and reports the success or failure of each test. If all tests are successful, the test runner returns 0 as an exit code; otherwise if any test fails, it returns 1. The test runner and the unit test library are packaged as NuGet packages and are restored as ordinary dependencies for the project.

Test projects specify the test runner using an ordinary `<PackageReference>` element, as seen in the following sample project file:

```
<Project Sdk="Microsoft.NET.Sdk">

    <PropertyGroup>
        <TargetFramework>netcoreapp2.2</TargetFramework>
    </PropertyGroup>

    <ItemGroup>
        <PackageReference Include="Microsoft.NET.Test.Sdk" Version="15.9.0" />
        <PackageReference Include="xunit" Version="2.4.0" />
        <PackageReference Include="xunit.runner.visualstudio" Version="2.4.0" />
    </ItemGroup>

</Project>
```

Arguments

`PROJECT`

Path to the test project. If not specified, it defaults to current directory.

Options

- .NET Core 2.1
- .NET Core 2.0
- .NET Core 1.x

```
-a|--test-adapter-path <PATH_TO_ADAPTER>
```

Use the custom test adapters from the specified path in the test run.

```
--blame
```

Runs the tests in blame mode. This option is helpful in isolating the problematic tests causing test host to crash. It creates an output file in the current directory as *Sequence.xml* that captures the order of tests execution before the crash.

```
-c|--configuration {Debug|Release}
```

Defines the build configuration. The default value is `Debug`, but your project's configuration could override this default SDK setting.

```
--collect <DATA_COLLECTOR_FRIENDLY_NAME>
```

Enables data collector for the test run. For more information, see [Monitor and analyze test run](#).

```
-d|--diag <PATH_TO_DIAGNOSTICS_FILE>
```

Enables diagnostic mode for the test platform and write diagnostic messages to the specified file.

```
-f|--framework <FRAMEWORK>
```

Looks for test binaries for a specific [framework](#).

```
--filter <EXPRESSION>
```

Filters out tests in the current project using the given expression. For more information, see the [Filter option details](#) section. For more information and examples on how to use selective unit test filtering, see [Running selective unit tests](#).

```
-h|--help
```

Prints out a short help for the command.

```
-l|--logger <LoggerUri/FriendlyName>
```

Specifies a logger for test results.

```
--no-build
```

Doesn't build the test project before running it. It also implicit sets the `--no-restore` flag.

```
--no-restore
```

Doesn't execute an implicit restore when running the command.

```
-o|--output <OUTPUT_DIRECTORY>
```

Directory in which to find the binaries to run.

```
-r|--results-directory <PATH>
```

The directory where the test results are going to be placed. If the specified directory doesn't exist, it's created.

```
-s|--settings <SETTINGS_FILE>
```

Settings to use when running tests.

```
-t|--list-tests
```

List all of the discovered tests in the current project.

```
-v|--verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

```
RunSettings arguments
```

Arguments passed as RunSettings configurations for the test. Arguments are specified as `[name]=[value]` pairs after `--` (note the space after `--`). A space is used to separate multiple `[name]=[value]` pairs.

Example: `dotnet test -- MSTest.DeploymentEnabled=false MSTest.MapInconclusiveToFailed=True`

For more information about RunSettings, see [vstest.console.exe: Passing RunSettings args](#).

Examples

Run the tests in the project in the current directory:

```
dotnet test
```

Run the tests in the `test1` project:

```
dotnet test ~/projects/test1/test1.csproj
```

Run the tests in the project in the current directory and generate a test results file in the trx format:

```
dotnet test --logger:trx
```

Filter option details

```
--filter <EXPRESSION>
```

`<Expression>` has the format `<property><operator><value>[|&<Expression>]`.

`<property>` is an attribute of the `Test Case`. The following are the properties supported by popular unit test frameworks:

TEST FRAMEWORK	SUPPORTED PROPERTIES
MSTest	<ul style="list-style-type: none">• FullyQualifiedName• Name• ClassName• Priority• TestCategory
xUnit	<ul style="list-style-type: none">• FullyQualifiedName• DisplayName• Traits

The `<operator>` describes the relationship between the property and the value:

OPERATOR	FUNCTION
<code>=</code>	Exact match
<code>!=</code>	Not exact match
<code>~</code>	Contains

`<value>` is a string. All the lookups are case insensitive.

An expression without an `<operator>` is automatically considered as a `contains` on `FullyQualifiedName` property (for example, `dotnet test --filter xyz` is same as `dotnet test --filter FullyQualifiedName~xyz`).

Expressions can be joined with conditional operators:

OPERATOR	FUNCTION
<code> </code>	OR
<code>&</code>	AND

You can enclose expressions in parenthesis when using conditional operators (for example, `(Name~TestMethod1) | (Name~TestMethod2)`).

For more information and examples on how to use selective unit test filtering, see [Running selective unit tests](#).

dotnet tool install

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

Name

`dotnet tool install` - Installs the specified .NET Core Global Tool on your machine.

Synopsis

```
dotnet tool install <PACKAGE_NAME> <-g|--global> [--add-source] [--configfile] [--framework] [-v|--verbosity]
[--version]
dotnet tool install <PACKAGE_NAME> <--tool-path> [--add-source] [--configfile] [--framework] [-v|--verbosity]
[--version]
dotnet tool install <-h|--help>
```

Description

The `dotnet tool install` command provides a way for you to install .NET Core Global Tools on your machine. To use the command, you either have to specify that you want a user-wide installation using the `--global` option or you specify a path to install it using the `--tool-path` option.

Global Tools are installed in the following directories by default when you specify the `-g` (or `--global`) option:

os	PATH
Linux/macOS	<code>\$HOME/.dotnet/tools</code>
Windows	<code>%USERPROFILE%\.dotnet\tools</code>

Arguments

`PACKAGE_NAME`

Name/ID of the NuGet package that contains the .NET Core Global Tool to install.

Options

`--add-source <SOURCE>`

Adds an additional NuGet package source to use during installation.

`--configfile <FILE>`

The NuGet configuration (*nuget.config*) file to use.

`--framework <FRAMEWORK>`

Specifies the [target framework](#) to install the tool for. By default, the .NET Core SDK tries to choose the most appropriate target framework.

```
-g|--global
```

Specifies that the installation is user wide. Can't be combined with the `--tool-path` option. If you don't specify this option, you must specify the `--tool-path` option.

```
-h|--help
```

Prints out a short help for the command.

```
--tool-path <PATH>
```

Specifies the location where to install the Global Tool. PATH can be absolute or relative. If PATH doesn't exist, the command tries to create it. Can't be combined with the `--global` option. If you don't specify this option, you must specify the `--global` option.

```
-v|--verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

```
--version <VERSION_NUMBER>
```

The version of the tool to install. By default, the latest stable package version is installed. Use this option to install preview or older versions of the tool.

Examples

Installs the [dotnetsay](#) Global Tool in the default location:

```
dotnet tool install -g dotnetsay
```

Installs the [dotnetsay](#) Global Tool on a specific Windows folder:

```
dotnet tool install dotnetsay --tool-path c:\global-tools
```

Installs the [dotnetsay](#) Global Tool on a specific Linux/macOS folder:

```
dotnet tool install dotnetsay --tool-path ~/bin
```

Installs version 2.0.0 of the [dotnetsay](#) Global Tool:

```
dotnet tool install -g dotnetsay --version 2.0.0
```

dotnet tool list

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

Name

`dotnet tool list` - Lists all .NET Core Global Tools currently installed in the default directory on your machine or in the specified path.

Synopsis

```
dotnet tool list <-g|--global>
dotnet tool list <--tool-path>
dotnet tool list <-h|--help>
```

Description

The `dotnet tool list` command provides a way for you to list all .NET Core Global Tools installed user-wide on your machine (current user profile) or in the specified path. The command lists the package name, version installed, and the Global Tool command. To use the list command, you either have to specify that you want to see all user-wide tools using the `--global` option or specify a custom path using the `--tool-path` option.

Options

`-g|--global`

Lists user-wide Global Tools. Can't be combined with the `--tool-path` option. If you don't specify this option, you must specify the `--tool-path` option.

`-h|--help`

Prints out a short help for the command.

`--tool-path <PATH>`

Specifies a custom location where to find Global Tools. PATH can be absolute or relative. Can't be combined with the `--global` option. If you don't specify this option, you must specify the `--global` option.

Examples

Lists all Global Tools installed user-wide on your machine (current user profile):

`dotnet tool list -g`

Lists the Global Tools from a specific Windows folder:

`dotnet tool list --tool-path c:\global-tools`

Lists the Global Tools from a specific Linux/macOS folder:

`dotnet tool list --tool-path ~/bin`

dotnet tool uninstall

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

Name

`dotnet tool uninstall` - Uninstalls the specified .NET Core Global Tool from your machine.

Synopsis

```
dotnet tool uninstall <PACKAGE_NAME> <-g|--global>
dotnet tool uninstall <PACKAGE_NAME> <--tool-path>
dotnet tool uninstall <-h|--help>
```

Description

The `dotnet tool uninstall` command provides a way for you to uninstall .NET Core Global Tools from your machine. To use the command, you either have to specify that you want to remove a user-wide tool using the `--global` option or specify a path to where the tool is installed using the `--tool-path` option.

Arguments

`PACKAGE_NAME`

Name/ID of the NuGet package that contains the .NET Core Global Tool to uninstall. You can find the package name using the [dotnet tool list](#) command.

Options

`-g|--global`

Specifies that the tool to be removed is from a user-wide installation. Can't be combined with the `--tool-path` option. If you don't specify this option, you must specify the `--tool-path` option.

`-h|--help`

Prints out a short help for the command.

`--tool-path <PATH>`

Specifies the location where to uninstall the Global Tool. PATH can be absolute or relative. Can't be combined with the `--global` option. If you don't specify this option, you must specify the `-g` option.

Examples

Uninstalls the [dotnetsay](#) Global Tool:

```
dotnet tool uninstall -g dotnetsay
```

Uninstalls the [dotnetsay](#) Global Tool from a specific Windows folder:

```
dotnet tool uninstall dotnetsay --tool-path c:\global-tools
```

Uninstalls the [dotnetsay](#) Global Tool from a specific Linux/macOS folder:

```
dotnet tool uninstall dotnetsay --tool-path ~/bin
```

dotnet tool update

1/23/2019 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 2.1 SDK and later versions

Name

`dotnet tool update` - Updates the specified .NET Core Global Tool on your machine.

Synopsis

```
dotnet tool update <PACKAGE_NAME> <-g|--global> [--configfile] [--framework] [-v|--verbosity]
dotnet tool update <PACKAGE_NAME> <--tool-path> [--configfile] [--framework] [-v|--verbosity]
dotnet tool update <-h|--help>
```

Description

The `dotnet tool update` command provides a way for you to update .NET Core Global Tools on your machine to the latest stable version of the package. The command uninstalls and reinstalls a tool, effectively updating it. To use the command, you either have to specify that you want to update a tool from a user-wide installation using the `--global` option or specify a path to where the tool is installed using the `--tool-path` option.

Arguments

`PACKAGE_NAME`

Name/ID of the NuGet package that contains the .NET Core Global Tool to update. You can find the package name using the [dotnet tool list](#) command.

Options

`--add-source <SOURCE>`

Adds an additional NuGet package source to use during installation.

`--configfile <FILE>`

The NuGet configuration (*nuget.config*) file to use.

`--framework <FRAMEWORK>`

Specifies the [target framework](#) to update the tool for.

`-g|--global`

Specifies that the update is for a user-wide tool. Can't be combined with the `--tool-path` option. If you don't specify this option, you must specify the `--tool-path` option.

`-h|--help`

Prints out a short help for the command.

`--tool-path <PATH>`

Specifies the location where the Global Tool is installed. PATH can be absolute or relative. Can't be combined with the `--global` option. If you don't specify this option, you must specify the `--global` option.

```
-v | --verbosity <LEVEL>
```

Sets the verbosity level of the command. Allowed values are `q[uiet]`, `m[inimal]`, `n[ormal]`, `d[etailed]`, and `diag[nostic]`.

Examples

Updates the [dotnetsay](#) Global Tool:

```
dotnet tool update -g dotnetsay
```

Updates the [dotnetsay](#) Global Tool located on a specific Windows folder:

```
dotnet tool update dotnetsay --tool-path c:\global-tools
```

Updates the [dotnetsay](#) Global Tool located on a specific Linux/macOS folder:

```
dotnet tool update dotnetsay --tool-path ~/bin
```

- [.NET Core Global Tools](#)

dotnet vstest

2/23/2019 • 6 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet-vstest` - Runs tests from the specified files.

Synopsis

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

```
dotnet vstest [<TEST_FILE_NAMES>] [--Settings|/Settings] [--Tests|/Tests] [--TestAdapterPath|/TestAdapterPath]
    [--Platform|/Platform] [--Framework|/Framework] [--Parallel|/Parallel] [--TestCaseFilter|/TestCaseFilter]
    [--logger|/logger]
    [-lt|--ListTests|/lt|/ListTests] [--ParentProcessId|/ParentProcessId] [--Port|/Port] [--Diag|/Diag] [--Blame|/Blame]
    [--InIsolation|/InIsolation]
    [[--] <args>...]] [-?|--Help|/?|/Help]
```

Description

The `dotnet-vstest` command runs the `VSTest.Console` command-line application to run automated unit tests.

Arguments

`TEST_FILE_NAMES`

Run tests from the specified assemblies. Separate multiple test assembly names with spaces.

Options

- [.NET Core 2.1](#)
- [.NET Core 2.0](#)
- [.NET Core 1.x](#)

`--Settings|/Settings:<Settings File>`

Settings to use when running tests.

`--Tests|/Tests:<Test Names>`

Run tests with names that match the provided values. Separate multiple values with commas.

`--TestAdapterPath|/TestAdapterPath`

Use custom test adapters from a given path (if any) in the test run.

`--Platform|/Platform:<Platform type>`

Target platform architecture used for test execution. Valid values are `x86`, `x64`, and `ARM`.

```
--Framework|/Framework:<Framework Version>
```

Target .NET Framework version used for test execution. Examples of valid values are `.NETFramework,Version=v4.6` or `.NETCoreApp,Version=v1.0`. Other supported values are `Framework40`, `Framework45`, `FrameworkCore10`, and `FrameworkUap10`.

```
--Parallel|/Parallel
```

Execute tests in parallel. By default, all available cores on the machine are available for use. Specify an explicit number of cores by setting the `MaxCpuCount` property under the `RunConfiguration` node in the `runsettings` file.

```
--TestCaseFilter|/TestCaseFilter:<Expression>
```

Run tests that match the given expression. `<Expression>` is of the format `<property>Operator<value>[|&<Expression>]`, where Operator is one of `=`, `!=`, or `~`. Operator `~` has 'contains' semantics and is applicable for string properties like `DisplayName`. Parenthesis `()` are used to group sub-expressions.

```
-?|--Help|/?|/Help
```

Prints out a short help for the command.

```
--logger|/logger:<Logger Uri/FriendlyName>
```

Specify a logger for test results.

- To publish test results to Team Foundation Server, use the `TfsPublisher` logger provider:

```
/logger:TfsPublisher;
    Collection=<team project collection url>;
    BuildName=<build name>;
    TeamProject=<team project name>
    [;Platform=<Defaults to "Any CPU">]
    [;Flavor=<Defaults to "Debug">]
    [;RunTitle=<title>]
```

- To log results to a Visual Studio Test Results File (TRX), use the `trx` logger provider. This switch creates a file in the test results directory with given log file name. If `LogFileName` isn't provided, a unique file name is created to hold the test results.

```
/logger:trx [;LogFileName=<Defaults to unique file name>]
```

```
-lt|--ListTests|/lt|/ListTests:<File Name>
```

Lists all discovered tests from the given test container.

```
--ParentProcessId|/ParentProcessId:<ParentProcessId>
```

Process ID of the parent process responsible for launching the current process.

```
--Port|/Port:<Port>
```

Specifies the port for the socket connection and receiving the event messages.

```
--Diag|/Diag:<Path to log file>
```

Enables verbose logs for the test platform. Logs are written to the provided file.

```
--Blame|/Blame
```

Runs the tests in blame mode. This option is helpful in isolating the problematic tests causing test host to crash. It creates an output file in the current directory as *Sequence.xml* that captures the order of tests execution before the crash.

```
--InIsolation|/InIsolation
```

Runs the tests in an isolated process. This makes *vstest.console.exe* process less likely to be stopped on an error in the tests, but tests may run slower.

```
@<file>
```

Reads response file for more options.

```
args
```

Specifies extra arguments to pass to the adapter. Arguments are specified as name-value pairs of the form `<n>=<v>`, where `<n>` is the argument name and `<v>` is the argument value. Use a space to separate multiple arguments.

Examples

Run tests in `mytestproject.dll`:

```
dotnet vstest mytestproject.dll
```

Run tests in `mytestproject.dll`, exporting to custom folder with custom name:

```
dotnet vstest mytestproject.dll --logger:"trx;LogFileName=custom_file_name.trx" --  
ResultsDirectory:custom/file/path
```

Run tests in `mytestproject.dll` and `myothertestproject.exe`:

```
dotnet vstest mytestproject.dll myothertestproject.exe
```

Run `TestMethod1` tests:

```
dotnet vstest /Tests:TestMethod1
```

Run `TestMethod1` and `TestMethod2` tests:

```
dotnet vstest /Tests:TestMethod1,TestMethod2
```

dotnet-install scripts reference

1/29/2019 • 4 minutes to read • [Edit Online](#)

Name

`dotnet-install.ps1` | `dotnet-install.sh` - Script used to install the .NET Core CLI tools and the shared runtime.

Synopsis

Windows:

```
dotnet-install.ps1 [-Channel] [-Version] [-InstallDir] [-Architecture] [-SharedRuntime] [-Runtime] [-DryRun]
[-NoPath] [-Verbose] [-AzureFeed] [-UncachedFeed] [-NoCdn] [-FeedCredential] [-ProxyAddress] [-ProxyUseDefaultCredentials]
[-SkipNonVersionedFiles] [-Help]
```

macOS/Linux:

```
dotnet-install.sh [--channel] [--version] [--install-dir] [--architecture] [--runtime] [--dry-run] [--no-path]
[--verbose] [--azure-feed] [--uncached-feed] [--no-cdn] [--feed-credential] [--runtime-id] [--skip-non-
versioned-files] [--help]
```

Description

The `dotnet-install` scripts are used to perform a non-admin installation of the .NET Core SDK, which includes the .NET Core CLI tools and the shared runtime.

We recommend that you use the stable version that is hosted on [.NET Core main website](#). The direct paths to the scripts are:

- <https://dot.net/v1/dotnet-install.sh> (bash, UNIX)
- <https://dot.net/v1/dotnet-install.ps1> (Powershell, Windows)

The main usefulness of these scripts is in automation scenarios and non-admin installations. There are two scripts: one is a PowerShell script that works on Windows, and the other is a bash script that works on Linux/macOS. Both scripts have the same behavior. The bash script also reads PowerShell switches, so you can use PowerShell switches with the script on Linux/macOS systems.

The installation scripts download the ZIP/tarball file from the CLI build drops and proceed to install it in either the default location or in a location specified by `-InstallDir|--install-dir`. By default, the installation scripts download the SDK and install it. If you wish to only obtain the shared runtime, specify the `--runtime` argument.

By default, the script adds the install location to the \$PATH for the current session. Override this default behavior by specifying the `--no-path` argument.

Before running the script, install the required [dependencies](#).

You can install a specific version using the `--version` argument. The version must be specified as a three-part version (for example, 1.0.0-13232). If not provided, it uses the `latest` version.

Options

- `-Channel <CHANNEL>`

Specifies the source channel for the installation. The possible values are:

- `Current` - Most current release.
- `LTS` - Long-Term Support channel (most current supported release).
- Two-part version in X.Y format representing a specific release (for example, `2.0` or `1.0`).
- Branch name. For example, `release/2.0.0`, `release/2.0.0-preview2`, or `master` (for nightly releases).

The default value is `LTS`. For more information on .NET support channels, see the [.NET Support Policy](#) page.

- `-Version <VERSION>`

Represents a specific build version. The possible values are:

- `latest` - Latest build on the channel (used with the `-Channel` option).
- `coherent` - Latest coherent build on the channel; uses the latest stable package combination (used with Branch name `-Channel` options).
- Three-part version in X.Y.Z format representing a specific build version; supersedes the `-Channel` option. For example: `2.0.0-preview2-006120`.

If not specified, `-Version` defaults to `latest`.

- `-InstallDir <DIRECTORY>`

Specifies the installation path. The directory is created if it doesn't exist. The default value is `%LocalAppData%\Microsoft\dotnet`. Binaries are placed directly in this directory.

- `-Architecture <ARCHITECTURE>`

Architecture of the .NET Core binaries to install. Possible values are `<auto>`, `amd64`, `x64`, `x86`, `arm64`, and `arm`. The default value is `<auto>`, which represents the currently running OS architecture.

- `-SharedRuntime`

NOTE

This parameter is obsolete and may be removed in a future version of the script. The recommended alternative is the `Runtime` option.

Installs just the shared runtime bits, not the entire SDK. This is equivalent to specifying `-Runtime dotnet`.

- `-Runtime <RUNTIME>`

Installs just the shared runtime, not the entire SDK. The possible values are:

- `dotnet` - the `Microsoft.NETCore.App` shared runtime.
- `aspnetcore` - the `Microsoft.AspNetCore.App` shared runtime.

- `-DryRun`

If set, the script won't perform the installation. Instead, it displays what command line to use to consistently install the currently requested version of the .NET Core CLI. For example, if you specify version `latest`, it displays a link with the specific version so that this command can be used deterministically in a build script. It also displays the binary's location if you prefer to install or download it yourself.

- `-NoPath`

If set, the installation folder isn't exported to the path for the current session. By default, the script modifies the PATH, which makes the CLI tools available immediately after install.

- `-Verbose`

Displays diagnostics information.

- `-AzureFeed`

Specifies the URL for the Azure feed to the installer. We recommended that you don't change this value.

The default value is `https://dotnetcli.azureedge.net/dotnet`.

- `-UncachedFeed`

Allows changing the URL for the uncached feed used by this installer. We recommended that you don't change this value.

- `-NoCdn`

Disables downloading from the [Azure Content Delivery Network \(CDN\)](#) and uses the uncached feed directly.

- `-FeedCredential`

Used as a query string to append to the Azure feed. It allows changing the URL to use non-public blob storage accounts.

- `-ProxyAddress`

If set, the installer uses the proxy when making web requests. (Only valid for Windows)

- `ProxyUseDefaultCredentials`

If set, the installer uses the credentials of the current user when using proxy address. (Only valid for Windows)

- `-SkipNonVersionedFiles`

Skips installing non-versioned files, such as `dotnet.exe`, if they already exist.

- `-Help`

Prints out help for the script.

Examples

- Install the latest long-term supported (LTS) version to the default location:

Windows:

```
./dotnet-install.ps1 -Channel LTS
```

macOS/Linux:

```
./dotnet-install.sh --channel LTS
```

- Install the latest version from 2.0 channel to the specified location:

Windows:

```
./dotnet-install.ps1 -Channel 2.0 -InstallDir C:\cli
```

macOS/Linux:

```
./dotnet-install.sh --channel 2.0 --install-dir ~/cli
```

- Install the 1.1.0 version of the shared runtime:

Windows:

```
./dotnet-install.ps1 -Runtime dotnet -Version 1.1.0
```

macOS/Linux:

```
./dotnet-install.sh --runtime dotnet --version 1.1.0
```

- Obtain script and install the 2.1.2 version behind a corporate proxy (Windows only):

```
Invoke-WebRequest 'https://dot.net/v1/dotnet-install.ps1' -Proxy $env:HTTP_PROXY -  
ProxyUseDefaultCredentials -OutFile 'dotnet-install.ps1';  
.dotnet-install.ps1 -InstallDir '~/.dotnet' -Version '2.1.2' -ProxyAddress $env:HTTP_PROXY -  
ProxyUseDefaultCredentials;
```

- Obtain script and install .NET Core CLI one-liner examples:

Windows:

```
@powershell -NoProfile -ExecutionPolicy unrestricted -Command "  
[Net.ServicePointManager]::SecurityProtocol = [Net.SecurityProtocolType]::Tls12; &  
([scriptblock]::Create((Invoke-WebRequest -useb 'https://dot.net/v1/dotnet-install.ps1'))) <additional  
install-script args>"
```

macOS/Linux:

```
curl -sSL https://dot.net/v1/dotnet-install.sh | bash /dev/stdin <additional install-script args>
```

dotnet-add reference

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet add reference` - Adds project-to-project (P2P) references.

Synopsis

```
dotnet add [<PROJECT>] reference [-f|--framework] <PROJECT_REFERENCES> [-h|--help]
```

Description

The `dotnet add reference` command provides a convenient option to add project references to a project. After running the command, the `<ProjectReference>` elements are added to the project file.

```
<ItemGroup>
  <ProjectReference Include="app.csproj" />
  <ProjectReference Include=".\\lib2\\lib2.csproj" />
  <ProjectReference Include=".\\lib1\\lib1.csproj" />
</ItemGroup>
```

Arguments

- `PROJECT`

Specifies the project file. If not specified, the command searches the current directory for one.

- `PROJECT_REFERENCES`

Project-to-project (P2P) references to add. Specify one or more projects. [Glob patterns](#) are supported on Unix/Linux-based systems.

Options

- `-h|--help`

Prints out a short help for the command.

- `-f|--framework <FRAMEWORK>`

Adds project references only when targeting a specific [framework](#).

Examples

- Add a project reference:

```
dotnet add app/app.csproj reference lib/lib.csproj
```

- Add multiple project references to the project in the current directory:

```
dotnet add reference lib1/lib1.csproj lib2/lib2.csproj
```

- Add multiple project references using a globbing pattern on Linux/Unix:

```
dotnet add app/app.csproj reference **/*.csproj
```

dotnet list reference

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet list reference` - Lists project-to-project references.

Synopsis

`dotnet list [<PROJECT>] reference [-h|--help]`

Description

The `dotnet list reference` command provides a convenient option to list project references for a given project or solution.

Arguments

- `PROJECT`

Specifies the project file to use for listing references. If not specified, the command searches the current directory for a project file.

Options

- `-h|--help`

Prints out a short help for the command.

Examples

- List the project references for the specified project:

```
dotnet list app/app.csproj reference
```

- List the project references for the project in the current directory:

```
dotnet list reference
```

dotnet remove reference

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet remove reference` - Removes project-to-project references.

Synopsis

`dotnet remove [<PROJECT>] reference [-f|--framework] <PROJECT_REFERENCES> [-h|--help]`

Description

The `dotnet remove reference` command provides a convenient option to remove project references from a project.

Arguments

`PROJECT`

Target project file. If not specified, the command searches the current directory for one.

`PROJECT_REFERENCES`

Project-to-project (P2P) references to remove. You can specify one or multiple projects. [Glob patterns](#) are supported on Unix/Linux based terminals.

Options

`-h|--help`

Prints out a short help for the command.

`-f|--framework <FRAMEWORK>`

Removes the reference only when targeting a specific [framework](#).

Examples

Remove a project reference from the specified project:

`dotnet remove app/app.csproj reference lib/lib.csproj`

Remove multiple project references from the project in the current directory:

`dotnet remove reference lib1/lib1.csproj lib2/lib2.csproj`

Remove multiple project references using a glob pattern on Unix/Linux:

`dotnet remove app/app.csproj reference **/*.csproj`

dotnet add package

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet add package` - Adds a package reference to a project file.

Synopsis

```
dotnet add [<PROJECT>] package <PACKAGE_NAME> [-h|--help] [-f|--framework] [--interactive] [-n|--no-restore]  
[--package-directory] [-s|--source] [-v|--version]
```

Description

The `dotnet add package` command provides a convenient option to add a package reference to a project file. After running the command, there's a compatibility check to ensure the package is compatible with the frameworks in the project. If the check passes, a `<PackageReference>` element is added to the project file and `dotnet restore` is run.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

For example, adding `Newtonsoft.Json` to `ToDo.csproj` produces output similar to the following example:

```
Writing C:\Users\mairaw\AppData\Local\Temp\tmp95A8.tmp
info : Adding PackageReference for package 'Newtonsoft.Json' into project 'C:\projects\ToDo\ToDo.csproj'.
log  : Restoring packages for C:\Temp\projects\consoleproj\consoleproj.csproj...
info :   GET https://api.nuget.org/v3-flatcontainer/newtonsoft.json/index.json
info :   OK https://api.nuget.org/v3-flatcontainer/newtonsoft.json/index.json 79ms
info :   GET https://api.nuget.org/v3-flatcontainer/newtonsoft.json/12.0.1/newtonsoft.json.12.0.1.nupkg
info :   OK https://api.nuget.org/v3-flatcontainer/newtonsoft.json/12.0.1/newtonsoft.json.12.0.1.nupkg 232ms
log  : Installing Newtonsoft.Json 12.0.1.
info : Package 'Newtonsoft.Json' is compatible with all the specified frameworks in project
'C:\projects\ToDo\ToDo.csproj'.
info : PackageReference for package 'Newtonsoft.Json' version '12.0.1' added to file
'C:\projects\ToDo\ToDo.csproj'.
```

The `ToDo.csproj` file now contains a `<PackageReference>` element for the referenced package.

```
<PackageReference Include="Newtonsoft.Json" Version="12.0.1" />
```

Arguments

- `PROJECT`

Specifies the project file. If not specified, the command searches the current directory for one.

- `<PACKAGE_NAME>`

The package reference to add.

Options

- `-f|--framework <FRAMEWORK>`

Adds a package reference only when targeting a specific [framework](#).

- `-h|--help`

Prints out a short help for the command.

- `--interactive`

Allows the command to stop and wait for user input or action (for example to complete authentication).

Available since .NET Core 2.1 SDK, version 2.1.400 or later.

- `-n|--no-restore`

Adds a package reference without performing a restore preview and compatibility check.

- `--package-directory <PACKAGE_DIRECTORY>`

Restores the package to the specified directory.

- `-s|--source <SOURCE>`

Uses a specific NuGet package source during the restore operation.

- `-v|--version <VERSION>`

Version of the package.

Examples

- Add `Newtonsoft.Json` NuGet package to a project:

```
dotnet add package Newtonsoft.Json
```

- Add a specific version of a package to a project:

```
dotnet add ToDo.csproj package Microsoft.Azure.DocumentDB.Core -v 1.0.0
```

- Add a package using a specific NuGet source:

```
dotnet add package Microsoft.AspNetCore.StaticFiles -s https://dotnet.myget.org/F/dotnet-core/api/v3/index.json
```

dotnet remove package

12/10/2018 • 2 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

Name

`dotnet remove package` - Removes package reference from a project file.

Synopsis

`dotnet remove [<PROJECT>] package <PACKAGE_NAME> [-h|--help]`

Description

The `dotnet remove package` command provides a convenient option to remove a NuGet package reference from a project.

Arguments

`PROJECT`

Specifies the project file. If not specified, the command searches the current directory for one.

`PACKAGE_NAME`

The package reference to remove.

Options

`-h|--help`

Prints out a short help for the command.

Examples

Removes `Newtonsoft.Json` NuGet package from a project in the current directory:

`dotnet remove package Newtonsoft.Json`

global.json overview

12/10/2018 • 4 minutes to read • [Edit Online](#)

This topic applies to: ✓ .NET Core 1.x SDK ✓ .NET Core 2.x SDK

The *global.json* file allows you to define which .NET Core SDK version is used when you run .NET Core CLI commands. Selecting the .NET Core SDK is independent from specifying the runtime your project targets. The .NET Core SDK version indicates which versions of the .NET Core CLI tools are used. In general, you want to use the latest version of the tools, so no *global.json* file is needed.

For more information about specifying the runtime instead, see [Target frameworks](#).

.NET Core SDK looks for a *global.json* file in the current working directory (which isn't necessarily the same as the project directory) or one of its parent directories.

global.json schema

sdk

Type: Object

Specifies information about the .NET Core SDK to select.

version

Type: String

The version of the .NET Core SDK to use.

Note that this field:

- Doesn't have globbing support, that is, the full version number has to be specified.
- Doesn't support version ranges.

The following example shows the contents of a *global.json* file:

```
{  
  "sdk": {  
    "version": "2.2.100"  
  }  
}
```

global.json and the .NET Core CLI

It's helpful to know which versions are available in order to set one in the *global.json* file. You can find the full list of supported available SDKs at the [.NET Downloads](#) site. Starting with .NET Core 2.1 SDK, you can run the following command to verify which SDK versions are already installed on your machine:

```
dotnet --list-sdks
```

To install additional .NET Core SDK versions on your machine, visit the [.NET Downloads](#) site.

You can create a new the *global.json* file in the current directory by executing the [dotnet new](#) command, similar to the following example:

```
dotnet new globaljson --sdk-version 2.2.100
```

Matching rules

NOTE

The matching rules are governed by the apphost, which is part of the .NET Core runtime. The latest version of the host is used when you have multiple runtimes installed side-by-side.

Starting with .NET Core 2.0, the following rules apply when determining which version of the SDK to use:

- If no *global.json* file is found or *global.json* doesn't specify an SDK version, the latest installed SDK version is used. Latest SDK version can be either release or pre-release - the highest version number wins.
- If *global.json* does specify an SDK version:
 - If the specified SDK version is found on the machine, that exact version is used.
 - If the specified SDK version can't be found on the machine, the latest installed SDK **patch version** of that version is used. Latest installed SDK **patch version** can be either release or pre-release - the highest version number wins. In .NET Core 2.1 and higher, the **patch versions** lower than the **patch version** specified are ignored in the SDK selection.
 - If the specified SDK version and an appropriate SDK **patch version** can't be found, an error is thrown.

The SDK version is currently composed of the following parts:

```
[.NET Core major version].[.NET Core minor version].[xyz][-optional preview name]
```

The **feature release** of the .NET Core SDK is represented by the first digit (`x`) in the last portion of the number (`xyz`) for SDK versions 2.1.100 and higher. In general, the .NET Core SDK has a faster release cycle than .NET Core.

The **patch version** is defined by the last two digits (`yz`) in the last portion of the number (`xyz`) for SDK versions 2.1.100 and higher. For example, if you specify `2.1.300` as the SDK version, SDK selection finds up to `2.1.399` but `2.1.400` isn't considered a patch version for `2.1.300`.

.NET Core SDK versions `2.1.100` through `2.1.201` were released during the transition between version number schemes and don't correctly handle the `xyz` notation. We highly recommend if you specify these versions in the *global.json* file, that you ensure the specified versions are on the target machines.

With .NET Core SDK 1.x, if you specified a version and no exact match was found, the latest installed SDK version was used. Latest SDK version can be either release or pre-release - the highest version number wins.

Troubleshooting build warnings

WARNING

You are working with a preview version of the .NET Core SDK. You can define the SDK version via a *global.json* file in the current project. More at <https://go.microsoft.com/fwlink/?linkid=869452>

This warning indicates that your project is being compiled using a preview version of the .NET Core SDK, as explained in the [Matching rules](#) section. .NET Core SDK versions have a history and commitment of being high quality. However, if you don't want to use a preview version, add a *global.json* file to your project hierarchy structure to specify which SDK version to use, and use `dotnet --list-sdks` to confirm that the version is installed on your machine. When a new version is released, to use the new version, either remove the *global.json* file or

update it to use the newer version.

WARNING

Startup project '{startupProject}' targets framework '.NETCoreApp' version '{targetFrameworkVersion}'. This version of the Entity Framework Core .NET Command-line Tools only supports version 2.0 or higher. For information on using older versions of the tools, see <https://go.microsoft.com/fwlink/?linkid=871254>

Starting with .NET Core 2.1 SDK (version 2.1.300), the `dotnet ef` command comes included in the SDK. This warning indicates that your project targets EF Core 1.0 or 1.1, which isn't compatible with .NET Core 2.1 SDK and later versions. To compile your project, install .NET Core 2.0 SDK (version 2.1.201) and earlier on your machine and define the desired SDK version using the *global.json* file. For more information about the `dotnet ef` command, see [EF Core .NET Command-line Tools](#).

.NET Core additional tools overview

12/11/2018 • 2 minutes to read • [Edit Online](#)

This section compiles a list of tools that support and extend the .NET Core functionality, in addition to the [.NET Core command-line interface \(CLI\)](#) tools.

WCF Web Service Reference tool

The WCF (Windows Communication Foundation) Web Service Reference is a Visual Studio connected service provider that made its debut in [Visual Studio 2017 version 15.5](#). This tool retrieves metadata from a web service in the current solution, on a network location, or from a WSDL file, and generates a source file compatible with .NET Core, defining a WCF proxy class with methods that you can use to access the web service operations.

WCF dotnet-svcutil tool

The WCF (Windows Communication Foundation) dotnet-svcutil tool is a .NET Core CLI tool that retrieves metadata from a web service on a network location or from a WSDL file, and generates a source file compatible with .NET Core, defining a WCF proxy class with methods that you can use to access the web service operations. The **dotnet-svcutil** tool is an alternative option to the [WCF Web Service Reference](#) Visual Studio connected service provider which first shipped with Visual Studio 2017 v15.5. The **dotnet-svcutil** tool as a .NET Core CLI tool, is available cross-platform on Linux, macOS, and Windows.

WCF dotnet-svcutil.xmlserializer tool

On the .NET Framework, you can pre-generate a serialization assembly using the svcutil tool. The dotnet-svcutil.xmlserializer NuGet package provides similar functionality on .NET Core. It pre-generates C# serialization code for the types in the client application that are used by the WCF Service Contract and that can be serialized by the [XmlSerializer](#). This improves the startup performance of XML serialization when serializing or deserializing objects of those types.

XML Serializer Generator

Like the [Xml Serializer Generator \(sgen.exe\)](#) for the .NET Framework, the [Microsoft.XmlSerializer.Generator NuGet package](#) is the solution for .NET Core and .NET Standard libraries. It creates an XML serialization assembly for types contained in an assembly to improve the startup performance of XML serialization when serializing or de-serializing objects of those types using [XmlSerializer](#).

Use the WCF Web Service Reference Provider Tool

12/11/2018 • 3 minutes to read • [Edit Online](#)

Over the years, many Visual Studio developers have enjoyed the productivity that the [Add Service Reference](#) tool provided when their .NET Framework projects needed to access web services. The **WCF Web Service Reference** tool is a Visual Studio connected service extension that provides an experience like the Add Service Reference functionality for .NET Core and ASP.NET Core projects. This tool retrieves metadata from a web service in the current solution, on a network location, or from a WSDL file, and generates a .NET Core compatible source file containing Windows Communication Foundation (WCF) client proxy code that you can use to access the web service.

IMPORTANT

You should only reference services from a trusted source. Adding references from an untrusted source may compromise security.

Prerequisites

- [Visual Studio 2017 15.5](#) or later versions

How to use the extension

NOTE

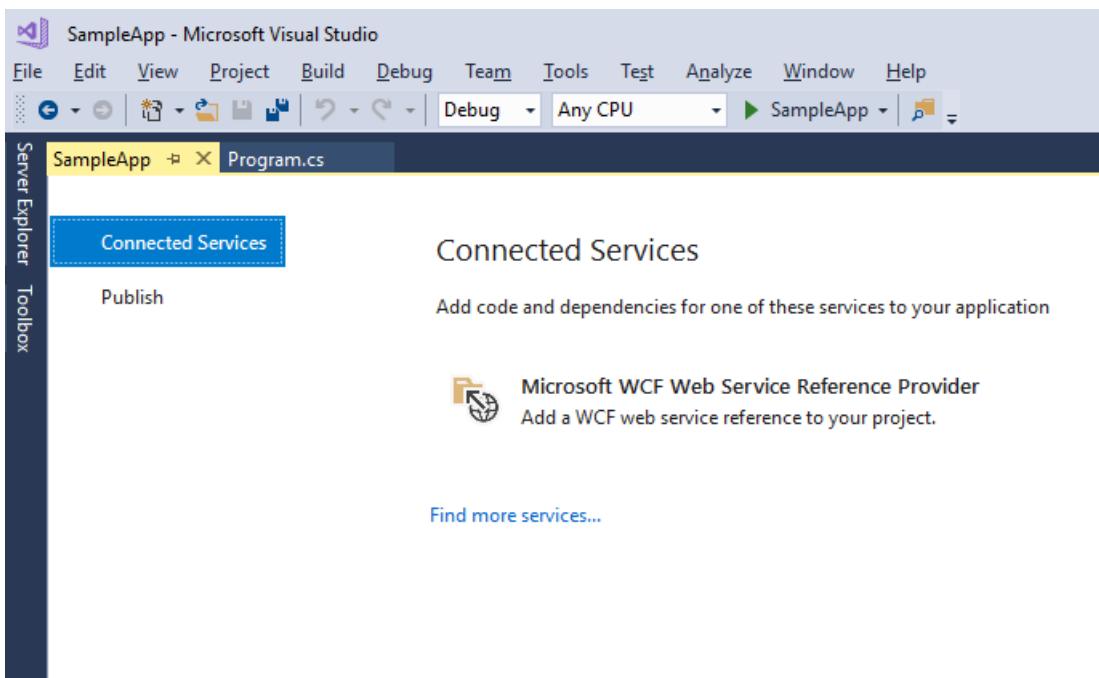

The **WCF Web Service Reference** option is applicable to projects created using the following project templates:

- **Visual C# > .NET Core**
- **Visual C# > .NET Standard**
- **Visual C# > Web > ASP.NET Core Web Application**

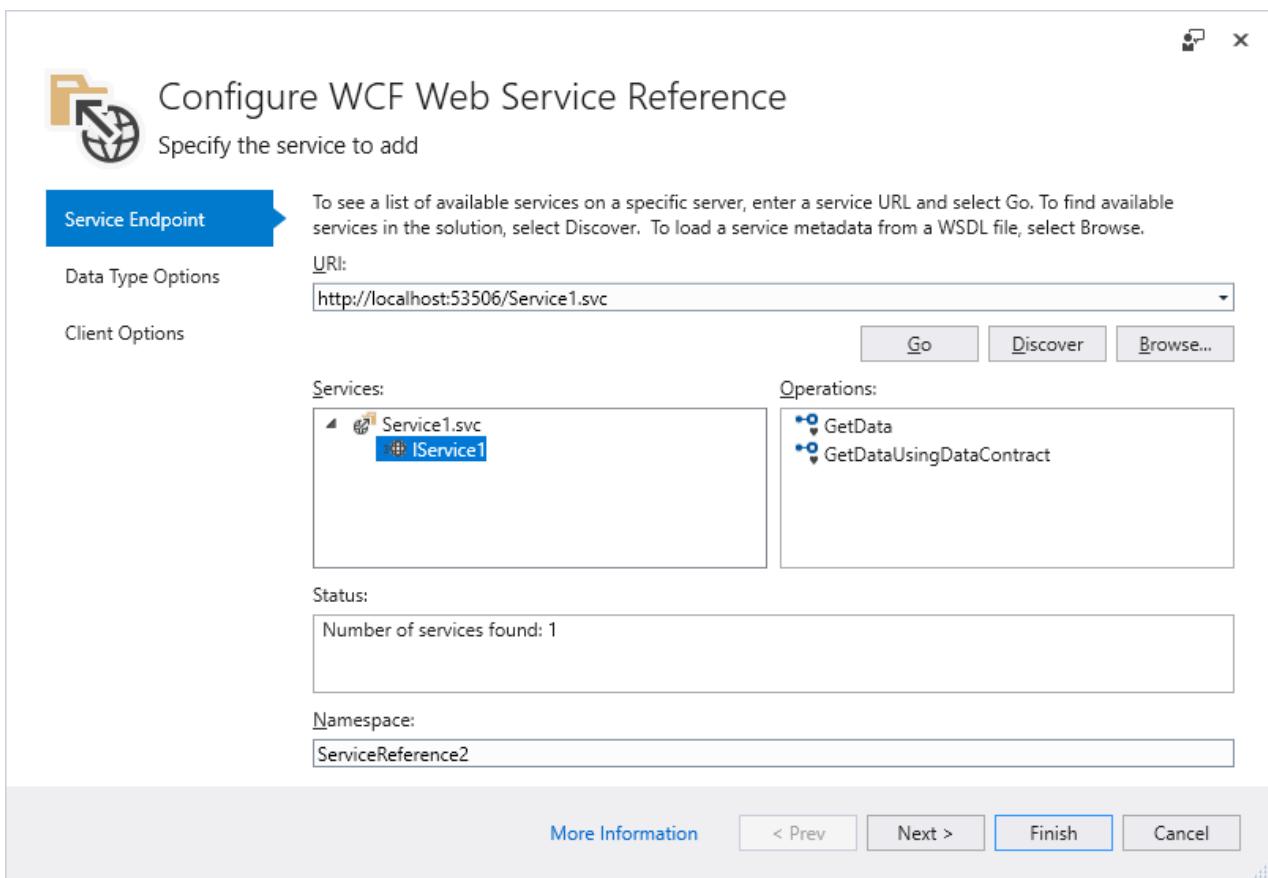

Using the **ASP.NET Core Web Application** project template as an example, this article walks you through adding a WCF service reference to the project:

1. In Solution Explorer, double-click the **Connected Services** node of the project (for a .NET Core or .NET Standard project this option is available when you right-click on the **Dependencies** node of the project in Solution Explorer).

The **Connected Services** page appears as shown in the following image:

2. On the **Connected Services** page, click **Microsoft WCF Web Service Reference Provider**. This brings up the **Configure WCF Web Service Reference** wizard:

3. Select a service.

3a. There are several services search options available within the **Configure WCF Web Service Reference** wizard:

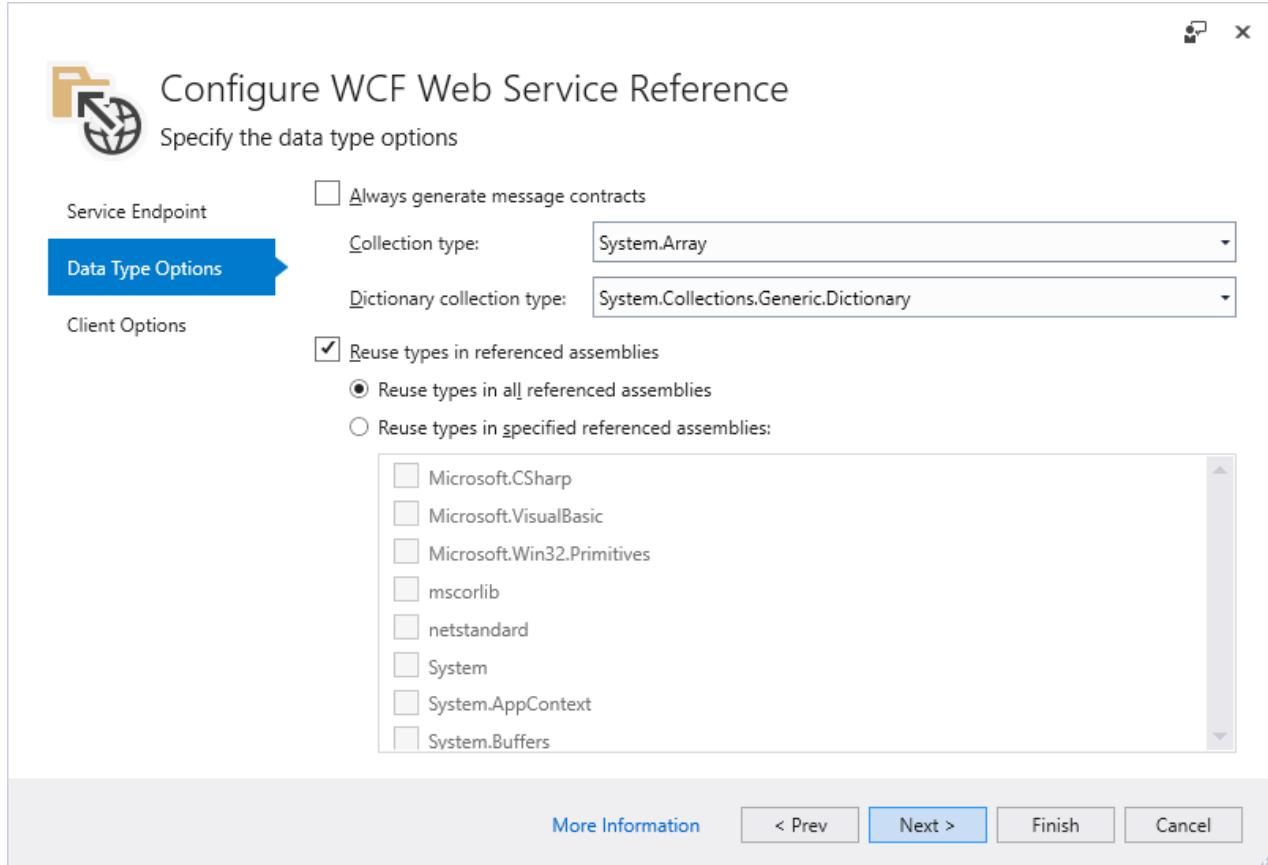

- To search for services defined in the current solution, click the **Discover** button.
- To search for services hosted at a specified address, enter a service URL in the **Address** box and click the **Go** button.
- To select a WSDL file that contains the web service metadata information, click the **Browse** button.

3b. Select the service from the search results list in the **Services** box. If needed, enter the namespace for

the generated code in the corresponding **Namespace** text box.

3c. Click the **Next** button to open the **Data Type Options** and the **Client Options** pages. Alternatively, click the **Finish** button to use the default options.

4. The **Data Type Options** form enables you to refine the generated service reference configuration settings:

NOTE

The **Reuse types in referenced assemblies** check box option is useful when data types needed for service reference code generation are defined in one of your project's referenced assemblies. It's important to reuse those existing data types to avoid compile-time type clash or runtime issues.

There may be a delay while type information is loaded, depending on the number of project dependencies and other system performance factors. The **Finish** button is disabled during loading unless the **Reuse types in referenced assemblies** check box is unchecked.

5. Click **Finish** when you are done.

While displaying progress, the tool:

- Downloads metadata from the WCF service.
- Generates the service reference code in a file named *reference.cs*, and adds it to your project under the **Connected Services** node.
- Updates the project file (.csproj) with NuGet package references required to compile and run on the target platform.

Microsoft WCF Web Service Reference Provider

Adding connected service to project...

Importing web service metadata ...

Number of service endpoints found: 1

Scaffolding service reference code ...

Restoring NuGet packages for bootstrapper ...

[Close](#)

[Abort](#)

When these processes complete, you can create an instance of the generated WCF client type and invoke the service operations.

Next steps

Feedback & questions

If you have any questions or feedback, [open an issue on GitHub](#). You can also review any existing questions or issues [at the WCF repo on GitHub](#).

Release notes

- Refer to the [Release notes](#) for updated release information, including known issues.

WCF dotnet-svcutil tool for .NET Core

2/23/2019 • 3 minutes to read • [Edit Online](#)

The Windows Communication Foundation (WCF) **dotnet-svcutil** tool is a .NET Core CLI tool that retrieves metadata from a web service on a network location or from a WSDL file, and generates a WCF class containing client proxy methods that access the web service operations.

Similar to the [Service Model Metadata - svcutil](#) tool for .NET Framework projects, the **dotnet-svcutil** is a command-line tool for generating a web service reference compatible with .NET Core and .NET Standard projects.

The **dotnet-svcutil** tool is an alternative option to the [WCF Web Service Reference](#) Visual Studio connected service provider that first shipped with Visual Studio 2017 v15.5. The **dotnet-svcutil** tool as a .NET Core CLI tool, is available cross-platform on Linux, macOS, and Windows.

IMPORTANT

You should only reference services from a trusted source. Adding references from an untrusted source may compromise security.

Prerequisites

- [dotnet-svcutil 2.x](#)
- [dotnet-svcutil 1.x](#)
- [.NET Core 2.1 SDK](#) or later versions
- Your favorite code editor

Getting started

The following example walks you through the steps required to add a web service reference to a .NET Core web project and invoke the service. You'll create a .NET Core web application named *HelloSvcutil* and add a reference to a web service that implements the following contract:

```
[ServiceContract]
public interface ISayHello
{
    [OperationContract]
    string Hello(string name);
}
```

For this example, let's assume the web service will be hosted at the following address:

<http://contoso.com/SayHello.svc>

From a Windows, macOS, or Linux command window perform the following steps:

1. Create a directory named *HelloSvcutil* for your project and make it your current directory, as in the following example:

```
mkdir HelloSvcutil
cd HelloSvcutil
```

2. Create a new C# web project in that directory using the `dotnet new` command as follows:

```
dotnet new web
```

3. Install the `dotnet-svcutil` NuGet package as a CLI tool:

- `dotnet-svcutil 2.x`
- `dotnet-svcutil 1.x`

```
dotnet tool install --global dotnet-svcutil
```

4. Run the `dotnet-svcutil` command to generate the web service reference file as follows:

- `dotnet-svcutil 2.x`
- `dotnet-svcutil 1.x`

```
dotnet-svcutil http://contoso.com/SayHello.svc
```

The generated file is saved as `HelloSvcutil/ServiceReference/Reference.cs`. The `dotnet-svcutil` tool also adds to the project the appropriate WCF packages required by the proxy code as package references.

Using the Service Reference

1. Restore the WCF packages using the `dotnet restore` command as follows:

```
dotnet restore
```

2. Find the name of the client class and operation you want to use. `Reference.cs` will contain a class that inherits from `System.ServiceModel.ClientBase`, with methods that can be used to call operations on the service. In this example, you want to call the `SayHello` service's `Hello` operation.

`ServiceReference.SayHelloClient` is the name of the client class, and has a method called `HelloAsync` that can be used to call the operation.

3. Open the `Startup.cs` file in your editor, and add a using statement for the service reference namespace at the top:

```
using ServiceReference;
```

4. Edit the `Configure` method to invoke the web service. You do this by creating an instance of the class that inherits from `ClientBase` and calling the method on the client object:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.Run(async (context) =>
    {
        var client = new SayHelloClient();
        var response = await client.HelloAsync();
        await context.Response.WriteAsync(response);
    });
}
```

5. Run the application using the `dotnet run` command as follows:

```
dotnet run
```

6. Navigate to the URL listed in the console (for example, `http://localhost:5000`) in your web browser.

You should see the following output: "Hello dotnet-svcutil!"

For a detailed description of the `dotnet-svcutil` tool parameters, invoke the tool passing the help parameter as follows:

- [dotnet-svcutil 2.x](#)
- [dotnet-svcutil 1.x](#)

```
dotnet-svcutil --help
```

Feedback & questions

If you have any questions or feedback, [open an issue on GitHub](#). You can also review any existing questions or issues [at the WCF repo on GitHub](#).

Release notes

- Refer to the [Release notes](#) for updated release information, including known issues.

Information

- [dotnet-svcutil NuGet Package](#)

Using dotnet-svcutil.xmlserializer on .NET Core

12/11/2018 • 2 minutes to read • [Edit Online](#)

The `dotnet-svcutil.xmlserializer` NuGet package can pre-generate a serialization assembly for .NET Core projects. It pre-generates C# serialization code for the types in the client application that are used by the WCF Service Contract and that can be serialized by the XmlSerializer. This improves the startup performance of XML serialization when serializing or deserializing objects of those types.

Prerequisites

- [.NET Core 2.1 SDK](#) or later
- Your favorite code editor

You can use the command `dotnet --info` to check which versions of .NET Core SDK and runtime you already have installed.

Getting started

To use `dotnet-svcutil.xmlserializer` in a .NET Core console application:

1. Create a WCF Service named 'MyWCFService' using the default template 'WCF Service Application' in .NET Framework. Add `[XmlSerializerFormat]` attribute on the service method like the following:

```
[ServiceContract]
public interface IService1
{
    [XmlSerializerFormat]
    [OperationContract(Action = "http://tempuri.org/IService1/GetData", ReplyAction =
    "http://tempuri.org/IService1/GetDataResponse")]
    string GetData(int value);
}
```

2. Create a .NET Core console application as WCF client application that targets at .NET Core 2.1 or later versions. For example, create an app named 'MyWCFClient' with the following command:

```
dotnet new console --name MyWCFClient
```

To ensure your project is targeting .NET Core 2.1 or later, inspect the `TargetFramework` XML element in your project file:

```
<TargetFramework>netcoreapp2.1</TargetFramework>
```

3. Add a package reference to `System.ServiceModel.Http` by running the following command:

```
dotnet add package System.ServiceModel.Http
```

4. Add the WCF Client code:

```

using System.ServiceModel;

class Program
{
    static void Main(string[] args)
    {
        var myBinding = new BasicHttpBinding();
        var myEndpoint = new EndpointAddress("http://localhost:2561/Service1.svc"); //Fill your
service url here
        var myChannelFactory = new ChannelFactory<IService1>(myBinding, myEndpoint);
        IService1 client = myChannelFactory.CreateChannel();
        string s = client.GetData(1);
        ((ICommunicationObject)client).Close();
    }
}

[ServiceContract]
public interface IService1
{
    [XmlSerializerFormat]
    [OperationContract(Action = "http://tempuri.org/IService1/GetData", ReplyAction =
"http://tempuri.org/IService1/GetDataResponse")]
    string GetData(int value);
}

```

- Add a reference to the `dotnet-svcutil.xmlserializer` package by running the following command:

```
dotnet add package dotnet-svcutil.xmlserializer
```

Running the command should add an entry to your project file similar to this:

```

<ItemGroup>
    <DotNetCliToolReference Include="dotnet-svcutil.xmlserializer" Version="1.0.0" />
</ItemGroup>

```

- Build the application by running `dotnet build`. If everything succeeds, an assembly named `MyWCFClient.XmlSerializers.dll` is generated in the output folder. If the tool failed to generate the assembly, you'll see warnings in the build output.
- Start the WCF service by, for example, running `http://localhost:2561/Service1.svc` in the browser. Then start the client application, and it will automatically load and use the pre-generated serializers at runtime.

Using Microsoft XML Serializer Generator on .NET Core

3/1/2019 • 2 minutes to read • [Edit Online](#)

This tutorial teaches you how to use the Microsoft XML Serializer Generator in a C# .NET Core application. During the course of this tutorial, you learn:

- How to create a .NET Core app
- How to add a reference to the `Microsoft.XmlSerializer.Generator` package
- How to edit your `MyApp.csproj` to add dependencies
- How to add a class and an `XmlSerializer`
- How to build and run the application

Like the [Xml Serializer Generator \(sgen.exe\)](#) for the .NET Framework, the [Microsoft.XmlSerializer.Generator NuGet package](#) is the equivalent for .NET Core and .NET Standard projects. It creates an XML serialization assembly for types contained in an assembly to improve the startup performance of XML serialization when serializing or de-serializing objects of those types using [XmlSerializer](#).

Prerequisites

To complete this tutorial:

- [.NET Core 2.1 SDK](#) or later
- Your favorite code editor.

TIP

Need to install a code editor? Try [Visual Studio!](#)

Use Microsoft XML Serializer Generator in a .NET Core console application

The following instructions show you how to use XML Serializer Generator in a .NET Core console application.

Create a .NET Core console application

Open a command prompt and create a folder named `MyApp`. Navigate to the folder you created and type the following command:

```
dotnet new console
```

Add a reference to the `Microsoft.XmlSerializer.Generator` package in the `MyApp` project

Use the `dotnet add package` command to add the reference in your project.

Type:

```
dotnet add package Microsoft.XmlSerializer.Generator -v 1.0.0
```

Verify changes to `MyApp.csproj` after adding the package

Open your code editor and let's get started! We're still working from the `MyApp` directory we built the app in.

Open `MyApp.csproj` in your text editor.

After running the `dotnet add package` command, the following lines are added to your `MyApp.csproj` project file:

```
<ItemGroup>
  <PackageReference Include="Microsoft.XmlSerializer.Generator" Version="1.0.0" />
</ItemGroup>
```

Add another `ItemGroup` section for .NET Core CLI Tool support

Add the following lines after the `ItemGroup` section that we inspected:

```
<ItemGroup>
  <DotNetCliToolReference Include="Microsoft.XmlSerializer.Generator" Version="1.0.0" />
</ItemGroup>
```

Add a class in the application

Open `Program.cs` in your text editor. Add the class named `MyClass` in `Program.cs`.

```
public class MyClass
{
    public int Value;
}
```

Create an `XmlSerializer` for `MyClass`

Add the following line inside `Main` to create an `XmlSerializer` for `MyClass`:

```
var serializer = new System.Xml.Serialization.XmlSerializer(typeof(MyClass));
```

Build and run the application

Still within the `MyApp` folder, run the application via `dotnet run` and it automatically loads and uses the pre-generated serializers at runtime.

Type the following command in your console window:

```
dotnet run
```

NOTE

`dotnet run` calls `dotnet build` to ensure that the build targets have been built, and then calls `dotnet <assembly.dll>` to run the target application.

IMPORTANT

The commands and steps shown in this tutorial to run your application are used during development time only. Once you're ready to deploy your app, take a look at the different [deployment strategies](#) for .NET Core apps and the `dotnet publish` command.

If everything succeeds, an assembly named *MyApp.XmlSerializers.dll* is generated in the output folder.

Congratulations! You have just:

- Created a .NET Core app.
- Added a reference to the Microsoft.XmlSerializer.Generator package.
- Edited your *MyApp.csproj* to add dependencies.
- Added a class and an XmlSerializer.
- Built and ran the application.

- [How to: Serialize Using XmlSerializer \(Visual Basic\)](#)

Port your code from .NET Framework to .NET Core

2/8/2019 • 2 minutes to read • [Edit Online](#)

If you've got code that runs on the .NET Framework, you may be interested in running your code on .NET Core, too. Here's an overview of the porting process and a list of the tools you may find helpful when porting your code to .NET Core.

Overview of the porting process

This is the process we recommend you take when porting your project to .NET Core. Each step of the process is covered in more detail in further articles.

1. Identify and account for your third-party dependencies.

This step involves understanding what your third-party dependencies are, how you depend on them, how to check if they also run on .NET Core, and steps you can take if they don't. It also covers how you can migrate your dependencies over to the [PackageReference](#) format that is used in .NET Core.

2. Retarget all projects you wish to port to target the .NET Framework 4.7.2 or higher.

This step ensures that you can use API alternatives for .NET Framework-specific targets when .NET Core doesn't support a particular API.

3. Use the [.NET Portability Analyzer](#) to analyze your assemblies and develop a plan to port based on its results.

The API Portability Analyzer tool analyzes your compiled assemblies and generates a report that shows a high-level portability summary and a breakdown of each API you're using that isn't available on .NET Core. You can use this report alongside an analysis of your codebase to develop a plan for how you'll port your code over.

4. Port your tests code.

Because porting to .NET Core is such a significant change to your codebase, it's highly recommended to get your tests ported, so that you can run tests as you port your code over. MSTest, xUnit, and NUnit all support .NET Core.

5. Execute your plan for porting!

The following list shows tools you might find helpful to use during the porting process:

- .NET Portability Analyzer - [command line tool](#) or [Visual Studio Extension](#), a toolchain that can generate a report of how portable your code is between .NET Framework and .NET Core, with an assembly-by-assembly breakdown of issues. For more information, see [.NET Portability Analyzer](#).
- .NET API analyzer - A Roslyn analyzer that discovers potential compatibility risks for C# APIs on different platforms and detects calls to deprecated APIs. For more information, see [.NET API analyzer](#).
- Reverse Package Search - A [useful web service](#) that allows you to search for a type and find packages containing that type.

Additionally, you can attempt to port smaller solutions or individual projects to the .NET Core project file format with the [CsprojToVs2017](#) tool.

WARNING

CsprojToVs2017 is a third-party tool. There is no guarantee that it will work for all of your projects, and it may cause subtle changes in behavior that you depend on. CsprojToVs2017 should be used as a *starting point* that automates the basic things that can be automated. It is not a guaranteed solution to migrating project file formats.

NEXT

.NET Framework technologies unavailable on .NET Core

3/19/2019 • 2 minutes to read • [Edit Online](#)

Several technologies available to .NET Framework libraries aren't available for use with .NET Core, such as AppDomains, Remoting, Code Access Security (CAS), and Security Transparency. If your libraries rely on one or more of these technologies, consider the alternative approaches outlined below. For more information on API compatibility, the CoreFX team maintains a [List of behavioral changes/compat breaks and deprecated/legacy APIs](#) at GitHub.

Just because an API or technology isn't currently implemented doesn't imply it's intentionally unsupported. You should first search the GitHub repositories for .NET Core to see if a particular issue you encounter is by design, but if you cannot find such an indicator, please file an issue in the [dotnet/corefx repository issues](#) at GitHub to ask for specific APIs and technologies. [Porting requests in the issues](#) are marked with the `port-to-core` label.

AppDomains

Application domains (AppDomains) isolate apps from one another. AppDomains require runtime support and are generally quite expensive. Creating additional app domains is not supported.. We don't plan on adding this capability in future. For code isolation, we recommend separate processes or using containers as an alternative. For the dynamic loading of assemblies, we recommend the new [AssemblyLoadContext](#) class.

To make code migration from .NET Framework easier, .NET Core exposes some of the [AppDomain](#) API surface. Some of the APIs function normally (for example, [AppDomain.UnhandledException](#)), some members do nothing (for example, [SetCachePath](#)), and some of them throw [PlatformNotSupportedException](#) (for example, [CreateDomain](#)). Check the types you use against the `System.AppDomain` reference source in the [dotnet/corefx GitHub repository](#), making sure to select the branch that matches your implemented version.

Remoting

.NET Remoting was identified as a problematic architecture. It's used for cross-AppDomain communication, which is no longer supported. Also, Remoting requires runtime support, which is expensive to maintain. For these reasons, .NET Remoting isn't supported on .NET Core, and we don't plan on adding support for it in the future.

For communication across processes, consider inter-process communication (IPC) mechanisms as an alternative to Remoting, such as the [System.IO.Pipes](#) or the [MemoryMappedFile](#) class.

Across machines, use a network-based solution as an alternative. Preferably, use a low-overhead plain text protocol, such as HTTP. The [Kestrel web server](#), the web server used by ASP.NET Core, is an option here. Also consider using [System.Net.Sockets](#) for network-based, cross-machine scenarios. For more options, see [.NET Open Source Developer Projects: Messaging](#).

Code Access Security (CAS)

Sandboxing, which relies on the runtime or the framework to constrain which resources a managed application or library uses or runs, [isn't supported on .NET Framework](#) and therefore is also not supported on .NET Core. There are too many cases in the .NET Framework and the runtime where an elevation of privileges occurs to continue treating CAS as a security boundary. In addition, CAS makes the implementation more complicated and often has correctness-performance implications for applications that don't intend to use it.

Use security boundaries provided by the operating system, such as virtualization, containers, or user accounts for running processes with the minimum set of privileges.

Security Transparency

Similar to CAS, Security Transparency separates sandboxed code from security critical code in a declarative fashion but is [no longer supported as a security boundary](#). This feature is heavily used by Silverlight.

Use security boundaries provided by the operating system, such as virtualization, containers, or user accounts for running processes with the least set of privileges.

Analyze your dependencies to port code to .NET Core

2/8/2019 • 5 minutes to read • [Edit Online](#)

To port your code to .NET Core or .NET Standard, you must understand your dependencies. External dependencies are the [NuGet packages](#) or [DLLs](#) you reference in your project, but that you don't build. Evaluate each dependency and develop a contingency plan for the ones that aren't compatible with .NET Core. Here's how to determine if a dependency is compatible with .NET Core.

Analyze referenced NuGet packages in your projects

If you reference NuGet packages in your project, you need to verify if they're compatible with .NET Core. There are two ways to accomplish that:

- [Using the NuGet Package Explorer app](#)
- [Using the nuget.org site](#)

After analyzing the packages, if they're not compatible with .NET Core and only target .NET Framework, you can check if the [.NET Framework compatibility mode](#) can help with your porting process.

Analyze NuGet packages using NuGet Package Explorer

A NuGet package is itself a set of folders that contain platform-specific assemblies. So you need to check if there's a folder that contains a compatible assembly inside the package.

The easiest way to inspect NuGet Package folders is to use the [NuGet Package Explorer](#) tool. After installing it, use the following steps to see the folder names:

1. Open the NuGet Package Explorer.
2. Click **Open package from online feed**.
3. Search for the name of the package.
4. Select the package name from the search results and click **open**.
5. Expand the *lib* folder on the right-hand side and look at folder names.

Look for a folder with any of the following names:

```
netstandard1.0
netstandard1.1
netstandard1.2
netstandard1.3
netstandard1.4
netstandard1.5
netstandard1.6
netstandard2.0
netcoreapp1.0
netcoreapp1.1
netcoreapp2.0
netcoreapp2.1
netcoreapp2.2
portable-net45-win8
portable-win8-wpa8
portable-net451-win81
portable-net45-win8-wpa8-wpa81
```

These values are the [Target Framework Monikers \(TFMs\)](#) that map to versions of the [.NET Standard](#), .NET Core, and traditional Portable Class Library (PCL) profiles that are compatible with .NET Core.

IMPORTANT

When looking at the TFMs that a package supports, note that `netcoreapp*`, while compatible, is for .NET Core projects only and not for .NET Standard projects. A library that only targets `netcoreapp*` and not `netstandard*` can only be consumed by other .NET Core apps.

Analyze NuGet packages using [nuget.org](#)

Alternatively, you can see the TFMs that each package supports on [nuget.org](#) under the **Dependencies** section of the package page.

Although using the site is an easier method to verify the compatibility, **Dependencies** information is not available on the site for all packages.

.NET Framework compatibility mode

After analyzing the NuGet packages, you might find that they only target the .NET Framework, as most NuGet packages do.

Starting with .NET Standard 2.0, the .NET Framework compatibility mode was introduced. This compatibility mode allows .NET Standard and .NET Core projects to reference .NET Framework libraries. Referencing .NET Framework libraries doesn't work for all projects, such as if the library uses Windows Presentation Foundation (WPF) APIs, but it does unblock many porting scenarios.

When you reference NuGet packages that target the .NET Framework in your project, such as [Huitian.PowerCollections](#), you get a package fallback warning ([NU1701](#)) similar to the following example:

NU1701: Package 'Huitian.PowerCollections 1.0.0' was restored using '.NETFramework,Version=v4.6.1' instead of the project target framework '.NETStandard,Version=v2.0'. This package may not be fully compatible with your project.

That warning is displayed when you add the package and every time you build to make sure you test that package with your project. If your project is working as expected, you can suppress that warning by editing the package properties in Visual Studio or by manually editing the project file in your favorite code editor.

To suppress the warning by editing the project file, find the `PackageReference` entry for the package you want to suppress the warning for and add the `NoWarn` attribute. The `NoWarn` attribute accepts a comma-separated list of all the warning IDs. The following example shows how to suppress the [NU1701](#) warning for the [Huitian.PowerCollections](#) package by editing your project file manually:

```
<ItemGroup>
  <PackageReference Include="Huitian.PowerCollections" Version="1.0.0" NoWarn="NU1701" />
</ItemGroup>
```

For more information on how to suppress compiler warnings in Visual Studio, see [Suppressing warnings for NuGet packages](#).

Port your packages to `PackageReference`

.NET Core uses `PackageReference` to specify package dependencies. If you are using `packages.config` to specify your packages, you will need to convert over to `PackageReference`.

You can learn more at [Migrate from packages.config to PackageReference](#).

What to do when your NuGet package dependency doesn't run on .NET Core

There are a few things you can do if a NuGet package you depend on doesn't run on .NET Core:

1. If the project is open source and hosted somewhere like GitHub, you can engage the developers directly.
2. You can contact the author directly on nuget.org. Search for the package and click **Contact Owners** on the left-hand side of the package's page.
3. You can search for another package that runs on .NET Core that accomplishes the same task as the package you were using.
4. You can attempt to write the code the package was doing yourself.
5. You could eliminate the dependency on the package by changing the functionality of your app, at least until a compatible version of the package becomes available.

Remember that open-source project maintainers and NuGet package publishers are often volunteers. They contribute because they care about a given domain, do it for free, and often have a different daytime job. So be mindful of that when contacting them to ask for .NET Core support.

If you can't resolve your issue with any of the above, you may have to port to .NET Core at a later date.

The .NET Team would like to know which libraries are the most important to support with .NET Core. You can send an email to dotnet@microsoft.com about the libraries you'd like to use.

Analyze dependencies that aren't NuGet packages

You may have a dependency that isn't a NuGet package, such as a DLL in the file system. The only way to determine the portability of that dependency is to run the [.NET Portability Analyzer](#) tool. The tool can analyze assemblies that target the .NET Framework and identify APIs that aren't portable to other .NET platforms such as .NET Core. You can run the tool as a console application or as a [Visual Studio extension](#).

NEXT

Port .NET Framework libraries to .NET Core

2/23/2019 • 6 minutes to read • [Edit Online](#)

Learn how to port .NET Framework library code to .NET Core, to run cross-platform and expand the reach of the apps that use it.

Prerequisites

This article assumes that you:

- Are using Visual Studio 2017 or later.
 - .NET Core isn't supported on earlier versions of Visual Studio
- Understand the [recommended porting process](#).
- Have resolved any issues with [third-party dependencies](#).

You should also become familiar with the content of the following topics:

[.NET Standard](#)

This topic describes the formal specification of .NET APIs that are intended to be available on all .NET implementations.

[Packages, Metapackages and Frameworks](#)

This article discusses how .NET Core defines and uses packages and how packages support code running on multiple .NET implementations.

[Developing Libraries with Cross Platform Tools](#)

This topic explains how to write libraries for .NET using cross-platform CLI tools.

[Additions to the *csproj* format for .NET Core](#)

This article outlines the changes that were added to the project file as part of the move to *csproj* and MSBuild.

[Porting to .NET Core - Analyzing your Third-Party Party Dependencies](#)

This topic discusses the portability of third-party dependencies and what to do when a NuGet package dependency doesn't run on .NET Core.

Retargeting your .NET Framework code to .NET Framework 4.7.2

If your code isn't targeting .NET Framework 4.7.2, we recommend that you retarget to .NET Framework 4.7.2. This ensures the availability of the latest API alternatives for cases where the .NET Standard doesn't support existing APIs.

For each of your projects in Visual Studio you wish to port, do the following:

1. Right-click on the project and select **Properties**.
2. In the **Target Framework** dropdown, select **.NET Framework 4.7.2**.
3. Recompile your projects.

Because your projects now target .NET Framework 4.7.2, use that version of the .NET Framework as your base for porting code.

Determining the portability of your code

The next step is to run the API Portability Analyzer (ApiPort) to generate a portability report for analysis.

Make sure you understand the [API Portability Analyzer \(ApiPort\)](#) and how to generate portability reports for targeting .NET Core. How you do this likely varies based on your needs and personal tastes. What follows are a few different approaches. You may find yourself mixing steps of these approaches depending on how your code is structured.

Dealing primarily with the compiler

This approach may be the best for small projects or projects which don't use many .NET Framework APIs. The approach is simple:

1. Optionally, run ApiPort on your project. If you run ApiPort, gain knowledge from the report on issues you'll need to address.
2. Copy all of your code over into a new .NET Core project.
3. While referring to the portability report (if generated), solve compiler errors until the project fully compiles.

Although this approach is unstructured, the code-focused approach often leads to resolving issues quickly and might be the best approach for smaller projects or libraries. A project that contains only data models might be an ideal candidate for this approach.

Staying on the .NET Framework until portability issues are resolved

This approach might be the best if you prefer to have code that compiles during the entire process. The approach is as follows:

1. Run ApiPort on a project.
2. Address issues by using different APIs that are portable.
3. Take note of any areas where you're prevented from using a direct alternative.
4. Repeat the prior steps for all projects you're porting until you're confident each is ready to be copied over into a new .NET Core project.
5. Copy the code into a new .NET Core project.
6. Work out any issues where you noted that a direct alternative doesn't exist.

This careful approach is more structured than simply working out compiler errors, but it's still relatively code-focused and has the benefit of always having code that compiles. The way you resolve certain issues that couldn't be addressed by just using another API varies greatly. You may find that you need to develop a more comprehensive plan for certain projects, which is covered as the next approach.

Developing a comprehensive plan of attack

This approach might be best for larger and more complex projects, where restructuring code or completely rewriting certain areas of code might be necessary to support .NET Core. The approach is as follows:

1. Run ApiPort on a project.
2. Understand where each non-portable type is used and how that affects overall portability.
 - Understand the nature of those types. Are they small in number but used frequently? Are they large in number but used infrequently? Is their use concentrated, or is it spread throughout your code?
 - Is it easy to isolate code that isn't portable so that you can deal with it more effectively?
 - Do you need to refactor your code?
 - For those types which aren't portable, are there alternative APIs that accomplish the same task? For example if you're using the [WebClient](#) class, you might be able to use the [HttpClient](#) class instead.
 - Are there different portable APIs available to accomplish a task, even if it's not a drop-in replacement? For example if you're using [XmlSchema](#) to parse XML but don't require XML schema discovery, you could use [System.Xml.Linq](#) APIs and implement parsing yourself as opposed to relying on an API.
3. If you have assemblies that are difficult to port, is it worth leaving them on .NET Framework for now? Here are some things to consider:
 - You may have some functionality in your library that's incompatible with .NET Core because it relies too

heavily on .NET Framework or Windows-specific functionality. Is it worth leaving that functionality behind for now and releasing a .NET Core version of your library with less features on a temporary basis until resources are available to port the features?

- Would a refactor help?
4. Is it reasonable to write your own implementation of an unavailable .NET Framework API? You could consider copying, modifying, and using code from the [.NET Framework Reference Source](#). The reference source code is licensed under the [MIT License](#), so you have significant freedom to use the source as a basis for your own code. Just be sure to properly attribute Microsoft in your code.
5. Repeat this process as needed for different projects.

The analysis phase could take some time depending on the size of your codebase. Spending time in this phase to thoroughly understand the scope of changes needed and to develop a plan usually saves you time in the long run, particularly if you have a complex codebase.

Your plan could involve making significant changes to your codebase while still targeting .NET Framework 4.7.2, making this a more structured version of the previous approach. How you go about executing your plan is dependent on your codebase.

Mixing approaches

It's likely that you'll mix the above approaches on a per-project basis. You should do what makes the most sense to you and for your codebase.

Porting your tests

The best way to make sure everything works when you've ported your code is to test your code as you port it to .NET Core. To do this, you'll need to use a testing framework that builds and runs tests for .NET Core. Currently, you have three options:

- [xUnit](#)
 - [Getting Started](#)
 - [Tool to convert an MSTest project to xUnit](#)
- [NUnit](#)
 - [Getting Started](#)
 - [Blog post about migrating from MSTest to NUnit](#)
- [MSTest](#)

Recommended approach to porting

Ultimately, the porting effort depends heavily on how your .NET Framework code is structured. A good way to port your code is to begin with the *base* of your library, which are the foundational components of your code. This might be data models or some other foundational classes and methods that everything else uses directly or indirectly.

1. Port the test project that tests the layer of your library that you're currently porting.
2. Copy over the base of your library into a new .NET Core project and select the version of the .NET Standard you wish to support.
3. Make any changes needed to get the code to compile. Much of this may require adding NuGet package dependencies to your `csproj` file.
4. Run the tests and make any needed adjustments.
5. Pick the next layer of code to port over and repeat the prior steps.

If you start with the base of your library and move outward from the base and test each layer as needed, porting is a systematic process where problems are isolated to one layer of code at a time.

NEXT

Organize your project to support both .NET Framework and .NET Core

3/19/2019 • 2 minutes to read • [Edit Online](#)

Learn how to create a solution that compiles for both .NET Framework and .NET Core side-by-side. See several options to organize projects to help you achieve this goal. Here are some typical scenarios to consider when you're deciding how to setup your project layout with .NET Core. The list may not cover everything you want; prioritize based on your project's needs.

- **Combine existing projects and .NET Core projects into single projects**

What this is good for:

- Simplifying your build process by compiling a single project rather than compiling multiple projects, each targeting a different .NET Framework version or platform.
- Simplifying source file management for multi-targeted projects because you must manage a single project file. When adding/removing source files, the alternatives require you to manually sync these with your other projects.
- Easily generating a NuGet package for consumption.
- Allows you to write code for a specific .NET Framework version in your libraries through the use of compiler directives.

Unsupported scenarios:

- Requires developers to use Visual Studio 2017 to open existing projects. To support older versions of Visual Studio, [keeping your project files in different folders](#) is a better option.

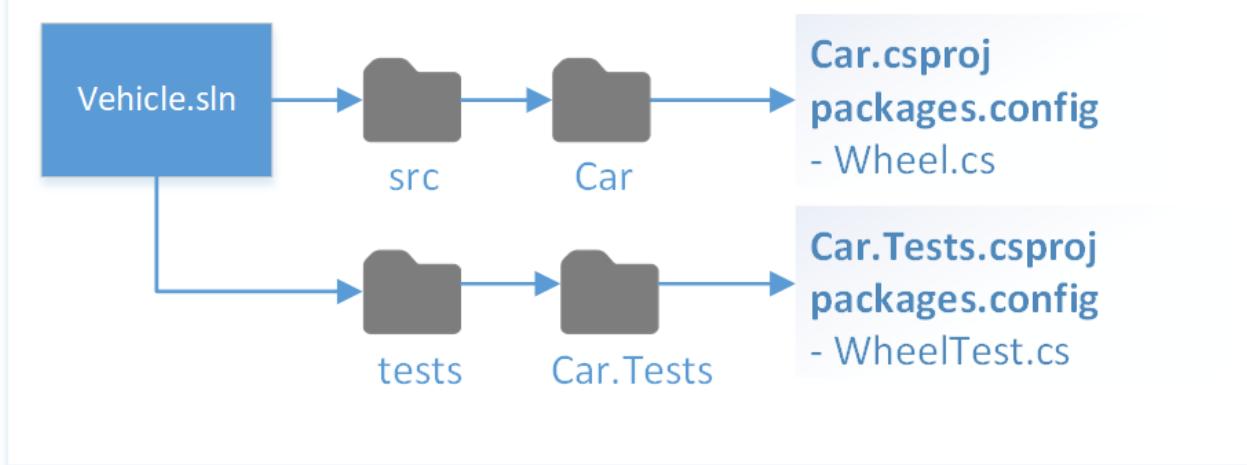

- **Keep existing projects and new .NET Core projects separate**

What this is good for:

- Continuing to support development on existing projects without having to upgrade for developers/contributors who may not have Visual Studio 2017.
- Decreasing the possibility of creating new bugs in existing projects because no code churn is required in those projects.

Example

Consider the repository below:

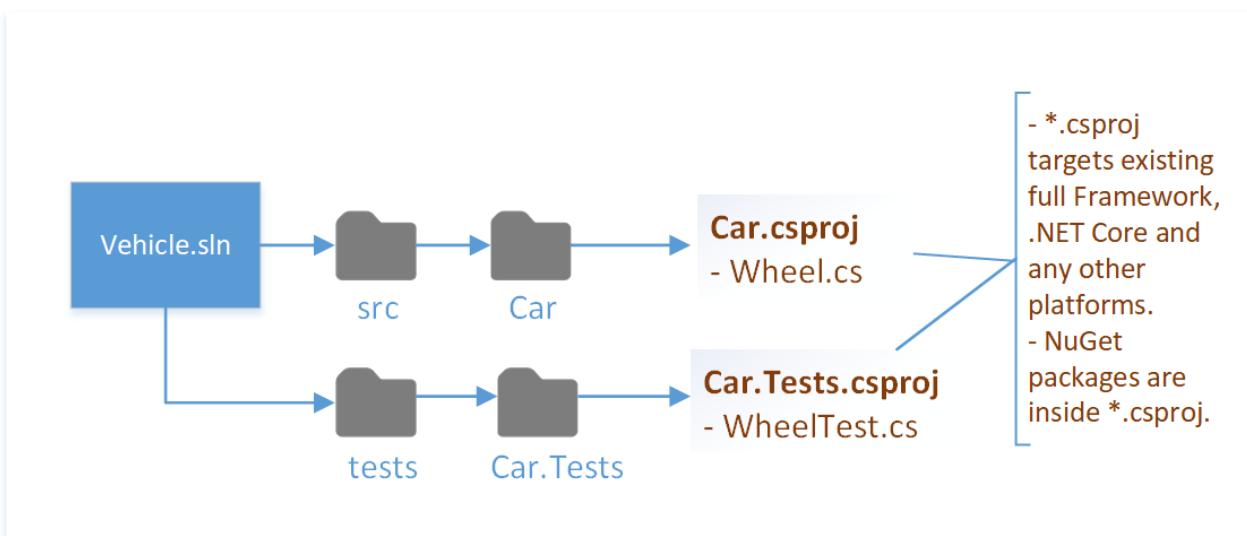

Source Code

The following describes several ways to add support for .NET Core for this repository depending on the constraints and complexity of the existing projects.

Replace existing projects with a multi-targeted .NET Core project

Reorganize the repository so that any existing *.csproj files are removed and a single *.csproj file is created that targets multiple frameworks. This is a great option because a single project is able to compile for different frameworks. It also has the power to handle different compilation options and dependencies per targeted framework.

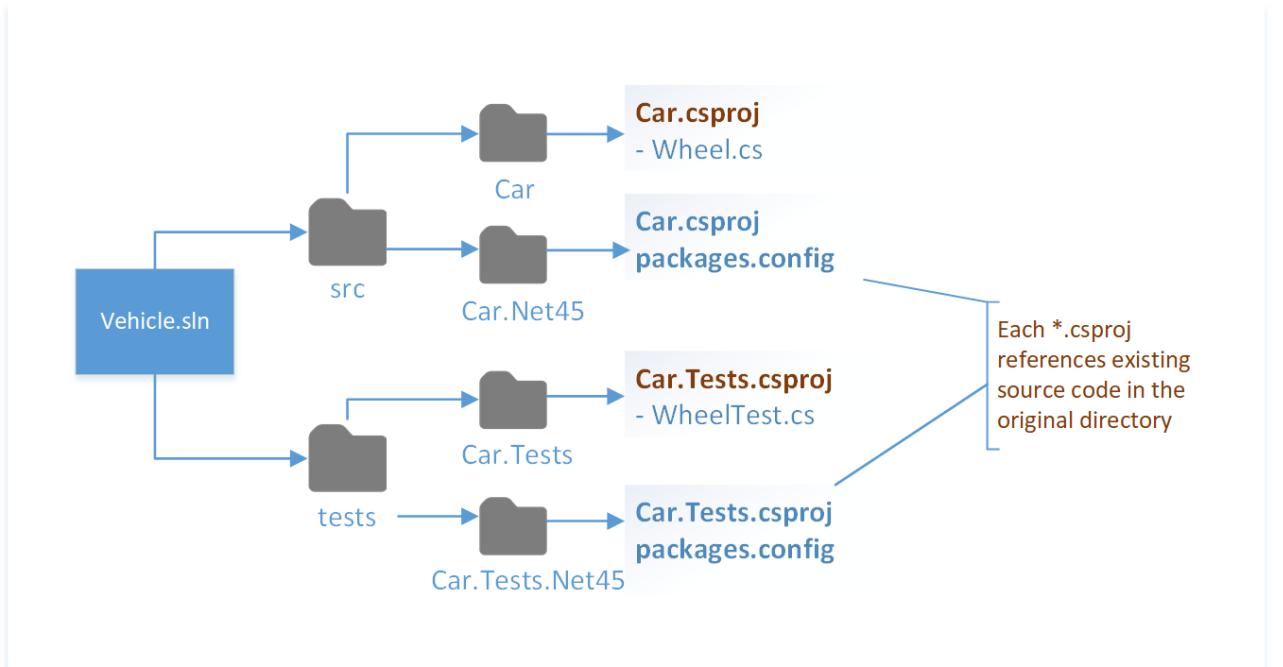

Source Code

Changes to note are:

- Replacement of `packages.config` and `*.csproj` with a new `.NET Core *.csproj`. NuGet packages are specified with `<PackageReference>` `ItemGroup`.

Keep existing projects and create a .NET Core project

If there are existing projects that target older frameworks, you may want to leave these projects untouched and use a .NET Core project to target future frameworks.

Source Code

Changes to note are:

- The .NET Core and existing projects are kept in separate folders.
 - Keeping projects in separate folders avoids forcing you to have Visual Studio 2017. You can create a separate solution that only opens the old projects.

See also

Please see the [.NET Core porting documentation](#) for more guidance on migrating to .NET Core.

Tools to help with porting to .NET Core

2/8/2019 • 2 minutes to read • [Edit Online](#)

You may find the tools listed in this article helpful when porting:

- [.NET Portability Analyzer](#), a toolchain that can generate a report of how portable your code is between .NET Framework and .NET Core: As a [command line tool](#) As a [Visual Studio Extension](#)
- [.NET API analyzer](#) - A Roslyn analyzer that discovers potential compatibility risks for C# APIs on different platforms and detects calls to deprecated APIs.

Additionally, you can attempt to port smaller solutions or individual projects to the .NET Core project file format with the [CsprojToVs2017](#) tool.

WARNING

CsprojToVs2017 is a third-party tool. There is no guarantee that it will work for all of your projects, and it may cause subtle changes in behavior that you depend on. CsprojToVs2017 should be used as a *starting point* that automates the basic things that can be automated. It is not a guaranteed solution to migrating project file formats.

Use the Windows Compatibility Pack to port code to .NET Core

3/9/2019 • 2 minutes to read • [Edit Online](#)

Some of the most common issues found when porting existing code to .NET Core are dependencies on APIs and technologies that are only found in the .NET Framework. The *Windows Compatibility Pack* provides many of these technologies, so it's much easier to build .NET Core applications and .NET Standard libraries.

This package is a logical [extension of .NET Standard 2.0](#) that significantly increases API set and existing code compiles with almost no modifications. But in order to keep the promise of .NET Standard ("it is the set of APIs that all .NET implementations provide"), this didn't include technologies that can't work across all platforms, such as registry, Windows Management Instrumentation (WMI), or reflection emit APIs.

The *Windows Compatibility Pack* sits on top of .NET Standard and provides access to technologies that are Windows only. It's especially useful for customers that want to move to .NET Core but plan to stay on Windows as a first step. In that scenario, not being able to use Windows-only technologies is only a migration hurdle with zero architectural benefits.

Package contents

The *Windows Compatibility Pack* is provided via the NuGet Package [Microsoft.Windows.Compatibility](#) and can be referenced from projects targeting .NET Core or .NET Standard.

It provides about 20,000 APIs, including Windows-only as well as cross-platform APIs from the following technology areas:

- Code Pages
- CodeDom
- Configuration
- Directory Services
- Drawing
- ODBC
- Permissions
- Ports
- Windows Access Control Lists (ACL)
- Windows Communication Foundation (WCF)
- Windows Cryptography
- Windows EventLog
- Windows Management Instrumentation (WMI)
- Windows Performance Counters
- Windows Registry
- Windows Runtime Caching
- Windows Services

For more information, see the [spec of the compatibility pack](#).

Get started

1. Before porting, make sure to take a look at the [Porting Process](#).
2. When porting existing code to .NET Core or .NET Standard, install the NuGet package [Microsoft.Windows.Compatibility](#).
3. If you want to stay on Windows, you're all set.
4. If you want to run the .NET Core application or .NET Standard library on Linux or macOS, use the [API Analyzer](#) to find usage of APIs that won't work cross-platform.
5. Either remove the usages of those APIs, replace them with cross-platform alternatives, or guard them using a platform check, like:

```
private static string GetLoggingPath()
{
    // Verify the code is running on Windows.
    if (RuntimeInformation.IsOSPlatform(OSPlatform.Windows))
    {
        using (var key = Registry.CurrentUser.OpenSubKey(@"Software\Fabrikam\AssetManagement"))
        {
            if (key?.GetValue("LoggingDirectoryPath") is string configuredPath)
                return configuredPath;
        }
    }

    // This is either not running on Windows or no logging path was configured,
    // so just use the path for non-roaming user-specific data files.
    var appDataPath = Environment.GetFolderPath(Environment.SpecialFolder.LocalApplicationData);
    return Path.Combine(appDataPath, "Fabrikam", "AssetManagement", "Logging");
}
```

For a demo, check out the [Channel 9 video of the Windows Compatibility Pack](#).

How to: Port a Windows Forms desktop app to .NET Core

3/8/2019 • 8 minutes to read • [Edit Online](#)

This article describes how to port your Windows Forms-based desktop app from .NET Framework to .NET Core 3.0. The .NET Core 3.0 SDK includes support for Windows Forms applications. Windows Forms is still a Windows-only framework and only runs on Windows. This example uses the .NET Core SDK CLI to create and manage your project.

In this article, various names are used to identify types of files used for migration. When migrating your project, your files will be named differently, so mentally match them to the ones listed below:

FILE	DESCRIPTION
MyApps.sln	The name of the solution file.
MyForms.csproj	The name of the .NET Framework Windows Forms project to port.
MyFormsCore.csproj	The name of the new .NET Core project you create.
MyAppCore.exe	The .NET Core Windows Forms app executable.

Prerequisites

- [Visual Studio 2019](#) for any designer work you want to do.

Install the following Visual Studio workloads:

- .NET desktop development
- .NET cross-platform development

- A working Windows Forms project in a solution that builds and runs without issue.
- Your project must be coded in C#.
- Install the latest [.NET Core 3.0](#) preview.

NOTE

Visual Studio 2017 doesn't support .NET Core 3.0 projects. **Visual Studio 2019 Preview/RC** supports .NET Core 3.0 projects but doesn't yet support the visual designer for .NET Core 3.0 Windows Forms projects. To use the visual designer, you must have a .NET Windows Forms project in your solution that shares the forms files with the .NET Core project.

Consider

When porting a .NET Framework Windows Forms application, there are a few things you must consider.

1. Check that your application is a good candidate for migration.

Use the [.NET Portability Analyzer](#) to determine if your project will migrate to .NET Core 3.0. If your project has issues with .NET Core 3.0, the analyzer helps you identify those problems.

2. You're using a different version of Windows Forms.

When .NET Core 3.0 Preview 1 was released, Windows Forms went open-source on GitHub. The code for .NET Core Windows Forms is a fork of the .NET Framework Windows Forms code base. It's possible some differences exist and your app won't port.

3. The [Windows Compatibility Pack](#) may help you migrate.

Some APIs that are available in .NET Framework aren't available in .NET Core 3.0. The [Windows Compatibility Pack](#) adds many of these APIs and may help your Windows Forms app become compatible with .NET Core.

4. Update the NuGet packages used by your project.

It's always a good practice to use the latest versions of NuGet packages before any migration. If your application is referencing any NuGet packages, update them to the latest version. Ensure your application builds successfully. After upgrading, if there are any package errors, downgrade the package to the latest version that doesn't break your code.

5. Visual Studio 2019 Preview/RC doesn't yet support the Forms Designer for .NET Core 3.0

Currently, you need to keep your existing .NET Framework Windows Forms project file if you want to use the Forms Designer from Visual Studio.

Create a new SDK project

The new .NET Core 3.0 project you create must be in a different directory from your .NET Framework project. If they're both in the same directory, you may run into conflicts with the files that are generated in the **obj** directory. In this example, we'll create a directory named **MyFormsAppCore** in the **SolutionFolder** directory:

```
SolutionFolder
├──MyApps.sln
├──MyFormsApp
│   └──MyForms.csproj
└──MyFormsAppCore      <--- New folder for core project
```

Next, you need to create the **MyFormsCore.csproj** project in the **MyFormsAppCore** directory. You can create this file manually by using the text editor of choice. Paste in the following XML:

```
<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">

    <PropertyGroup>
        <OutputType>WinExe</OutputType>
        <TargetFramework>netcoreapp3.0</TargetFramework>
        <UseWindowsForms>true</UseWindowsForms>
    </PropertyGroup>

</Project>
```

If you don't want to create the project file manually, you can use Visual Studio or the .NET Core SDK to generate the project. However, you must delete all other files generated by the project template except for the project file. To use the SDK, run the following command from the **SolutionFolder** directory:

```
dotnet new winforms -o MyFormsAppCore -n MyFormsCore
```

After you create the **MyFormsCore.csproj**, your directory structure should look like the following:

```
SolutionFolder
├── MyApps.sln
├── MyFormsApp
│   └── MyForms.csproj
└── MyFormsAppCore
    └── MyFormsCore.csproj
```

You'll want to add the **MyFormsCore.csproj** project to **MyApps.sln** with either Visual Studio or the .NET Core CLI from the **SolutionFolder** directory:

```
dotnet sln add .\MyFormsAppCore\MyFormsCore.csproj
```

Fix assembly info generation

Windows Forms projects that were created with .NET Framework include an `AssemblyInfo.cs` file, which contains assembly attributes such as the version of the assembly to be generated. SDK-style projects automatically generate this information for you based on the SDK project file. Having both types of "assembly info" creates a conflict. Resolve this problem by disabling automatic generation, which forces the project to use your existing `AssemblyInfo.cs` file.

There are three settings to add to the main `<PropertyGroup>` node.

- **GenerateAssemblyInfo**

When you set this property to `false`, it won't generate the assembly attributes. This avoids the conflict with the existing `AssemblyInfo.cs` file from the .NET Framework project.

- **AssemblyName**

The value of this property is the output binary created when you compile. The name doesn't need an extension added to it. For example, using `MyCoreApplication` produces `MyCoreApplication.exe`.

- **RootNamespace**

The default namespace used by your project. This should match the default namespace of the .NET Framework project.

Add these three elements to the `<PropertyGroup>` node in the `MyFormsCore.csproj` file:

```
<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">

    <PropertyGroup>
        <OutputType>WinExe</OutputType>
        <TargetFramework>netcoreapp3.0</TargetFramework>
        <UseWindowsForms>true</UseWindowsForms>

        <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
        <AssemblyName>MyCoreApplication</AssemblyName>
        <RootNamespace>WindowsFormsApp1</RootNamespace>
    </PropertyGroup>

</Project>
```

Add source code

Right now, the **MyFormsCore.csproj** project doesn't compile any code. By default, .NET Core projects automatically include all source code in the current directory and any child directories. You must configure the project to include code from the .NET Framework project using a relative path. If your .NET Framework project used `.resx` files for icons and resources for your forms, you'll need to include those too.

Add the following `<ItemGroup>` node to your project. Each statement includes a file glob pattern that includes child directories.

```
<ItemGroup>
  <Compile Include="..\MyFormsApp\**\*.cs" />
  <EmbeddedResource Include="..\MyFormsApp\**\*.resx" />
</ItemGroup>
```

Alternatively, you can create a `<Compile>` or `<EmbeddedResource>` entry for each file in your .NET Framework project.

Add NuGet packages

Add each NuGet package referenced by the .NET Framework project to the .NET Core project.

Most likely your .NET Framework Windows Forms app has a **packages.config** file that contains a list of all of the NuGet packages that are referenced by your project. You can look at this list to determine which NuGet packages to add to the .NET Core project. For example, if the .NET Framework project referenced the `MetroFramework`, `MetroFramework.Design`, and `MetroFramework.Flights` NuGet packages, add each to the project with either Visual Studio or the .NET Core CLI from the **SolutionFolder** directory:

```
dotnet add .\MyFormsAppCore\MyFormsCore.csproj package MetroFramework
dotnet add .\MyFormsAppCore\MyFormsCore.csproj package MetroFramework.Design
dotnet add .\MyFormsAppCore\MyFormsCore.csproj package MetroFramework.Flights
```

The previous commands would add the following NuGet references to the **MyFormsCore.csproj** project:

```
<ItemGroup>
  <PackageReference Include="MetroFramework" Version="1.2.0.3" />
  <PackageReference Include="MetroFramework.Design" Version="1.2.0.3" />
  <PackageReference Include="MetroFramework.Flights" Version="1.2.0.3" />
</ItemGroup>
```

Port control libraries

If you have a Windows Forms Controls library project to port, the directions are the same as porting a .NET Framework Windows Forms app project, except for a few settings. And instead of compiling to an executable, you compile to a library. The difference between the executable project and the library project, besides paths for the file globs that include your source code, is minimal.

Using the previous step's example, let's expand what projects and files we're working with.

FILE	DESCRIPTION
MyApps.sln	The name of the solution file.
MyControls.csproj	The name of the .NET Framework Windows Forms Controls project to port.
MyControlsCore.csproj	The name of the new .NET Core library project you create.
MyCoreControls.dll	The .NET Core Windows Forms Controls library.

```

SolutionFolder
├── MyApps.sln
├── MyFormsApp
│   └── MyForms.csproj
├── MyFormsAppCore
│   └── MyFormsCore.csproj
|
└── MyFormsControls
    └── MyControls.csproj
└── MyFormsControlsCore
    └── MyControlsCore.csproj    <--- New project for core controls

```

Consider the differences between the `MyControlsCore.csproj` project and the previously created `MyFormsCore.csproj` project.

```

<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">

    <PropertyGroup>
        <OutputType>WinExe</OutputType>
        <TargetFramework>netcoreapp3.0</TargetFramework>
        <UseWindowsForms>true</UseWindowsForms>

        <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
        <AssemblyName>MyCoreApplication</AssemblyName>
        <RootNamespace>WindowsFormsApp1</RootNamespace>
        <AssemblyName>MyCoreControls</AssemblyName>
        <RootNamespace>WindowsFormsControlLibrary1</RootNamespace>
    </PropertyGroup>

    <ItemGroup>
        <Compile Include=".\\MyFormsApp\\**\\*.cs" />
        <EmbeddedResource Include=".\\MyFormsApp\\**\\*.resx" />
        <Compile Include=".\\MyFormsControls\\**\\*.cs" />
        <EmbeddedResource Include=".\\MyFormsControls\\**\\*.resx" />
    </ItemGroup>
</Project>

```

Here is an example of what the .NET Core Windows Forms Controls library project file would look like:

```

<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">

    <PropertyGroup>
        <TargetFramework>netcoreapp3.0</TargetFramework>
        <UseWindowsForms>true</UseWindowsForms>

        <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
        <AssemblyName>MyCoreControls</AssemblyName>
        <RootNamespace>WindowsFormsControlLibrary1</RootNamespace>
    </PropertyGroup>

    <ItemGroup>
        <Compile Include=".\\MyFormsControls\\**\\*.cs" />
        <EmbeddedResource Include=".\\MyFormsControls\\**\\*.resx" />
    </ItemGroup>
</Project>

```

As you can see, the `<OutputType>` node was removed, which defaults the compiler to produce a library instead of an executable. The `<AssemblyName>` and `<RootNamespace>` were changed. Specifically the `<RootNamespace>` should match the namespace of the Windows Forms Controls library you are porting. And finally, the `<Compile>` and

<EmbeddedResource> nodes were adjusted to point to the folder of the Windows Forms Controls library you are porting.

Next, in the main .NET Core **MyFormsCore.csproj** project add reference to the new .NET Core Windows Forms Control library. Add a reference with either Visual Studio or the .NET Core CLI from the **SolutionFolder** directory:

```
dotnet add .\MyFormsAppCore\MyFormsCore.csproj reference ..\MyFormsControlsCore\MyControlsCoreProject.csproj
```

The previous command adds the following to the **MyFormsCore.csproj** project:

```
<ItemGroup>
  <ProjectReference Include="..\MyFormsControlsCore\MyControlsCoreProject.csproj" />
</ItemGroup>
```

Problems compiling

If you have problems compiling your projects, you may be using some Windows-only APIs that are available in .NET Framework but not available in .NET Core. You can try adding the [Windows Compatibility Pack](#) NuGet package to your project. This package only runs on Windows and adds about 20,000 Windows APIs to .NET Core and .NET Standard projects.

```
dotnet add .\MyFormsAppCore\MyFormsCore.csproj package Microsoft.Windows.Compatibility
```

The previous command adds the following to the **MyFormsCore.csproj** project:

```
<ItemGroup>
  <PackageReference Include="Microsoft.Windows.Compatibility" Version="2.0.1" />
</ItemGroup>
```

Windows Forms Designer

As detailed in this article, Visual Studio 2019 Preview/RC only supports the Forms Designer in .NET Framework projects. By creating a side-by-side .NET Core project, you can test your project with .NET Core while you use the .NET Framework project to design forms. Your solution file includes both the .NET Framework and .NET Core projects. Add and design your forms and controls in the .NET Framework project, and based on the file glob patterns we added to the .NET Core projects, any new or changed files will automatically be included in the .NET Core projects.

Once Visual Studio 2019 supports the Windows Forms Designer, you can copy/paste the content of your .NET Core project file into the .NET Framework project file. Then delete the file glob patterns added with the `<Source>` and `<EmbeddedResource>` items. Fix the paths to any project reference used by your app. This effectively upgrades the .NET Framework project to a .NET Core project.

Next steps

- Read more about the [Windows Compatibility Pack](#).
- Watch a [video on porting](#) your .NET Framework Windows Forms project to .NET Core.

Build .NET Core from source

1/23/2019 • 3 minutes to read • [Edit Online](#)

The ability to build .NET Core from its source code is important in multiple ways: it makes it easier to port .NET Core to new platforms, it enables contributions and fixes to the product, and it enables the creation of custom versions of .NET. This article gives guidance to developers who want to build and distribute their own versions of .NET Core.

Build the CLR from source

The source code for the .NET CoreCLR can be found in the [dotnet/coreclr](#) repository on GitHub.

The build currently depends on the following prerequisites:

- [Git](#)
- [CMake](#)
- [Python](#)
- a C++ compiler.

After you've installed these prerequisites, you can build the CLR by invoking the build script (`build.cmd` on Windows, or `build.sh` on Linux and macOS) at the base of the [dotnet/coreclr](#) repository.

Installing the components differ depending on the operating system (OS). See the build instructions for your specific OS:

- [Windows](#)
- [Linux](#)
- [macOS](#)
- [FreeBSD](#)
- [NetBSD](#)

There is no cross-building across OS (only for ARM, which is built on X64).

You have to be on the particular platform to build that platform.

The build has two main `buildTypes` :

- Debug (default)- Compiles the runtime with minimal optimizations and additional runtime checks (asserts). This reduction in optimization level and the additional checks slow runtime execution but are valuable for debugging. This is the recommended setting for development and testing environments.
- Release - Compiles the runtime with full optimizations and without the additional runtime checks. This will yield much faster run time performance but it can take a bit longer to build and can be difficult to debug. Pass `release` to the build script to select this build type.

In addition, by default the build not only creates the runtime executables, but it also builds all the tests. There are quite a few tests, taking a significant amount of time that isn't necessary if you just want to experiment with changes. You can skip the tests builds by adding the `skiptests` argument to the build script, like in the following example (replace `.\build` with `./build.sh` on Unix machines):

```
.\build skiptests
```

The previous example showed how to build the `Debug` flavor, which has development time checks (asserts) enabled

and optimizations disabled. To build the release (full speed) flavor, do the following:

```
.\build release skiptests
```

You can find more build options with build by using the -? or -help qualifier.

Using Your Build

The build places all of its generated files under the `bin` directory at the base of the repository. There is a `bin\Log` directory that contains log files generated during the build (Most useful when the build fails). The actual output is placed in a `bin\Product[platform].[CPU architecture].[build type]` directory, such as `bin\Product\Windows_NT.x64.Release`.

While the 'raw' output of the build is sometimes useful, normally you're only interested in the NuGet packages, which are placed in the `.nuget\pkg` subdirectory of the previous output directory.

There are two basic techniques for using your new runtime:

1. **Use dotnet.exe and NuGet to compose an application.** See [Using Your Build](#) for instructions on creating a program that uses your new runtime by using the NuGet packages you just created and the 'dotnet' command-line interface (CLI). This technique is the expected way non-runtime developers are likely to consume your new runtime.
2. **Use corerun.exe to run an application using unpackaged DLLs.** This repository also defines a simple host called corerun.exe that does NOT take any dependency on NuGet. You need to tell the host where to get the required DLLs you actually use, and you have to manually gather them together. This technique is used by all the tests in the [dotnet/coreclr](#) repo, and is useful for quick local 'edit-compile-debug' loop such as preliminary unit testing. See [Executing .NET Core Apps with CoreRun.exe](#) for details on using this technique.

Build the CLI from source

The source code for the .NET Core CLI can be found in the [dotnet/cli](#) repository on GitHub.

In order to build the .NET Core CLI, you need the following installed on your machine.

- Windows & Linux:
 - git on the PATH
- macOS:
 - git on the PATH
 - Xcode
 - OpenSSL

In order to build, run `build.cmd` on Windows, or `build.sh` on Linux and macOS from the root. If you don't want to execute tests, run `build.cmd -t:Compile` or `./build.sh -t:Compile`. To build the CLI in macOS Sierra, you need to set the `DOTNET_RUNTIME_ID` environment variable by running `export DOTNET_RUNTIME_ID=osx.10.11-x64`.

Using your build

Use the `dotnet` executable from `artifacts/{os}-{arch}/stage2` to try out the newly built CLI. If you want to use the build output when invoking `dotnet` from the current console, you can also add `artifacts/{os}-{arch}/stage2` to the PATH.

.NET Core distribution packaging

12/10/2018 • 4 minutes to read • [Edit Online](#)

As .NET Core becomes available on more and more platforms, it's useful to learn how to package, name, and version it. This way, package maintainers can help ensure a consistent experience no matter where users choose to run .NET.

Disk layout

When installed, .NET Core consists of several components that are layed out as follows in the filesystem:

```
.
├── dotnet          (1)
├── LICENSE.txt    (8)
├── ThirdPartyNotices.txt (8)
└── host
    └── fxr
        └── <fxr version>      (2)
├── sdk
    ├── <sdk version>      (3)
    └── NuGetFallbackFolder (4)
└── shared
    ├── Microsoft.NETCore.App
    │   └── <runtime version>  (5)
    ├── Microsoft.AspNetCore.App
    │   └── <aspnetcore version> (6)
    └── Microsoft.AspNetCore.All
        └── <aspnetcore version> (7)
/
├──usr/share/man/man1
    └── dotnet.1.gz        (9)
└──usr/bin
    └── dotnet            (10)
```

- (1) **dotnet** The host (also known as the "muxer") has two distinct roles: activate a runtime to launch an application, and activate an SDK to dispatch commands to it. The host is a native executable (`dotnet.exe`).

While there is a single host, most of the other components are in versioned directories (2,3,5,6). This means multiple versions can be present on the system since they are installed side-by-side.

- (2) **host/fxr/<fxr version>** contains the framework resolution logic used by the host. The host uses the latest hostfxr that is installed. The hostfxr is responsible for selecting the appropriate runtime when executing a .NET Core application. For example, an application built for .NET Core 2.0.0 will use the 2.0.5 runtime when it is available. Similarly, hostfxr selects the appropriate SDK during development.
- (3) **sdk/<sdk version>** The SDK (also known as "the tooling") is a set of managed tools that can be used to write and build .NET Core libraries and applications. The SDK includes the CLI, the Roslyn compiler, MSBuild, and associated build tasks and targets, NuGet, new project templates, etc.
- (4) **sdk/NuGetFallbackFolder** contains a cache of NuGet packages used by an SDK during the `dotnet restore` step.

The **shared** folder contains frameworks. A shared framework provides a set of libraries at a central location so they can be used by different applications.

- (5) **shared/Microsoft.NETCore.App/<runtime version>** This framework contains the .NET Core

runtime and supporting managed libraries.

- (6,7) **shared/Microsoft.AspNetCore.{App,All}/<aspnetcore version>** contains the ASP.NET Core libraries. The libraries under `Microsoft.AspNetCore.App` are developed and supported as part of the .NET Core project. The libraries under `Microsoft.AspNetCore.All` are a superset which also contains 3rd party libraries.
- (8) **LICENSE.txt,ThirdPartyNotices.txt** are the .NET Core license and licenses of third-party libraries used in .NET Core.
- (9,10) **dotnet.1.gz, dotnet** `dotnet.1.gz` is the dotnet man page. `dotnet` is a symlink to the dotnet host(1). These files are installed at well known locations for system integration.

Recommended packages

.NET Core versioning is based on the runtime component `[major].[minor]` version numbers. The SDK version uses the same `[major].[minor]` and has an independent `[patch]` which combines feature and patch semantics for the SDK. For example: SDK version 2.2.302 is the 2nd patch release of the 3rd feature release of the SDK that supports the 2.2 runtime.

Some of the packages include part of the version number in their name. This allows the end-user to install a specific version. The remainder of the version is not included in the version name. This allows the OS package manager to update the packages (e.g. automatically installing security fixes).

The following tables shows the recommended packages.

NAME	EXAMPLE	USE CASE: INSTALL ...	CONTAINS	DEPENDENCIES	VERSION
dotnet-sdk-[major]	dotnet-sdk-2	Latest sdk for runtime major		dotnet-sdk-[major].[latestminor]	<sdk version>
dotnet-sdk-[major].[minor]	dotnet-sdk-2.1	Latest sdk for specific runtime		dotnet-sdk-[major].[minor].[latest sdk feat]xx	<sdk version>
dotnet-sdk-[major].[minor].[sdk feat]xx	dotnet-sdk-2.1.3xx	Specific sdk feature release	(3),(4)	aspnetcore-runtime-[major].[minor]	<sdk version>
aspnetcore-runtime-[major].[minor]	aspnetcore-runtime-2.1	Specific ASP.NET Core runtime	(6),[(7)]	dotnet-runtime-[major].[minor]	<runtime version>
dotnet-runtime-[major].[minor]	dotnet-runtime-2.1	Specific runtime	(5)	host-fxr:<runtime version>+	<runtime version>
dotnet-host-fxr	dotnet-host-fxr	<i>dependency</i>	(2)	host:<runtime version>+	<runtime version>
dotnet-host	dotnet-host	<i>dependency</i>	(1),(8),(9),(10)		<runtime version>

Most distributions require all artifacts to be built from source. This has some impact on the packages:

- The 3rd party libraries under `shared/Microsoft.AspNetCore.All` cannot be easily built from source. So that

folder is omitted from the `aspnetcore-runtime` package.

- The `NuGetFallbackFolder` is populated using binary artifacts from nuget.org. It should remain empty.

Multiple `dotnet-sdk` packages may provide the same files for the `NuGetFallbackFolder`. To avoid issues with the package manager, these files should be identical (checksum, modification date, ...).

Preview versions

Package maintainers may decide to provide preview versions of the shared framework and SDK. Preview releases may be provided using the `dotnet-sdk-[major].[minor].[sdk feat]xx`, `aspnetcore-runtime-[major].[minor]`, `dotnet-runtime-[major].[minor]` packages. For preview releases, the package version major must be set to zero. This way, the final release will be installed as an upgrade of the package.

Patch packages

Since a patch version of a packages may cause a breaking change, a package maintainer may want to provide *patch packages*. These packages allows to install a specific patch version which is not automatically upgraded. Patch packages should only be used in rare circumstances as they will not be upgraded with (security) fixes.

The following table shows the recommended packages and **patch packages**.

NAME	EXAMPLE	CONTAINS	DEPENDENCIES
<code>dotnet-sdk-[major]</code>	<code>dotnet-sdk-2</code>		<code>dotnet-sdk-[major].[latest sdk minor]</code>
<code>dotnet-sdk-[major].[minor]</code>	<code>dotnet-sdk-2.1</code>		<code>dotnet-sdk-[major].[minor].[latest sdk feat]xx</code>
<code>dotnet-sdk-[major].[minor].[sdk feat]xx</code>	<code>dotnet-sdk-2.1.3xx</code>		<code>dotnet-sdk-[major].[minor].[latest sdk patch]</code>
<code>dotnet-sdk-[major].[minor].[patch]</code>	<code>dotnet-sdk-2.1.300</code>	(3),(4)	<code>aspnetcore-runtime-[major].[minor].[sdk runtime patch]</code>
<code>aspnetcore-runtime-[major].[minor]</code>	<code>aspnetcore-runtime-2.1</code>		<code>aspnetcore-runtime-[major].[minor].[latest runtime patch]</code>
<code>aspnetcore-runtime-[major].[minor].[patch]</code>	<code>aspnetcore-runtime-2.1.0</code>	(6),[(7)]	<code>dotnet-runtime-[major].[minor].[patch]</code>
<code>dotnet-runtime-[major].[minor]</code>	<code>dotnet-runtime-2.1</code>		<code>dotnet-runtime-[major].[minor].[latest runtime patch]</code>
<code>dotnet-runtime-[major].[minor].[patch]</code>	<code>dotnet-runtime-2.1.0</code>	(5)	<code>host-fxr:<runtime version>+</code>
<code>dotnet-host-fxr</code>	<code>dotnet-host-fxr</code>	(2)	<code>host:<runtime version>+</code>
<code>dotnet-host</code>	<code>dotnet-host</code>	(1),(8),(9),(10)	

An alternative to using patch packages is *pinning* the packages to a specific version using the package manager. To avoid affecting other applications/users, such applications can be built and deployed in a container.

Building packages

The [dotnet/source-build](#) repository provides instructions on how to build a source tarball of the .NET Core SDK and all its components. The output of the source-build repository matches the layout described in the first section of this article.

project.json and Visual Studio 2015 with .NET Core

1/17/2019 • 2 minutes to read • [Edit Online](#)

On March 7, 2017, the .NET Core and ASP.NET Core documentation was updated for the release of Visual Studio 2017. The previous version of the documentation used Visual Studio 2015 and pre-release tooling based on the *project.json* file.

The documentation version from before the March 7 update is available in a PDF file and in a branch in the documentation repository.

PDF documentation

The best source of the earlier documentation is the [.NET Core - PDF for project.json and Visual Studio 2015](#).

Documentation repository branch

You can view the earlier version of the documentation in the repository, but many links won't work and many code snippets are references that aren't expanded.

- [.NET Core - project.json branch in the documentation repository](#)

Current version of the documentation

- [ASP.NET Core documentation](#)

.NET Framework Guide

10/17/2018 • 2 minutes to read • [Edit Online](#)

NOTE

This .NET Framework content set includes information for .NET Framework versions 4.5, 4.5.1, 4.5.2, 4.6, 4.6.1, 4.6.2, 4.7, 4.7.1, and 4.7.2. To download the .NET Framework, see [Installing the .NET Framework](#). For a list of new features and changes in the .NET Framework 4.5, the .NET Framework 4.6, their point releases, and the .NET Framework 4.7, 4.7.1, and 4.7.2, see [What's New in the .NET Framework](#). For a list of supported platforms, see [.NET Framework System Requirements](#).

The .NET Framework is a development platform for building apps for web, Windows, Windows Phone, Windows Server, and Microsoft Azure. It consists of the common language runtime (CLR) and the .NET Framework class library, which includes a broad range of functionality and support for many industry standards.

The .NET Framework provides many services, including memory management, type and memory safety, security, networking, and application deployment. It provides easy-to-use data structures and APIs that abstract the lower-level Windows operating system. You can use a variety of programming languages with the .NET Framework, including C#, F#, and Visual Basic.

For a general introduction to the .NET Framework for both users and developers, see [Getting Started](#). For an introduction to the architecture and key features of the .NET Framework, see the [overview](#).

The .NET Framework can be used with Docker and with [Windows Containers](#). See [Deploying .NET Framework applications with Docker](#) to learn how to run your applications in Docker containers.

Installation

The .NET Framework comes with Windows, enabling you to run .NET Framework applications. You may need a later version of the .NET Framework than comes with your Windows version. For more information, see [Install the .NET Framework on Windows](#).

See [Repair the .NET Framework](#) to learn how to repair your .NET Framework installation if you are experiencing errors when installing the .NET Framework.

For more detailed information on downloading the .NET Framework, see [Install the .NET Framework for developers](#).

In This Section

[What's New](#)

Describes key new features and changes in the latest versions of the .NET Framework. Includes lists of obsolete types and members, and provides a guide for migrating your applications from the previous version of the .NET Framework.

[Getting Started](#)

Provides a comprehensive overview of the .NET Framework and links to additional resources.

[Migration Guide](#)

Provides resources and a list of changes you need to consider if you're migrating your application to a new version of the .NET Framework.

[Development Guide](#)

Provides a guide to all key technology areas and tasks for application development, including creating, configuring, debugging, securing, and deploying your application, and information about dynamic programming, interoperability, extensibility, memory management, and threading.

Tools

Describes the tools that help you develop, configure, and deploy applications by using .NET Framework technologies.

[.NET Framework Class Library](#)

Supplies syntax, code examples, and related information for each class contained in the .NET Framework namespaces.

[Additional Class Libraries and APIs](#)

Provides documentation for classes contained in out-of-band (OOB) releases, as well as for classes that target specific platforms or implementations of the .NET Framework.

What's new in the .NET Framework

3/26/2019 • 80 minutes to read • [Edit Online](#)

This article summarizes key new features and improvements in the following versions of the .NET Framework:

- [.NET Framework 4.7.2](#)
- [.NET Framework 4.7.1](#)
- [.NET Framework 4.7](#)
- [.NET Framework 4.6.2](#)
- [.NET Framework 4.6.1](#)
- [.NET 2015 and .NET Framework 4.6](#)
- [.NET Framework 4.5.2](#)
- [.NET Framework 4.5.1](#)
- [.NET Framework 4.5](#)

This article does not provide comprehensive information about each new feature and is subject to change. For general information about the .NET Framework, see [Getting Started](#). For supported platforms, see [System Requirements](#). For download links and installation instructions, see [Installation Guide](#).

NOTE

The .NET Framework team also releases features out of band with NuGet to expand platform support and to introduce new functionality, such as immutable collections and SIMD-enabled vector types. For more information, see [Additional Class Libraries and APIs](#) and [The .NET Framework and Out-of-Band Releases](#). See a [complete list of NuGet packages](#) for the .NET Framework, or subscribe to [our feed](#).

Introducing the .NET Framework 4.7.2

The .NET Framework 4.7.2 builds on previous versions of the .NET Framework 4.x by adding many new fixes and several new features while remaining a very stable product.

Downloading and installing the .NET Framework 4.7.2

You can download the .NET Framework 4.7.2 from the following locations:

- [.NET Framework 4.7.2 Web Installer](#)
- [.NET Framework 4.7.2 Offline Installer](#)

The .NET Framework 4.7.2 can be installed on Windows 10, Windows 8.1, Windows 7 SP1, and the corresponding server platforms starting with Windows Server 2008 R2 SP1. You can install the .NET Framework 4.7.2 by using either the web installer or the offline installer. The recommended way for most users is to use the web installer.

You can target the .NET Framework 4.7.2 in Visual Studio 2012 or later by installing the [.NET Framework 4.7.2 Developer Pack](#).

What's new in the .NET Framework 4.7.2

The .NET Framework 4.7.2 includes new features in the following areas:

- [Core](#)
- [ASP.NET](#)
- [Networking](#)
- [SQL](#)
- [WPF](#)
- [ClickOnce](#)

A continuing focus in the .NET Framework 4.7.2 is improved accessibility, which allows an application to provide an appropriate experience for users of Assistive Technology. For information on accessibility improvement in the .NET Framework 4.7.2, see [What's new in accessibility in the .NET Framework](#).

Core

The .NET Framework 4.7.2 features a large number of cryptographic enhancements, better decompression support for ZIP archives, and additional collection APIs.

New overloads of RSA.Create and DSA.Create

The [DSA.Create\(DSAParameters\)](#) and [RSA.Create\(RSAParameters\)](#) methods let you supply key parameters when instantiating a new [DSA](#) or [RSA](#) key. They allow you to replace code like the following:

```
// Before .NET Framework 4.7.2
using (RSA rsa = RSA.Create())
{
    rsa.ImportParameters(rsaParameters);
    // Other code to execute using the RSA instance.
}
```

```
' Before .NET Framework 4.7.2
Using rsa = RSA.Create()
    rsa.ImportParameters(rsaParameters)
    ' Other code to execute using the rsa instance.
End Using
```

with code like this:

```
// Starting with .NET Framework 4.7.2
using (RSA rsa = RSA.Create(rsaParameters))
{
    // Other code to execute using the rsa instance.
}
```

```
' Starting with .NET Framework 4.7.2
Using rsa = RSA.Create(rsaParameters)
    ' Other code to execute using the rsa instance.
End Using
```

The [DSA.Create\(Int32\)](#) and [RSA.Create\(Int32\)](#) methods let you generate new [DSA](#) or [RSA](#) keys with a specific key size. For example:

```
using (DSA dsa = DSA.Create(2048))
{
    // Other code to execute using the dsa instance.
}
```

```
Using dsa = DSA.Create(2048)
    ' Other code to execute using the dsa instance.
End Using
```

Rfc2898DeriveBytes constructors accept a hash algorithm name

The [Rfc2898DeriveBytes](#) class has three new constructors with a [HashAlgorithmName](#) parameter that identifies the HMAC algorithm to use when deriving keys. Instead of using SHA-1, developers should use a SHA-2-based HMAC like SHA-256, as shown in the following example:

```
private static byte[] DeriveKey(string password, out int iterations, out byte[] salt,
                               out HashAlgorithmName algorithm)
{
    iterations = 100000;
    algorithm = HashAlgorithmName.SHA256;

    const int SaltSize = 32;
    const int DerivedValueSize = 32;

    using (Rfc2898DeriveBytes pbkdf2 = new Rfc2898DeriveBytes(password, SaltSize,
                                                               iterations, algorithm))
    {
        salt = pbkdf2.Salt;
        return pbkdf2.GetBytes(DerivedValueSize);
    }
}
```

```
Private Shared Function DeriveKey(password As String, ByRef iterations As Integer,
                                   ByRef salt As Byte(), ByRef algorithm As HashAlgorithmName) As Byte()
    iterations = 100000
    algorithm = HashAlgorithmName.SHA256

    Const SaltSize As Integer = 32
    Const DerivedValueSize As Integer = 32

    Using pbkdf2 = New Rfc2898DeriveBytes(password, SaltSize, iterations, algorithm)
        salt = pbkdf2.Salt
        Return pbkdf2.GetBytes(DerivedValueSize)
    End Using
End Function
```

Support for ephemeral keys

PFX import can optionally load private keys directly from memory, bypassing the hard drive. When the new [X509KeyStorageFlags.EphemeralKeySet](#)

flag is specified in an `X509Certificate2` constructor or one of the overloads of the `X509Certificate2.Import` method, the private keys will be loaded as ephemeral keys. This prevents the keys from being visible on the disk. However:

- Since the keys are not persisted to disk, certificates loaded with this flag are not good candidates to add to an `X509Store`.
- Keys loaded in this manner are almost always loaded via Windows CNG. Therefore, callers must access the private key by calling extension methods, such as `cert.GetRSAPrivateKey()`. The `X509Certificate2.PrivateKey` property does not function.
- Since the legacy `X509Certificate2.PrivateKey` property does not work with certificates, developers should perform rigorous testing before switching to ephemeral keys.

Programmatic creation of PKCS#10 certification signing requests and X.509 public key certificates

Starting with the .NET Framework 4.7.2, workloads can generate certificate signing requests (CSRs), which allows certificate request generation to be staged into existing tooling. This is frequently useful in test scenarios.

For more information and code examples, see "Programmatic creation of PKCS#10 certification signing requests and X.509 public key certificates" in the [.NET Blog](#).

New `SignerInfo` members

Starting with the .NET Framework 4.7.2, the `SignerInfo` class exposes more information about the signature. You can retrieve the value of the `System.Security.Cryptography.Pkcs.SignerInfo.SignatureAlgorithm` property to determine the signature algorithm used by the signer. `SignerInfo.GetSignature` can be called to get a copy of the cryptographic signature for this signer.

Leaving a wrapped stream open after `CryptoStream` is disposed

Starting with the .NET Framework 4.7.2, the `CryptoStream` class has an additional constructor that allows `Dispose` to not close the wrapped stream. To leave the wrapped stream open after the `CryptoStream` instance is disposed, call the new `CryptoStream` constructor as follows:

```
var cStream = new CryptoStream(stream, transform, mode, leaveOpen: true);
```

```
Dim cStream = New CryptoStream(stream, transform, mode, leaveOpen:=true)
```

Decompression changes in `DeflateStream`

Starting with the .NET Framework 4.7.2, the implementation of decompression operations in the `DeflateStream` class has changed to use native Windows APIs by default. Typically, this results in a substantial performance improvement.

Support for decompression by using Windows APIs is enabled by default for applications that target .NET Framework 4.7.2. Applications that target earlier versions of .NET Framework but are running under .NET Framework 4.7.2 can opt into this behavior by adding the following `AppContext switch` to the application configuration file:

```
<AppContextSwitchOverrides value="Switch.System.IO.Compression.DoNotUseNativeZipLibraryForDecompression=false" />
```

Additional collection APIs

The .NET Framework 4.7.2 adds a number of new APIs to the `SortedSet<T>` and `HashSet<T>` types. These include:

- `TryGetValue` methods, which extend the try pattern used in other collection types to these two types. The methods are:
 - `public bool HashSet<T>.TryGetValue(T equalValue, out T actualValue)`
 - `public bool SortedSet<T>.TryGetValue(T equalValue, out T actualValue)`
- `Enumerable.To*` extension methods, which convert a collection to a `HashSet<T>`:
 - `public static HashSet<TSource> ToHashSet<TSource>(this IEnumerable<TSource> source)`
 - `public static HashSet<TSource> ToHashSet<TSource>(this IEnumerable<TSource> source, IEqualityComparer<TSource> comparer)`
- New `HashSet<T>` constructors that let you set the collection's capacity, which yields a performance benefit when you know the size of the `HashSet<T>` in advance:
 - `public HashSet(int capacity)`
 - `public HashSet(int capacity, IEqualityComparer<T> comparer)`

The `ConcurrentDictionary< TKey, TValue >` class includes new overloads of the `AddOrUpdate` and `GetOrAdd` methods to retrieve a value from the dictionary or to add it if it is not found, and to add a value to the dictionary or to update it if it already exists.

```
public TValue AddOrUpdate<TArg>(TKey key, Func<TKey, TArg, TValue> addValueFactory, Func<TKey, TValue, TArg, TValue> updateValueFactory, TArg factoryArgument)

public TValue GetOrAdd<TArg>(TKey key, Func<TKey, TArg, TValue> valueFactory, TArg factoryArgument)
```

```
Public AddOrUpdate(Of TArg)(key As TKey, addValueFactory As Func(Of TKey, TArg, TValue), updateValueFactory As Func(Of TKey, TValue, TArg, TValue),
factoryArgument As TArg) As TValue

Public GetOrAdd(Of TArg)(key As TKey, valueFactory As Func(Of TKey, TArg, TValue), factoryArgument As TArg) As TValue
```

ASP.NET

Support for dependency injection in Web Forms

Dependency injection (DI) decouples objects and their dependencies so that an object's code no longer needs to be changed just because a dependency has changed. When developing ASP.NET applications that target the .NET Framework 4.7.2, you can:

- Use setter-based, interface-based, and constructor-based injection in [handlers and modules](#), [Page instances](#), and [user controls](#) of ASP.NET web application projects.
- Use setter-based and interface-based injection in [handlers and modules](#), [Page instances](#), and [user controls](#) of ASP.NET web site projects.
- Plug in different dependency injection frameworks.

Support for same-site cookies

[SameSite](#) prevents a browser from sending a cookie along with a cross-site request. The .NET Framework 4.7.2 adds a [HttpCookie.SameSite](#) property whose value is a [System.Web.SameSiteMode](#) enumeration member. If its value is [SameSiteMode.Strict](#) or [SameSiteMode.Lax](#), ASP.NET adds the [SameSite](#) attribute to the set-cookie header. SameSite support applies to [HttpCookie](#) objects, as well as to [FormsAuthentication](#) and [System.Web.SessionState](#) cookies.

You can set SameSite for an [HttpCookie](#) object as follows:

```
var c = new HttpCookie("secureCookie", "same origin");
c.SameSite = SameSiteMode.Lax;
```

```
Dim c As New HttpCookie("secureCookie", "same origin")
c.SameSite = SameSiteMode.Lax
```

You can also configure SameSite cookies at the application level by modifying the web.config file:

```
<system.web>
  <httpCookies sameSite="Strict" />
</system.web>
```

You can add SameSite for [FormsAuthentication](#) and [System.Web.SessionState](#) cookies by modifying the web config file:

```
<system.web>
  <authentication mode="Forms">
    <forms cookieSameSite="Lax">
      <!-- ... -->
    </forms>
  </authentication>
  <sessionState cookieSameSite="Lax"></sessionState>
</system.web>
```

Networking

Implementation of HttpClientHandler properties

The .NET Framework 4.7.1 added eight properties to the [System.Net.Http.HttpClientHandler](#) class. However, two threw a [PlatformNotSupportedException](#). The .NET Framework 4.7.2 now provides an implementation for these properties. The properties are:

- [CheckCertificateRevocationList](#)
- [SslProtocols](#)

SQLClient

Support for Azure Active Directory Universal Authentication and Multi-Factor authentication

Growing compliance and security demands require that many customers use multi-factor authentication (MFA). In addition, current best practices discourage including user passwords directly in connection strings. To support these changes, the .NET Framework 4.7.2 extends [SQLClient connection strings](#) by adding a new value, "Active Directory Interactive", for the existing "Authentication" keyword to support MFA and [Azure AD Authentication](#). The new interactive method supports native and federated Azure AD users as well as Azure AD guest users. When this method is used, the MFA authentication imposed by Azure AD is supported for SQL databases. In addition, the authentication process requests a user password to adhere to security best practices.

In previous versions of the .NET Framework, SQL connectivity supported only the [SqlAuthenticationMethod.ActiveDirectoryPassword](#) and [SqlAuthenticationMethod.ActiveDirectoryIntegrated](#) options. Both of these are part of the non-interactive [ADAL protocol](#), which does not support MFA. With the new [SqlAuthenticationMethod.ActiveDirectoryInteractive](#) option, SQL connectivity supports MFA as well as existing authentication methods (password and integrated authentication), which allows users to enter user passwords interactively without persisting passwords in the connection string.

For more information and an example, see "SQL -- Azure AD Universal and Multi-factor Authentication Support" in the [.NET Blog](#).

Support for Always Encrypted version 2

.NET Framework 4.7.2 adds supports for enclave-based Always Encrypted. The original version of Always Encrypted is a client-side encryption technology in which encryption keys never leave the client. In enclave-based Always Encrypted, the client can optionally send the encryption keys to a secure enclave, which is a secure computational entity that can be considered part of SQL Server but that SQL Server code cannot tamper with. To support enclave-based Always Encrypted, the .NET Framework 4.7.2 adds the following types and members to the [System.Data.SqlClient](#) namespace:

- [SqlConnectionStringBuilder.EnclaveAttestationUrl](#), which specifies the Uri for enclave-based Always Encrypted.
- [SqlColumnEncryptionEnclaveProvider](#), which is an abstract class from which all enclave providers are derived.
- [SqlEnclaveSession](#), which encapsulates the state for a given enclave session.
- [SqlEnclaveAttestationParameters](#), which provides the attestation parameters used by SQL Server to get information required to execute a particular Attestation Protocol.

The application configuration file then specifies a concrete implementation of the abstract [System.Data.SqlClient.SqlColumnEncryptionEnclaveProvider](#) class that provides the functionality for the enclave provider. For example:

```
<configuration>
  <configSections>
    <section name="SqlColumnEncryptionEnclaveProviders"
      type="System.Data.SqlClient.SqlColumnEncryptionEnclaveProviderConfigurationSection, System.Data, Version=4.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089"/>
  </configSections>
  <SqlColumnEncryptionEnclaveProviders>
    <providers>
      <add name="Azure" type="Microsoft.SqlServer.Management.AlwaysEncrypted.AzureEnclaveProvider, MyApp"/>
      <add name="HGS" type="Microsoft.SqlServer.Management.AlwaysEncrypted.HGSEnclaveProvider, MyApp" />
    </providers>
  </SqlColumnEncryptionEnclaveProviders >
</configuration>
```

The basic flow of enclave-based Always Encrypted is:

1. The user creates an AlwaysEncrypted connection to SQL Server that supported enclave-based Always Encrypted. The driver contacts the attestation service to ensure that it is connecting to right enclave.
2. Once the enclave has been attested, the driver establishes a secure channel with the secure enclave hosted on SQL Server.
3. The driver shares encryption keys authorized by the client with the secure enclave for the duration of the SQL connection.

Windows Presentation Foundation

Finding ResourceDictionaries by Source

Starting with the .NET Framework 4.7.2, a diagnostic assistant can locate the [ResourceDictionaries](#) that have been created from a given source Uri. (This feature is for use by diagnostic assistants, not by production applications.) A diagnostic assistant such as Visual Studio's "Edit-and-Continue" facility lets its user edit a ResourceDictionary with the intent that the changes be applied to the running application. One step in achieving this is finding all the ResourceDictionaries that the running application has created from the dictionary that's being edited. For example, an application can declare a ResourceDictionary whose content is copied from a given source URI:

```
<ResourceDictionary Source="MyRD.xaml">
```

A diagnostic assistant that edits the original markup in *MyRD.xaml* can use the new feature to locate the dictionary. The feature is implemented by a new static method, [ResourceDictionaryDiagnostics.GetResourceDictionariesForSource](#). The diagnostic assistant calls the new method using an absolute Uri that identifies the original markup, as illustrated by the following code:

```
IEnumerable<ResourceDictionary> dictionaries = ResourceDictionaryDiagnostics.GetResourceDictionariesForSource(new Uri("pack://application:,,,/MyApp;component/MyRD.xaml"));
```

```
Dim dictionaries As IEnumerable(Of ResourceDictionary) = ResourceDictionaryDiagnostics.GetResourceDictionariesForSource(New Uri("pack://application:,,,/MyApp;component/MyRD.xaml"))
```

The method returns an empty enumerable unless [VisualDiagnostics](#) is enabled and the [ENABLE_XAML_DIAGNOSTICS_SOURCE_INFO](#) environment variable is set.

Finding ResourceDictionary owners

Starting with the .NET Framework 4.7.2, a diagnostic assistant can locate the owners of a given [ResourceDictionary](#). (The feature is for use by diagnostic assistants and not by production applications.) Whenever a change is made to a [ResourceDictionary](#), WPF automatically finds all [DynamicResource](#) references that might be affected by the change.

A diagnostic assistant such as Visual Studio's "Edit-and-Continue" facility may want extend this to handle [StaticResource](#) references. The first step in this process is to find the owners of the dictionary; that is, to find all the objects whose [Resources](#) property refers to the dictionary (either directly, or

indirectly via the `ResourceDictionary.MergedDictionaries` property). Three new static methods implemented on the `System.Windows.Diagnostics.ResourceDictionaryDiagnostics` class, one for each of the base types that has a `Resources` property, support this step:

- `public static IEnumerable<FrameworkElement> GetFrameworkElementOwners(ResourceDictionary dictionary);`
- `public static IEnumerable<FrameworkContentElement> GetFrameworkContentElementOwners(ResourceDictionary dictionary);`
- `public static IEnumerable<Application> GetApplicationOwners(ResourceDictionary dictionary);`

These methods return an empty enumerable unless `VisualDiagnostics` is enabled and the `ENABLE_XAML_DIAGNOSTICS_SOURCE_INFO` environment variable is set.

Finding StaticResource references

A diagnostic assistant can now receive a notification whenever a `StaticResource` reference is resolved. (The feature is for use by diagnostic assistants, not by production applications.) A diagnostic assistant such as Visual Studio's "Edit-and-Continue" facility may want to update all uses of a resource when its value in a `ResourceDictionary` changes. WPF does this automatically for `DynamicResource` references, but it intentionally does not do so for `StaticResource` references. Starting with the .NET Framework 4.7.2, the diagnostic assistant can use these notifications to locate those uses of the static resource.

The notification is implemented by the new `ResourceDictionaryDiagnostics.StaticResourceResolved` event:

```
public static event EventHandler<StaticResourceResolvedEventArgs> StaticResourceResolved;  
  
Public Shared Event StaticResourceResolved As EventHandler(Of StaticResourceResolvedEventArgs)
```

This event is raised whenever the runtime resolves a `StaticResource` reference. The `StaticResourceResolvedEventArgs` arguments describe the resolution, and indicate the object and property that host the `StaticResource` reference and the `ResourceDictionary` and key used for the resolution:

```
public class StaticResourceResolvedEventArgs : EventArgs  
{  
    public Object TargetObject { get; }  
  
    public Object TargetProperty { get; }  
  
    public ResourceDictionary ResourceDictionary { get; }  
  
    public object ResourceKey { get; }  
}
```

The event is not raised (and its `add` accessor is ignored) unless `VisualDiagnostics` is enabled and the `ENABLE_XAML_DIAGNOSTICS_SOURCE_INFO` environment variable is set.

ClickOnce

HDPI-aware applications for Windows Forms, Windows Presentation Foundation (WPF), and Visual Studio Tools for Office (VSTO) can all be deployed by using ClickOnce. If the following entry is found in the application manifest, deployment will succeed under .NET Framework 4.7.2:

```
<windowsSettings>  
    <dpiAware xmlns="http://schemas.microsoft.com/SMI/2005/WindowsSettings">true</dpiAware>  
</windowsSettings>
```

For Windows Forms application, the previous workaround of setting DPI awareness in the application configuration file rather than the application manifest is no longer necessary for ClickOnce deployment to succeed.

What's new in the .NET Framework 4.7.1

The .NET Framework 4.7.1 includes new features in the following areas:

- [Core](#)
- [Common language runtime \(CLR\)](#)
- [Networking](#)
- [ASP.NET](#)

In addition, a major focus in the .NET Framework 4.7.1 is improved accessibility, which allows an application to provide an appropriate experience for users of Assistive Technology. For information on accessibility improvements in the .NET Framework 4.7.1, see [What's new in accessibility in the .NET Framework](#).

Core

Support for .NET Standard 2.0

.NET Standard defines a set of APIs that must be available on each .NET implementation that supports that version of the standard. The .NET Framework 4.7.1 fully supports .NET Standard 2.0 and adds [about 200 APIs](#) that are defined in .NET Standard 2.0 and are missing from the .NET Framework 4.6.1, 4.6.2, and 4.7. (Note that these versions of the .NET Framework support .NET Standard 2.0 only if additional .NET Standard support files are also deployed on the target system.) For more information, see "BCL - .NET Standard 2.0 Support" in the [.NET Framework 4.7.1 Runtime and](#)

[Compiler Features](#) blog post.

Support for configuration builders

Configuration builders allow developers to inject and build configuration settings for applications dynamically at run time. Custom configuration builders can be used to modify existing data in a configuration section or to build a configuration section entirely from scratch. Without configuration builders, .config files are static, and their settings are defined some time before an application is launched.

To create a custom configuration builder, you derive your builder from the abstract [ConfigurationBuilder](#) class and override its [ConfigurationBuilder.ProcessConfigurationSection](#) and [ConfigurationBuilder.ProcessRawXml](#). You also define your builders in your .config file. For more information, see the "Configuration Builders" section in the [.NET Framework 4.7.1 ASP.NET and Configuration Features](#) blog post.

Run-time feature detection

The [System.Runtime.CompilerServices.RuntimeFeature](#) class provides a mechanism for determine whether a predefined feature is supported on a given .NET implementation at compile time or run time. At compile time, a compiler can check whether a specified field exists to determine whether the feature is supported; if so, it can emit code that takes advantage of that feature. At run time, an application can call the [RuntimeFeature.IsEnabled](#) method before emitting code at runtime. For more information, see [Add helper method to describe features supported by the runtime](#).

Value tuple types are serializable

Starting with the .NET Framework 4.7.1, [System.ValueTuple](#) and its associated generic types are marked as [Serializable](#), which allows binary serialization. This should make migrating Tuple types, such as [Tuple<T1,T2,T3>](#) and [Tuple<T1,T2,T3,T4>](#), to value tuple types easier. For more information, see "Compiler -- ValueTuple is Serializable" in the [.NET Framework 4.7.1 Runtime and Compiler Features](#) blog post.

Support for read-only references

The .NET Framework 4.7.1 adds the [System.Runtime.CompilerServices.IsReadOnlyAttribute](#). This attribute is used by language compilers to mark members that have read-only ref return types or parameters. For more information, see "Compiler -- Support for ReadOnlyReferences" in the [.NET Framework 4.7.1 Runtime and Compiler Features](#) blog post. For information on ref return values, see [Ref return values and ref locals \(C# Guide\)](#) and [Ref return values \(Visual Basic\)](#).

Common language runtime (CLR)

Garbage collection performance improvements

Changes to garbage collection (GC) in the .NET Framework 4.7.1 improve overall performance, especially for Large Object Heap (LOH) allocations. In the .NET Framework 4.7.1, separate locks are used for Small Object Heap (SOH) and LOH allocations, which allows LOH allocations to occur when Background GC (BGC) is sweeping the SOH. As a result, applications that make a large number of LOH allocations should see a reduction in allocation lock contention and improved performance. For more information, see the "Runtime -- GC Performance Improvements" section in the [.NET Framework 4.7.1 Runtime and Compiler Features](#) blog post.

Networking

SHA-2 support for Message.HashAlgorithm

In the .NET Framework 4.7 and earlier versions, the [Message.HashAlgorithm](#) property supported values of [HashAlgorithm.Md5](#) and [HashAlgorithm.Sha](#) only. Starting with the .NET Framework 4.7.1, [HashAlgorithm.Sha256](#), [HashAlgorithm.Sha384](#), and [HashAlgorithm.Sha512](#) are also supported. Whether this value is actually used depends on MSMQ, since the [Message](#) instance itself does no hashing but simply passes on values to MSMQ. For more information, see the "SHA-2 support for Message.HashAlgorithm" section in the [.NET Framework 4.7.1 ASP.NET and Configuration features](#) blog post.

ASP.NET

Execution steps in ASP.NET applications

ASP.NET processes requests in a predefined pipeline that includes 23 events. ASP.NET executes each event handler as an execution step. In versions of ASP.NET up to the .NET Framework 4.7, ASP.NET can't flow the execution context due to switching between native and managed threads. Instead, ASP.NET selectively flows only the [HttpContext](#). Starting with the .NET Framework 4.7.1, the [HttpApplication.OnExecuteRequestStep\(Action<HttpContextBase,Action>\)](#) method also allows modules to restore ambient data. This feature is targeted at libraries concerned with tracing, profiling, diagnostics, or transactions, for example, that care about the execution flow of the application. For more information, see the "ASP.NET Execution Step Feature" in the [.NET Framework 4.7.1 ASP.NET and Configuration Features](#) blog post.

ASP.NET HttpCookie parsing

The .NET Framework 4.7.1 includes a new method, [HttpCookie.TryParse](#), that provides a standardized way to create an [HttpCookie](#) object from a string and accurately assign cookie values such as expiration date and path. For more information, see "ASP.NET HttpCookie parsing" in the [.NET Framework 4.7.1 ASP.NET and Configuration Features](#) blog post.

SHA-2 hash options for ASP.NET forms authentication credentials

In the .NET Framework 4.7 and earlier versions, ASP.NET allowed developers to store user credentials with hashed passwords in configuration files using either MD5 or SHA1. Starting with the .NET Framework 4.7.1, ASP.NET also supports new secure SHA-2 hash options such as SHA256, SHA384, and SHA512. SHA1 remains the default, and a non-default hash algorithm can be defined in the web configuration file. For example:

```
<system.web>
  <authentication mode="Forms">
    <forms loginUrl="~/login.aspx">
      <credentials passwordFormat="SHA512">
        <user name="jdoe"
password="6D003E98EA1C7F04ABF8FCB375388907B7F3EE06F278DB966BE960E7CBBD103DF30CA6D61F7E7FD981B2E4E3A64D43C836A4BEDCA165C33B163E6BCDC538A664" />
        </credentials>
      </forms>
    </authentication>
  </system.web>
```

What's new in the .NET Framework 4.7

The .NET Framework 4.7 includes new features in the following areas:

- [Core](#)
- [Networking](#)
- [ASP.NET](#)
- [Windows Communication Foundation \(WCF\)](#)
- [Windows Forms](#)
- [Windows Presentation Foundation \(WPF\)](#)

For a list of new APIs added to the .NET Framework 4.7, see [.NET Framework 4.7 API Changes](#) on GitHub. For a list of feature improvements and bug fixes in the .NET Framework 4.7, see [.NET Framework 4.7 List of Changes](#) on GitHub. For additional information, see [Announcing the .NET Framework 4.7](#) in the .NET blog.

Core

The .NET Framework 4.7 improves serialization by the [DataContractJsonSerializer](#):

Enhanced functionality with Elliptic Curve Cryptography (ECC)*

In the .NET Framework 4.7, `ImportParameters(ECParameters)` methods were added to the [ECDsa](#) and [ECDiffieHellman](#) classes to allow for an object to represent an already-established key. An `ExportParameters(Boolean)` method was also added for exporting the key using explicit curve parameters.

The .NET Framework 4.7 also adds support for additional curves (including the Brainpool curve suite), and has added predefined definitions for ease-of-creation through the new [Create](#) and [Create](#) factory methods.

You can see an [example of .NET Framework 4.7 cryptography improvements](#) on GitHub.

Better support for control characters by the [DataContractJsonSerializer](#)

In the .NET Framework 4.7, the [DataContractJsonSerializer](#) serializes control characters in conformity with the ECMAScript 6 standard. This behavior is enabled by default for applications that target the .NET Framework 4.7, and is an opt-in feature for applications that are running under the .NET Framework 4.7 but target a previous version of the .NET Framework. For more information, see [Retargeting Changes in the .NET Framework 4.7](#).

Networking

The .NET Framework 4.7 adds the following network-related feature:

Default operating system support for TLS protocols*

The TLS stack, which is used by [System.Net.Security.SslStream](#) and up-stack components such as HTTP, FTP, and SMTP, allows developers to use the default TLS protocols supported by the operating system. Developers need no longer hard-code a TLS version.

ASP.NET

In the .NET Framework 4.7, ASP.NET includes the following new features:

Object Cache Extensibility

Starting with the .NET Framework 4.7, ASP.NET adds a new set of APIs that allow developers to replace the default ASP.NET implementations for in-memory object caching and memory monitoring. Developers can now replace any of the following three components if the ASP.NET implementation is not adequate:

- **Object Cache Store.** By using the new cache providers configuration section, developers can plug in new implementations of an object cache for an ASP.NET application by using the new [ICacheStoreProvider](#) interface.
- **Memory monitoring.** The default memory monitor in ASP.NET notifies applications when they are running close to the configured private bytes limit for the process, or when the machine is low on total available physical RAM. When these limits are near, notifications are fired. For some applications, notifications are fired too close to the configured limits to allow for useful reactions. Developers can now write their own memory monitors to replace the default by using the [ApplicationMonitors.MemoryMonitor](#) property.
- **Memory Limit Reactions.** By default, ASP.NET attempts to trim the object cache and periodically call [GC.Collect](#) when the private byte process limit is near. For some applications, the frequency of calls to [GC.Collect](#) or the amount of cache that is trimmed are inefficient. Developers can now replace or supplement the default behavior by subscribing [IObserver](#) implementations to the application's memory monitor.

Windows Communication Foundation (WCF)

Windows Communication Foundation (WCF) adds the following features and changes:

Ability to configure the default message security settings to TLS 1.1 or TLS 1.2

Starting with the .NET Framework 4.7, WCF allows you to configure TSL 1.1 or TLS 1.2 in addition to SSL 3.0 and TSL 1.0 as the default message security protocol. This is an opt-in setting; to enable it, you must add the following entry to your application configuration file:

```
<runtime>
  <AppContextSwitchOverrides
    value="Switch.System.ServiceModel.DisableUsingServicePointManagerSecurityProtocols=false;Switch.System.Net.DontEnableSchUseStrongCrypto=false" />
</runtime>
```

Improved reliability of WCF applications and WCF serialization

WCF includes a number of code changes that eliminate race conditions, thereby improving performance and the reliability of serialization options. These include:

- Better support for mixing asynchronous and synchronous code in calls to **SocketConnection.BeginRead** and **SocketConnection.Read**.
- Improved reliability when aborting a connection with **SharedConnectionListener** and **DuplexChannelBinder**.
- Improved reliability of serialization operations when calling the **FormatterServices.GetSerializableMembers(Type)** method.
- Improved reliability when removing a waiter by calling the **ChannelSynchronizer.RemoveWaiter** method.

Windows Forms

In the .NET Framework 4.7, Windows Forms improves support for high DPI monitors.

High DPI support

Starting with applications that target the .NET Framework 4.7, the .NET Framework features high DPI and dynamic DPI support for Windows Forms applications. High DPI support improves the layout and appearance of forms and controls on high DPI monitors. Dynamic DPI changes the layout and appearance of forms and controls when the user changes the DPI or display scale factor of a running application.

High DPI support is an opt-in feature that you configure by defining a **<System.Windows.Forms.ConfigurationSection>** section in your application configuration file. For more information on adding high DPI support and dynamic DPI support to your Windows Forms application, see [High DPI Support in Windows Forms](#).

Windows Presentation Foundation (WPF)

In the .NET Framework 4.7, WPF includes the following enhancements:

Support for a touch/stylus stack based on Windows WM_POINTER messages

You now have the option of using a touch/stylus stack based on [WM_POINTER messages](#) instead of the Windows Ink Services Platform (WISP). This is an opt-in feature in the .NET Framework. For more information, see [Retargeting Changes in the .NET Framework 4.7](#).

New implementation for WPF printing APIs

WPF's printing APIs in the [System.Printing.PrintQueue](#) class call the Windows [Print Document Package API](#) instead of the deprecated [XPS Print API](#). For the impact of this change on application compatibility, see [Retargeting Changes in the .NET Framework 4.7](#).

What's new in the .NET Framework 4.6.2

The .NET Framework 4.6.2 includes new features in the following areas:

- [ASP.NET](#)
- [Character categories](#)
- [Cryptography](#)
- [SqlClient](#)
- [Windows Communication Foundation](#)
- [Windows Presentation Foundation \(WPF\)](#)
- [Windows Workflow Foundation \(WF\)](#)
- [ClickOnce](#)
- [Converting Windows Forms and WPF apps to UWP apps](#)
- [Debugging improvements](#)

For a list of new APIs added to the .NET Framework 4.6.2, see [.NET Framework 4.6.2 API Changes](#) on GitHub. For a list of feature improvements and bug fixes in the .NET Framework 4.6.2, see [.NET Framework 4.6.2 List of Changes](#) on GitHub. For additional information, see [Announcing .NET Framework 4.6.2](#) in the .NET blog.

ASP.NET

In the .NET Framework 4.6.2, ASP.NET includes the following enhancements:

Improved support for localized error messages in data annotation validators

Data annotation validators enable you to perform validation by adding one or more attributes to a class property. The attribute's [ValidationAttribute.ErrorMessage](#) element defines the text of the error message if validation fails. Starting with the .NET Framework 4.6.2, ASP.NET makes it easy to localize error messages. Error messages will be localized if:

1. The [ValidationAttribute\(ErrorMessage\)](#) is provided in the validation attribute.
2. The resource file is stored in the App_LocalResources folder.
3. The name of the localized resources file has the form `DataAnnotation.Localization.{name}.resx`, where `name` is a culture name in the format `languageCode - country/regionCode or languageCode`.
4. The key name of the resource is the string assigned to the [ValidationAttribute\(ErrorMessage\)](#) attribute, and its value is the localized error message.

For example, the following data annotation attribute defines the default culture's error message for an invalid rating.

```
public class RatingInfo
{
    [Required(ErrorMessage = "The rating must be between 1 and 10.")]
    [Display(Name = "Your Rating")]
    public int Rating { get; set; }
}
```

```
Public Class RatingInfo
<Required(ErrorMessage = "The rating must be between 1 and 10.")>
<Display(Name = "Your Rating")>
Public Property Rating As Integer = 1
End Class
```

You can then create a resource file, DataAnnotation.Localization.fr.resx, whose key is the error message string and whose value is the localized error message. The file must be found in the `App.LocalResources` folder. For example, the following is the key and its value in a localized French (fr) language error message:

NAME	VALUE
The rating must be between 1 and 10.	La note doit être comprise entre 1 et 10.

In addition, data annotation localization is extensible. Developers can plug in their own string localizer provider by implementing the [IStringLocalizerProvider](#) interface to store localization string somewhere other than in a resource file.

Async support with session-state store providers

ASP.NET now allows task-returning methods to be used with session-state store providers, thereby allowing ASP.NET apps to get the scalability benefits of async. To support asynchronous operations with session state store providers, ASP.NET includes a new interface, [System.Web.SessionState.ISessionStateModule](#), which inherits from [IHttpModule](#) and allows developers to implement their own session-state module and async session store providers. The interface is defined as follows:

```
public interface ISessionStateModule : IHttpModule {
    void ReleaseSessionState(HttpContext context);
    Task ReleaseSessionStateAsync(HttpContext context);
}
```

In addition, the [SessionStateUtility](#) class includes two new methods, [IsSessionStateReadOnly](#) and [IsSessionStateRequired](#), that can be used to support asynchronous operations.

Async support for output-cache providers

Starting with the .NET Framework 4.6.2, task-returning methods can be used with output-cache providers to provide the scalability benefits of async. Providers that implement these methods reduce thread-blocking on a web server and improve the scalability of an ASP.NET service.

The following APIs have been added to support asynchronous output-cache providers:

- The [System.Web.Caching.OutputCacheProviderAsync](#) class, which inherits from [System.Web.Caching.OutputCacheProvider](#) and allows developers to implement an asynchronous output-cache provider.
- The [OutputCacheUtility](#) class, which provides helper methods for configuring the output cache.
- 18 new methods in the [System.Web.HttpCachePolicy](#) class. These include [GetCacheability](#), [GetCacheExtensions](#), [GetETag](#), [GetETagFromFileDependencies](#), [GetMaxAge](#), [GetMaxAge](#), [GetNoStore](#), [GetNoTransforms](#), [GetOmitVaryStar](#), [GetProxyMaxAge](#), [GetRevalidation](#), [GetUtcLastModified](#), [GetVaryByCustom](#), [HasSlidingExpiration](#), and [IsValidUntilExpires](#).
- 2 new methods in the [System.Web.HttpCacheVaryByContentEncodings](#) class: [GetContentEncodings](#) and [SetContentEncodings](#).
- 2 new methods in the [System.Web.HttpCacheVaryByHeaders](#) class: [GetHeaders](#) and [SetHeaders](#).
- 2 new methods in the [System.Web.HttpCacheVaryByParams](#) class: [GetParams](#) and [SetParams](#).
- In the [System.Web.Caching.AggregateCacheDependency](#) class, the [GetFileDependencies](#) method.
- In the [CacheDependency](#), the [GetFileDependencies](#) method.

Character categories

Characters in the .NET Framework 4.6.2 are classified based on the [Unicode Standard, Version 8.0.0](#). In .NET Framework 4.6 and .NET Framework 4.6.1,

characters were classified based on Unicode 6.3 character categories.

Support for Unicode 8.0 is limited to the classification of characters by the [CharUnicodeInfo](#) class and to types and methods that rely on it. These include the [StringInfo](#) class, the overloaded [Char.GetUnicodeCategory](#) method, and the [character classes](#) recognized by the .NET Framework regular expression engine. Character and string comparison and sorting is unaffected by this change and continues to rely on the underlying operating system or, on Windows 7 systems, on character data provided by the .NET Framework.

For changes in character categories from Unicode 6.0 to Unicode 7.0, see [The Unicode Standard, Version 7.0.0](#) at The Unicode Consortium website. For changes from Unicode 7.0 to Unicode 8.0, see [The Unicode Standard, Version 8.0.0](#) at The Unicode Consortium website.

Cryptography

Support for X509 certificates containing FIPS 186-3 DSA

The .NET Framework 4.6.2 adds support for DSA (Digital Signature Algorithm) X509 certificates whose keys exceed the FIPS 186-2 1024-bit limit.

In addition to supporting the larger key sizes of FIPS 186-3, the .NET Framework 4.6.2 allows computing signatures with the SHA-2 family of hash algorithms (SHA256, SHA384, and SHA512). FIPS 186-3 support is provided by the new [System.Security.Cryptography.DSACng](#) class.

In keeping with recent changes to the [RSA](#) class in the .NET Framework 4.6 and the [ECDsa](#) class in the .NET Framework 4.6.1, the [DSA](#) abstract base class in .NET Framework 4.6.2 has additional methods to allow callers to use this functionality without casting. You can call the [DSACertificateExtensions.GetDSAPrivateKey](#) extension method to sign data, as the following example shows.

```
public static byte[] SignDataDsaSha384(byte[] data, X509Certificate2 cert)
{
    using (DSA dsa = cert.GetDSAPrivateKey())
    {
        return dsa.SignData(data, HashAlgorithmName.SHA384);
    }
}
```

```
Public Shared Function SignDataDsaSha384(data As Byte(), cert As X509Certificate2) As Byte()
    Using DSA As DSA = cert.GetDSAPrivateKey()
        Return DSA.SignData(data, HashAlgorithmName.SHA384)
    End Using
End Function
```

And you can call the [DSACertificateExtensions.GetDSAPublicKey](#) extension method to verify signed data, as the following example shows.

```
public static bool VerifyDataDsaSha384(byte[] data, byte[] signature, X509Certificate2 cert)
{
    using (DSA dsa = cert.GetDSAPublicKey())
    {
        return dsa.VerifyData(data, signature, HashAlgorithmName.SHA384);
    }
}
```

```
Public Shared Function VerifyDataDsaSha384(data As Byte(), signature As Byte(), cert As X509Certificate2) As Boolean
    Using dsa As DSA = cert.GetDSAPublicKey()
        Return dsa.VerifyData(data, signature, HashAlgorithmName.SHA384)
    End Using
End Function
```

Increased clarity for inputs to ECDiffieHellman key derivation routines

The .NET Framework 3.5 added support for Elliptic Curve Diffie-Hellman Key Agreement with three different Key Derivation Function (KDF) routines. The inputs to the routines, and the routines themselves, were configured via properties on the [ECDiffieHellmanCng](#) object. But since not every routine read every input property, there was ample room for confusion on the part of the developer.

To address this in the .NET Framework 4.6.2, the following three methods have been added to the [ECDiffieHellman](#) base class to more clearly represent these KDF routines and their inputs:

ECDIFFIEHELLMAN METHOD	DESCRIPTION
DeriveKeyFromHash(ECDiffieHellmanPublicKey, HashAlgorithmName, Byte[], Byte[])	Derives key material using the formula HASH(secretPrepend x secretAppend) HASH(secretPrepend OrElse x OrElse secretAppend) where x is the computed result of the EC Diffie-Hellman algorithm.

ECDIFFIEHELLMAN METHOD	DESCRIPTION
DeriveKeyFromHmac(ECDiffieHellmanPublicKey, HashAlgorithmName, Byte[], Byte[], Byte[])	<p>Derives key material using the formula</p> $\text{HMAC}(\text{hmacKey}, \text{secretPrepend} \parallel x \parallel \text{secretAppend})$ $\text{HMAC}(\text{hmacKey}, \text{secretPrepend OrElse } x \text{ OrElse } \text{secretAppend})$ <p>where x is the computed result of the EC Diffie-Hellman algorithm.</p>
DeriveKeyTls(ECDiffieHellmanPublicKey, Byte[], Byte[])	Derives key material using the TLS pseudo-random function (PRF) derivation algorithm.

Support for persisted-key symmetric encryption

The Windows cryptography library (CNG) added support for storing persisted symmetric keys and using hardware-stored symmetric keys, and the .NET Framework 4.6.2 made it possible for developers to make use of this feature. Since the notion of key names and key providers is implementation-specific, using this feature requires utilizing the constructor of the concrete implementation types instead of the preferred factory approach (such as calling `Aes.Create`).

Persisted-key symmetric encryption support exists for the AES ([AesCng](#)) and 3DES ([TripleDESCng](#)) algorithms. For example:

```
public static byte[] EncryptDataWithPersistedKey(byte[] data, byte[] iv)
{
    using (Aes aes = new AesCng("AesDemoKey", CngProvider.MicrosoftSoftwareKeyStorageProvider))
    {
        aes.IV = iv;

        // Using the zero-argument overload is required to make use of the persisted key
        using (ICryptoTransform encryptor = aes.CreateEncryptor())
        {
            if (!encryptor.CanTransformMultipleBlocks)
            {
                throw new InvalidOperationException("This is a sample, this case wasn't handled...");
            }

            return encryptor.TransformFinalBlock(data, 0, data.Length);
        }
    }
}
```

```
Public Shared Function EncryptDataWithPersistedKey(data As Byte(), iv As Byte()) As Byte()
    Using Aes As Aes = New AesCng("AesDemoKey", CngProvider.MicrosoftSoftwareKeyStorageProvider)
        Aes.IV = iv

        ' Using the zero-argument overload Is required to make use of the persisted key
        Using encryptor As ICryptoTransform = Aes.CreateEncryptor()
            If Not encryptor.CanTransformMultipleBlocks Then
                Throw New InvalidOperationException("This is a sample, this case wasn't handled...")
            End If
            Return encryptor.TransformFinalBlock(data, 0, data.Length)
        End Using
    End Using
End Function
```

SignedXml support for SHA-2 hashing

The .NET Framework 4.6.2 adds support to the [SignedXml](#) class for RSA-SHA256, RSA-SHA384, and RSA-SHA512 PKCS#1 signature methods, and SHA256, SHA384, and SHA512 reference digest algorithms.

The URI constants are all exposed on [SignedXml](#):

SIGNEDXML FIELD	CONSTANT
XmlDsigSHA256Url	"http://www.w3.org/2001/04/xmlenc#sha256"
XmlDsigRSASHA256Url	"http://www.w3.org/2001/04/xmldsig-more#rsa-sha256"
XmlDsigSHA384Url	"http://www.w3.org/2001/04/xmldsig-more#sha384"
XmlDsigRSASHA384Url	"http://www.w3.org/2001/04/xmldsig-more#rsa-sha384"
XmlDsigSHA512Url	"http://www.w3.org/2001/04/xmlenc#sha512"
XmlDsigRSASHA512Url	"http://www.w3.org/2001/04/xmldsig-more#rsa-sha512"

Any programs that have registered a custom [SignatureDescription](#) handler into [CryptoConfig](#) to add support for these algorithms will continue to function as they did in the past, but since there are now platform defaults, the [CryptoConfig](#) registration is no longer necessary.

SqlClient

.NET Framework Data Provider for SQL Server ([System.Data.SqlClient](#)) includes the following new features in the .NET Framework 4.6.2:

Connection pooling and timeouts with Azure SQL databases

When connection pooling is enabled and a timeout or other login error occurs, an exception is cached, and the cached exception is thrown on any subsequent connection attempt for the next 5 seconds to 1 minute. For more details, see [SQL Server Connection Pooling \(ADO.NET\)](#).

This behavior is not desirable when connecting to Azure SQL Databases, since connection attempts can fail with transient errors that are typically recovered quickly. To better optimize the connection retry experience, the connection pool blocking period behavior is removed when connections to Azure SQL Databases fail.

The addition of the new `PoolBlockingPeriod` keyword lets you to select the blocking period best suited for your app. Values include:

[Auto](#)

The connection pool blocking period for an application that connects to an Azure SQL Database is disabled, and the connection pool blocking period for an application that connects to any other SQL Server instance is enabled. This is the default value. If the Server endpoint name ends with any of the following, they are considered Azure SQL Databases:

- `.database.windows.net`
- `.database.chinacloudapi.cn`
- `.database.usgovcloudapi.net`
- `.database.cloudapi.de`

[AlwaysBlock](#)

The connection pool blocking period is always enabled.

[NeverBlock](#)

The connection pool blocking period is always disabled.

Enhancements for Always Encrypted

SQLClient introduces two enhancements for Always Encrypted:

- To improve performance of parameterized queries against encrypted database columns, encryption metadata for query parameters is now cached. With the `SqlConnection.ColumnEncryptionQueryMetadataCacheEnabled` property set to `true` (which is the default value), if the same query is called multiple times, the client retrieves parameter metadata from the server only once.
- Column encryption key entries in the key cache are now evicted after a configurable time interval, set using the `SqlConnection.ColumnEncryptionKeyCacheTtl` property.

Windows Communication Foundation

In the .NET Framework 4.6.2, Windows Communication Foundation has been enhanced in the following areas:

WCF transport security support for certificates stored using CNG

WCF transport security supports certificates stored using the Windows cryptography library (CNG). In the .NET Framework 4.6.2, this support is limited to using certificates with a public key that has an exponent no more than 32 bits in length. When an application targets the .NET Framework 4.6.2, this feature is on by default.

For applications that target the .NET Framework 4.6.1 and earlier but are running on the .NET Framework 4.6.2, this feature can be enabled by adding the following line to the `<runtime>` section of the app.config or web.config file.

```
<AppContextSwitchOverrides  
    value="Switch.System.ServiceModel.DisableCngCertificates=false"  
/>
```

This can also be done programmatically with code like the following:

```
private const string DisableCngCertificates = @"Switch.System.ServiceModel.DisableCngCertificates";  
AppContext.SetSwitch(disableCngCertificates, false);
```

```
Const DisableCngCertificates As String = "Switch.System.ServiceModel.DisableCngCertificates"  
AppContext.SetSwitch(disableCngCertificates, False)
```

Better support for multiple daylight saving time adjustment rules by the `DataContractJsonSerializer` class

Customers can use an application configuration setting to determine whether the `DataContractJsonSerializer` class supports multiple adjustment rules for a single time zone. This is an opt-in feature. To enable it, add the following setting to your app.config file:

```
<runtime>
  <AppContextSwitchOverrides value="Switch.System.Runtime.Serialization.DoNotUseTimeZoneInfo=false" />
</runtime>
```

When this feature is enabled, a [DataContractJsonSerializer](#) object uses the [TimeZoneInfo](#) type instead of the [TimeZone](#) type to deserialize date and time data. [TimeZoneInfo](#) supports multiple adjustment rules, which makes it possible to work with historic time zone data; [TimeZone](#) does not.

For more information on the [TimeZoneInfo](#) structure and time zone adjustments, see [Time Zone Overview](#).

NetNamedPipeBinding best match

WCF has a new app setting that can be set on client applications to ensure they always connect to the service listening on the URI that best matches the one that they request. With this app setting set to `false` (the default), it is possible for clients using [NetNamedPipeBinding](#) to attempt to connect to a service listening on a URI that is a substring of the requested URI.

For example, a client tries to connect to a service listening at `net.pipe://localhost/Service1`, but a different service on that machine running with administrator privilege is listening at `net.pipe://localhost`. With this app setting set to `false`, the client would attempt to connect to the wrong service. After setting the app setting to `true`, the client will always connect to the best matching service.

NOTE

Clients using [NetNamedPipeBinding](#) find services based on the service's base address (if it exists) rather than the full endpoint address. To ensure this setting always works the service should use a unique base address.

To enable this change, add the following app setting to your client application's App.config or Web.config file:

```
<configuration>
  <appSettings>
    <add key="wcf:useBestMatchNamedPipeUri" value="true" />
  </appSettings>
</configuration>
```

SSL 3.0 is not a default protocol

When using NetTcp with transport security and a credential type of certificate, SSL 3.0 is no longer a default protocol used for negotiating a secure connection. In most cases, there should be no impact to existing apps, because TLS 1.0 is included in the protocol list for NetTcp. All existing clients should be able to negotiate a connection using at least TLS 1.0. If Ssl3 is required, use one of the following configuration mechanisms to add it to the list of negotiated protocols.

- The [SslStreamSecurityBindingElement.SslProtocols](#) property
- The [TcpTransportSecurity.SslProtocols](#) property
- The [<transport>](#) section of the [<netTcpBinding>](#) section
- The [<sslStreamSecurity>](#) section of the [<customBinding>](#) section

Windows Presentation Foundation (WPF)

In the .NET Framework 4.6.2, Windows Presentation Foundation has been enhanced in the following areas:

Group sorting

An application that uses a [CollectionView](#) object to group data can now explicitly declare how to sort the groups. Explicit sorting addresses the problem of non-intuitive ordering that occurs when an app dynamically adds or removes groups, or when it changes the value of item properties involved in grouping. It can also improve the performance of the group creation process by moving comparisons of the grouping properties from the sort of the full collection to the sort of the groups.

To support group sorting, the new [GroupDescription.SortDescriptions](#) and [GroupDescription.CustomSort](#) properties describe how to sort the collection of groups produced by the [GroupDescription](#) object. This is analogous to the way the identically named [ListCollectionView](#) properties describe how to sort the data items.

Two new static properties of the [PropertyGroupDescription](#) class, [CompareNameAscending](#) and [CompareNameDescending](#), can be used for the most common cases.

For example, the following XAML groups data by age, sort the age groups in ascending order, and group the items within each age group by last name.

```

<GroupDescriptions>
    <PropertyGroupDescription
        PropertyName="Age"
        CustomSort=
            "<x:Static PropertyGroupDescription.CompareNamesAscending>" />
    </PropertyGroupDescription>
</GroupDescriptions>

<SortDescriptions>
    <SortDescription PropertyName="LastName" />
</SortDescriptions>

```

Soft keyboard support

Soft Keyboard support enables focus tracking in a WPF applications by automatically invoking and dismissing the new Soft Keyboard in Windows 10 when the touch input is received by a control that can take textual input.

In previous versions of the .NET Framework, WPF applications cannot opt into the focus tracking without disabling WPF pen/touch gesture support. As a result, WPF applications must choose between full WPF touch support or rely on Windows mouse promotion.

Per-monitor DPI

To support the recent proliferation of high-DPI and hybrid-DPI environments for WPF apps, WPF in the .NET Framework 4.6.2 enables per-monitor awareness. See the [samples and developer guide](#) on GitHub for more information about how to enable your WPF app to become per-monitor DPI aware.

In previous versions of the .NET Framework, WPF apps are system-DPI aware. In other words, the application's UI is scaled by the OS as appropriate, depending on the DPI of the monitor on which the app is rendered.,

For apps running under the .NET Framework 4.6.2, you can disable per-monitor DPI changes in WPF apps by adding a configuration statement to the `<runtime>` section of your application configuration file, as follows:

```

<runtime>
    <AppContextSwitchOverrides value="Switch.System.Windows.DoNotScaleForDpiChanges=false" />
</runtime>

```

Windows Workflow Foundation (WF)

In the .NET Framework 4.6.2, Windows Workflow Foundation has been enhanced in the following area:

Support for C# expressions and IntelliSense in the Re-hosted WF Designer

Starting with the .NET Framework 4.5, WF supports C# expressions in both the Visual Studio Designer and in code workflows. The Re-hosted Workflow Designer is a key feature of WF that allows for the Workflow Designer to be in an application outside Visual Studio (for example, in WPF). Windows Workflow Foundation provides the ability to support C# expressions and IntelliSense in the Re-hosted Workflow Designer. For more information, see the [Windows Workflow Foundation blog](#).

Availability of IntelliSense when a customer rebuilds a workflow project from Visual Studio In versions of the .NET Framework prior to the .NET Framework 4.6.2, WF Designer IntelliSense is broken when a customer rebuilds a workflow project from Visual Studio. While the project build is successful, the workflow types are not found on the designer, and warnings from IntelliSense for the missing workflow types appear in the **Error List** window. The .NET Framework 4.6.2 addresses this issue and makes IntelliSense available.

Workflow V1 applications with Workflow Tracking on now run under FIPS-mode

Machines with FIPS Compliance Mode enabled can now successfully run a workflow Version 1-style application with Workflow tracking on. To enable this scenario, you must make the following change to your app.config file:

```

<add key="microsoft:WorkflowRuntime:FIPSRequired" value="true" />

```

If this scenario is not enabled, running the application continues to generate an exception with the message, "This implementation is not part of the Windows Platform FIPS validated cryptographic algorithms."

Workflow Improvements when using Dynamic Update with Visual Studio Workflow Designer

The Workflow Designer, FlowChart Activity Designer, and other Workflow Activity Designers now successfully load and display workflows that have been saved after calling the [DynamicUpdateServices.PrepareForUpdate](#) method. In versions of the .NET Framework before the .NET Framework 4.6.2, loading a XAML file in Visual Studio for a workflow that has been saved after calling [DynamicUpdateServices.PrepareForUpdate](#) can result in the following issues:

- The Workflow Designer can't load the XAML file correctly (when the [ViewStateData.Id](#) is at the end of the line).
- Flowchart Activity Designer or other Workflow Activity Designers may display all objects in their default locations as opposed to attached property values.

ClickOnce

ClickOnce has been updated to support TLS 1.1 and TLS 1.2 in addition to the 1.0 protocol, which it already supports. ClickOnce automatically detects which protocol is required; no extra steps within the ClickOnce application are required to enable TLS 1.1 and 1.2 support.

Converting Windows Forms and WPF apps to UWP apps

Windows now offers capabilities to bring existing Windows desktop apps, including WPF and Windows Forms apps, to the Universal Windows Platform (UWP). This technology acts as a bridge by enabling you to gradually migrate your existing code base to UWP, thereby bringing your app to all Windows 10 devices.

Converted desktop apps gain an app identity similar to the app identity of UWP apps, which makes UWP APIs accessible to enable features such as Live Tiles and notifications. The app continues to behave as before and runs as a full trust app. Once the app is converted, an app container process can be added to the existing full trust process to add an adaptive user interface. When all functionality is moved to the app container process, the full trust process can be removed and the new UWP app can be made available to all Windows 10 devices.

Debugging improvements

The *unmanaged debugging API* has been enhanced in the .NET Framework 4.6.2 to perform additional analysis when a `NullReferenceException` is thrown so that it is possible to determine which variable in a single line of source code is `null`. To support this scenario, the following APIs have been added to the unmanaged debugging API.

- The `ICorDebugCode4`, `ICorDebugVariableHome`, and `ICorDebugVariableHomeEnum` interfaces, which expose the native homes of managed variables. This enables debuggers to do some code flow analysis when a `NullReferenceException` occurs and to work backwards to determine the managed variable that corresponds to the native location that was `null`.
- The `ICorDebugType2::GetTypeID` method provides a mapping for `ICorDebugType` to `COR_TYPEID`, which allows the debugger to obtain a `COR_TYPEID` without an instance of the `ICorDebugType`. Existing APIs on `COR_TYPEID` can then be used to determine the class layout of the type.

What's new in the .NET Framework 4.6.1

The .NET Framework 4.6.1 includes new features in the following areas:

- [Cryptography](#)
- [ADO.NET](#)
- [Windows Presentation Foundation \(WPF\)](#)
- [Windows Workflow Foundation](#)
- [Profiling](#)
- [NGen](#)

For more information on the .NET Framework 4.6.1, see the following topics:

- The [.NET Framework 4.6.1 list of changes](#)
- [Application Compatibility in 4.6.1](#)
- [The .NET Framework API diff](#) (on GitHub)

Cryptography: Support for X509 certificates containing ECDSA

The .NET Framework 4.6 added RSACng support for X509 certificates. The .NET Framework 4.6.1 adds support for ECDSA (Elliptic Curve Digital Signature Algorithm) X509 certificates.

ECDSA offers better performance and is a more secure cryptography algorithm than RSA, providing an excellent choice where Transport Layer Security (TLS) performance and scalability is a concern. The .NET Framework implementation wraps calls into existing Windows functionality.

The following example code shows how easy it is to generate a signature for a byte stream by using the new support for ECDSA X509 certificates included in the .NET Framework 4.6.1.

```
using System;
using System.Security.Cryptography;
using System.Security.Cryptography.X509Certificates;

public class Net461Code
{
    public static byte[] SignECDSAsha512(byte[] data, X509Certificate2 cert)
    {
        using (ECDsa privateKey = cert.GetECDsaPrivateKey())
        {
            return privateKey.SignData(data, HashAlgorithmName.SHA512);
        }
    }

    public static byte[] SignECDSAsha512(byte[] data, ECDsa privateKey)
    {
        return privateKey.SignData(data, HashAlgorithmName.SHA512);
    }
}
```

```

Imports System
Imports System.Security.Cryptography
Imports System.Security.Cryptography.X509Certificates

Public Class Net461Code
    Public Shared Function SignECDsaSha512(data As Byte(), cert As X509Certificate2) As Byte()
        Using privateKey As ECDsa = cert.GetECDsaPrivateKey()
            Return privateKey.SignData(data, HashAlgorithmName.SHA512)
        End Using
    End Function

    Public Shared Function SignECDsaSha512(data As Byte, privateKey As ECDsa) As Byte()
        Return privateKey.SignData(data, HashAlgorithmName.SHA512)
    End Function
End Class

```

This offers a marked contrast to the code needed to generate a signature in the .NET Framework 4.6.

```

using System;
using System.Security.Cryptography;
using System.Security.Cryptography.X509Certificates;

public class Net46Code
{
    public static byte[] SignECDsaSha512(byte[] data, X509Certificate2 cert)
    {
        // This would require using cert.Handle and a series of p/invoke to get at the
        // underlying key, then passing that to a CngKey object, and passing that to
        // new ECDsa(CngKey). It's a lot of work.
        throw new Exception("That's a lot of work...");
    }

    public static byte[] SignECDsaSha512(byte[] data, ECDsa privateKey)
    {
        // This way works, but SignData probably better matches what you want.
        using (SHA512 hasher = SHA512.Create())
        {
            byte[] signature1 = privateKey.SignHash(hasher.ComputeHash(data));
        }

        // This might not be the ECDsa you got!
        ECDsaCng ecDsaCng = (ECDsaCng)privateKey;
        ecDsaCng.HashAlgorithm = CngAlgorithm.Sha512;
        return ecDsaCng.SignData(data);
    }
}

```

```

Imports System
Imports System.Security.Cryptography
Imports System.Security.Cryptography.X509Certificates

Public Class Net46Code
    Public Shared Function SignECDsaSha512(data As Byte(), cert As X509Certificate2) As Byte()
        ' This would require using cert.Handle and a series of p/invoke to get at the
        ' underlying key, then passing that to a CngKey object, and passing that to
        ' new ECDsa(CngKey). It's a lot of work.
        Throw New Exception("That's a lot of work...")
    End Function

    Public Shared Function SignECDsaSha512(data As Byte(), privateKey As ECDsa) As Byte()
        ' This way works, but SignData probably better matches what you want.
        Using hasher As SHA512 = SHA512.Create()
            Dim signature1 As Byte() = privateKey.SignHash(hasher.ComputeHash(data))
        End Using

        ' This might not be the ECDsa you got!
        Dim ecDsaCng As ECDsaCng = CType(privateKey, ECDsaCng)
        ecDsaCng.HashAlgorithm = CngAlgorithm.Sha512
        Return ecDsaCng.SignData(data)
    End Function
End Class

```

ADO.NET

The following have been added to ADO.NET:

Always Encrypted support for hardware protected keys

ADO.NET now supports storing Always Encrypted column master keys natively in Hardware Security Modules (HSMs). With this support, customers can leverage asymmetric keys stored in HSMs without having to write custom column master key store providers and registering them in applications.

Customers need to install the HSM vendor-provided CSP provider or CNG key store providers on the app servers or client computers in order to access Always Encrypted data protected with column master keys stored in a HSM.

Improved MultiSubnetFailover connection behavior for AlwaysOn

SqlClient now automatically provides faster connections to an AlwaysOn Availability Group (AG). It transparently detects whether your application is connecting to an AlwaysOn availability group (AG) on a different subnet and quickly discovers the current active server and provides a connection to the server. Prior to this release, an application had to set the connection string to include `"MultisubnetFailover=true"` to indicate that it was connecting to an AlwaysOn Availability Group. Without setting the connection keyword to `true`, an application might experience a timeout while connecting to an AlwaysOn Availability Group. With this release, an application does *not* need to set `MultiSubnetFailover` to `true` anymore. For more information about SqlClient support for Always On Availability Groups, see [SqlClient Support for High Availability, Disaster Recovery](#).

Windows Presentation Foundation (WPF)

Windows Presentation Foundation includes a number of improvements and changes.

Improved performance

The delay in firing touch events has been fixed in the .NET Framework 4.6.1. In addition, typing in a `RichTextBox` control no longer ties up the render thread during fast input.

Spell checking improvements

The spell checker in WPF has been updated on Windows 8.1 and later versions to leverage operating system support for spell-checking additional languages. There is no change in functionality on Windows versions prior to Windows 8.1.

As in previous versions of the .NET Framework, the language for a `TextBox` control or a `RichTextBox` block is detected by looking for information in the following order:

- `xml:lang`, if it is present.
- Current input language.
- Current thread culture.

For additional information on language support in WPF, see the [WPF blog post on .NET Framework 4.6.1 features](#).

Additional support for per-user custom dictionaries

In .NET Framework 4.6.1, WPF recognizes custom dictionaries that are registered globally. This capability is available in addition to the ability to register them per-control.

In previous versions of WPF, custom dictionaries did not recognize Excluded Words and AutoCorrect lists. They are supported on Windows 8.1 and Windows 10 through the use of files that can be placed under the `%AppData%\Microsoft\Spelling\<language tag>` directory. The following rules apply to these files:

- The files should have extensions of .dic (for added words), .exc (for excluded words), or .acl (for AutoCorrect).
- The files should be UTF-16 LE plaintext that starts with the Byte Order Mark (BOM).
- Each line should consist of a word (in the added and excluded word lists), or an autocorrect pair with the words separated by a vertical bar ("|") (in the AutoCorrect word list).
- These files are considered read-only and are not modified by the system.

NOTE

These new file-formats are not directly supported by the WPF spell checking APIs, and the custom dictionaries supplied to WPF in applications should continue to use .lex files.

Samples

There are a number of WPF samples on the [Microsoft/WPF-Samples](#) GitHub repository. Help us improve our samples by sending us a pull-request or opening a [GitHub issue](#).

DirectX extensions

WPF includes a [NuGet package](#) that provides new implementations of `D3DImage` that make it easy for you to interoperate with DX10 and Dx11 content. The code for this package has been open sourced and is available on [GitHub](#).

Windows Workflow Foundation: Transactions

The `Transaction.EnlistPromotableSinglePhase` method can now use a distributed transaction manager other than MSDTC to promote the transaction. You do this by specifying a GUID transaction promoter identifier to the new `Transaction.EnlistPromotableSinglePhase(IPromotableSinglePhaseNotification, Guid)` overload. If this operation is successful, there are limitations placed on the capabilities of the transaction. Once a non-MSDTC transaction promoter is enlisted, the following methods throw a `TransactionPromotionException` because these methods require promotion to MSDTC:

- `Transaction.EnlistDurable`
- `TransactionInterop.GetDtcTransaction`
- `TransactionInterop.GetExportCookie`

- [TransactionInterop.GetTransmitterPropagationToken](#)

Once a non-MSDTC transaction promoter is enlisted, it must be used for future durable enlistments by using protocols that it defines. The [Guid](#) of the transaction promoter can be obtained by using the [PromoterType](#) property. When the transaction promotes, the transaction promoter provides a [Byte](#) array that represents the promoted token. An application can obtain the promoted token for a non-MSDTC promoted transaction with the [GetPromotedToken](#) method.

Users of the new [Transaction.EnlistPromotableSinglePhase\(IPromotableSinglePhaseNotification, Guid\)](#) overload must follow a specific call sequence in order for the promotion operation to complete successfully. These rules are documented in the method's documentation.

Profiling

The unmanaged profiling API has been enhanced as follows:

- Better support for accessing PDBs in the [ICorProfilerInfo7](#) interface.

In ASP.NET Core, it is becoming much more common for assemblies to be compiled in-memory by Roslyn. For developers making profiling tools, this means that PDBs that historically were serialized on disk may no longer be present. Profiler tools often use PDBs to map code back to source lines for tasks such as code coverage or line-by-line performance analysis. The [ICorProfilerInfo7](#) interface now includes two new methods, [ICorProfilerInfo7::GetInMemorySymbolsLength](#) and [ICorProfilerInfo7::ReadInMemorySymbols](#), to provide these profiler tools with access to the in-memory PDB data. By using the new APIs, a profiler can obtain the contents of an in-memory PDB as a byte array and then process it or serialize it to disk.

- Better instrumentation with the [ICorProfiler](#) interface.

Profilers that are using the [ICorProfiler](#) APIs ReJit functionality for dynamic instrumentation can now modify some metadata. Previously such tools could instrument IL at any time, but metadata could only be modified at module load time. Because IL refers to metadata, this limited the kinds of instrumentation that could be done. We have lifted some of those limits by adding the [ICorProfilerInfo7::ApplyMetaData](#) method to support a subset of metadata edits after the module loads, in particular by adding new [AssemblyRef](#), [TypeRef](#), [TypeSpec](#), [MemberRef](#), [MemberSpec](#), and [UserString](#) records. This change makes a much broader range of on-the-fly instrumentation possible.

Native Image Generator (NGEN) PDBs

Cross-machine event tracing allows customers to profile a program on Machine A and look at the profiling data with source line mapping on Machine B. Using previous versions of the .NET Framework, the user would copy all the modules and native images from the profiled machine to the analysis machine that contains the IL PDB to create the source-to-native mapping. While this process may work well when the files are relatively small, such as for phone applications, the files can be very large on desktop systems and require significant time to copy.

With Ngen PDBs, NGen can create a PDB that contains the IL-to-native mapping without a dependency on the IL PDB. In our cross-machine event tracing scenario, all that is needed is to copy the native image PDB that is generated by Machine A to Machine B and to use [Debug Interface Access APIs](#) to read the IL PDB's source-to-IL mapping and the native image PDB's IL-to-native mapping. Combining both mappings provides a source-to-native mapping. Since the native image PDB is much smaller than all the modules and native images, the process of copying from Machine A to Machine B is much faster.

What's new in .NET 2015

.NET 2015 introduces the .NET Framework 4.6 and .NET Core. Some new features apply to both, and other features are specific to .NET Framework 4.6 or .NET Core.

• [ASP.NET Core](#)

.NET 2015 includes ASP.NET Core, which is a lean .NET implementation for building modern cloud-based apps. ASP.NET Core is modular so you can include only those features that are needed in your application. It can be hosted on IIS or self-hosted in a custom process, and you can run apps with different versions of the .NET Framework on the same server. It includes a new environment configuration system that is designed for cloud deployment.

MVC, Web API, and Web Pages are unified into a single framework called MVC 6. You build ASP.NET Core apps through tools in Visual Studio 2015 or later. Your existing applications will work on the new .NET Framework; however to build an app that uses MVC 6 or SignalR 3, you must use the project system in Visual Studio 2015 or later.

For information, see [ASP.NET Core](#).

• [ASP.NET Updates](#)

◦ [Task-based API for Asynchronous Response Flushing](#)

ASP.NET now provides a simple task-based API for asynchronous response flushing, [HttpResponse.FlushAsync](#), that allows responses to be flushed asynchronously by using your language's [async/await](#) support.

◦ [Model binding supports task-returning methods](#)

In the .NET Framework 4.5, ASP.NET added the Model Binding feature that enabled an extensible, code-focused approach to CRUD-based data operations in Web Forms pages and user controls. The Model Binding system now supports [Task](#)-returning model binding methods. This feature allows Web Forms developers to get the scalability benefits of async with the ease of the data-binding system when using newer versions of ORMs, including the Entity Framework.

Async model binding is controlled by the [aspnet:EnableAsyncModelBinding](#) configuration setting.

```
<appSettings>
  <add key="aspnet:EnableAsyncModelBinding" value="true|false" />
</appSettings>
```

On apps that target the .NET Framework 4.6, it defaults to `true`. On apps running on the .NET Framework 4.6 that target an earlier version of the .NET Framework, it is `false` by default. It can be enabled by setting the configuration setting to `true`.

- **HTTP/2 Support (Windows 10)**

[HTTP/2](#) is a new version of the HTTP protocol that provides much better connection utilization (fewer round-trips between client and server), resulting in lower latency web page loading for users. Web pages (as opposed to services) benefit the most from HTTP/2, since the protocol optimizes for multiple artifacts being requested as part of a single experience. HTTP/2 support has been added to ASP.NET in the .NET Framework 4.6. Because networking functionality exists at multiple layers, new features were required in Windows, in IIS, and in ASP.NET to enable HTTP/2. You must be running on Windows 10 to use HTTP/2 with ASP.NET.

HTTP/2 is also supported and on by default for Windows 10 Universal Windows Platform (UWP) apps that use the [System.Net.Http.HttpClient](#) API.

In order to provide a way to use the [PUSH_PROMISE](#) feature in ASP.NET applications, a new method with two overloads, [PushPromise\(String\)](#) and [PushPromise\(String, String, NameValueCollection\)](#), has been added to the [HttpResponse](#) class.

NOTE

While ASP.NET Core supports HTTP/2, support for the PUSH PROMISE feature has not yet been added.

The browser and the web server (IIS on Windows) do all the work. You don't have to do any heavy-lifting for your users.

Most of the [major browsers support HTTP/2](#), so it's likely that your users will benefit from HTTP/2 support if your server supports it.

- **Support for the Token Binding Protocol**

Microsoft and Google have been collaborating on a new approach to authentication, called the [Token Binding Protocol](#). The premise is that authentication tokens (in your browser cache) can be stolen and used by criminals to access otherwise secure resources (e.g. your bank account) without requiring your password or any other privileged knowledge. The new protocol aims to mitigate this problem.

The Token Binding Protocol will be implemented in Windows 10 as a browser feature. ASP.NET apps will participate in the protocol, so that authentication tokens are validated to be legitimate. The client and the server implementations establish the end-to-end protection specified by the protocol.

- **Randomized string hash algorithms**

The .NET Framework 4.5 introduced a [randomized string hash algorithm](#). However, it was not supported by ASP.NET because of some ASP.NET features depended on a stable hash code. In .NET Framework 4.6, randomized string hash algorithms are now supported. To enable this feature, use the `aspnet:UseRandomizedStringHashAlgorithm` config setting.

```
<appSettings>
  <add key="aspnet:UseRandomizedStringHashAlgorithm" value="true|false" />
</appSettings>
```

- **ADO.NET**

ADO .NET now supports the Always Encrypted feature available in SQL Server 2016 Community Technology Preview 2 (CTP2). With Always Encrypted, SQL Server can perform operations on encrypted data, and best of all the encryption key resides with the application inside the customer's trusted environment and not on the server. Always Encrypted secures customer data so DBAs do not have access to plain text data. Encryption and decryption of data happens transparently at the driver level, minimizing changes that have to be made to existing applications. For details, see [Always Encrypted \(Database Engine\)](#) and [Always Encrypted \(client development\)](#).

- **64-bit JIT Compiler for managed code**

The .NET Framework 4.6 features a new version of the 64-bit JIT compiler (originally code-named RyuJIT). The new 64-bit compiler provides significant performance improvements over the older 64-bit JIT compiler. The new 64-bit compiler is enabled for 64-bit processes running on top of the .NET Framework 4.6. Your app will run in a 64-bit process if it is compiled as 64-bit or AnyCPU and is running on a 64-bit operating system. While care has been taken to make the transition to the new compiler as transparent as possible, changes in behavior are possible. We would like to hear directly about any issues encountered when using the new JIT compiler. Please contact us through [Microsoft Connect](#) if you encounter an issue that may be related to the new 64-bit JIT compiler.

The new 64-bit JIT compiler also includes hardware SIMD acceleration features when coupled with SIMD-enabled types in the [System.Numerics](#) namespace, which can yield good performance improvements.

- **Assembly loader improvements**

The assembly loader now uses memory more efficiently by unloading IL assemblies after a corresponding NGEN image is loaded. This change decreases virtual memory, which is particularly beneficial for large 32-bit apps (such as Visual Studio), and also saves physical memory.

- **Base class library changes**

Many new APIs have been added around to .NET Framework 4.6 to enable key scenarios. These include the following changes and additions:

- **IReadOnlyCollection<T> implementations**

Additional collections implement [IReadOnlyCollection<T>](#) such as [Queue<T>](#) and [Stack<T>](#).

- **CultureInfo.CurrentCulture and CultureInfo.CurrentUICulture**

The [CultureInfo.CurrentCulture](#) and [CultureInfo.CurrentUICulture](#) properties are now read-write rather than read-only. If you assign a new [CultureInfo](#) object to these properties, the current thread culture defined by the [Thread.CurrentThread.CurrentCulture](#) property and the current UI thread culture defined by the [Thread.CurrentThread.CurrentUICulture](#) properties also change.

- **Enhancements to garbage collection (GC)**

The [GC](#) class now includes [TryStartNoGCRegion](#) and [EndNoGCRegion](#) methods that allow you to disallow garbage collection during the execution of a critical path.

A new overload of the [GC.Collect\(Int32, GCCollectionMode, Boolean, Boolean\)](#) method allows you to control whether both the small object heap and the large object heap are swept and compacted or swept only.

- **SIMD-enabled types**

The [System.Numerics](#) namespace now includes a number of SIMD-enabled types, such as [Matrix3x2](#), [Matrix4x4](#), [Plane](#), [Quaternion](#), [Vector2](#), [Vector3](#), and [Vector4](#).

Because the new 64-bit JIT compiler also includes hardware SIMD acceleration features, there are especially significant performance improvements when using the SIMD-enabled types with the new 64-bit JIT compiler.

- **Cryptography updates**

The [System.Security.Cryptography](#) API is being updated to support the [Windows CNG cryptography APIs](#). Previous versions of the .NET Framework have relied entirely on an [earlier version of the Windows Cryptography APIs](#) as the basis for the [System.Security.Cryptography](#) implementation. We have had requests to support the CNG API, since it supports [modern cryptography algorithms](#), which are important for certain categories of apps.

The .NET Framework 4.6 includes the following new enhancements to support the Windows CNG cryptography APIs:

- A set of extension methods for X509 Certificates,

```
System.Security.Cryptography.X509Certificates.RSACertificateExtensions.GetRSAPublicKey(System.Security.Cryptography.X509Certificates.X509Certificate2)  
and  
System.Security.Cryptography.X509Certificates.RSACertificateExtensions.GetRSAPrivateKey(System.Security.Cryptography.X509Certificates.X509Certificate2);  
, that return a CNG-based implementation rather than a CAPI-based implementation when possible. (Some smartcards, etc., still require CAPI, and the APIs handle the fallback).
```

- The [System.Security.Cryptography.RSACng](#) class, which provides a CNG implementation of the RSA algorithm.

- Enhancements to the RSA API so that common actions no longer require casting. For example, encrypting data using an [X509Certificate2](#) object requires code like the following in previous versions of the .NET Framework.

```
RSACryptoServiceProvider rsa = (RSACryptoServiceProvider)cert.PrivateKey;  
byte[] oaepEncrypted = rsa.Encrypt(data, true);  
byte[] pkcs1Encrypted = rsa.Encrypt(data, false);
```

```
Dim rsa As RSACryptoServiceProvider = CType(cert.PrivateKey, RSACryptoServiceProvider)  
Dim oaepEncrypted() As Byte = rsa.Encrypt(data, True)  
Dim pkcs1Encrypted() As Byte = rsa.Encrypt(data, False)
```

Code that uses the new cryptography APIs in the .NET Framework 4.6 can be rewritten as follows to avoid the cast.

```
RSA rsa = cert.GetRSAPrivateKey();  
if (rsa == null)  
    throw new InvalidOperationException("An RSA certificate was expected");  
  
byte[] oaepEncrypted = rsa.Encrypt(data, RSAEncryptionPadding.OaepSHA1);  
byte[] pkcs1Encrypted = rsa.Encrypt(data, RSAEncryptionPadding.Pkcs1);
```

```
Dim rsa As RSA = cert.GetRSAPrivateKey()  
If rsa Is Nothing Then  
    Throw New InvalidOperationException("An RSA certificate was expected")  
End If  
  
Dim oaepEncrypted() As Byte = rsa.Encrypt(data, RSAEncryptionPadding.OaepSHA1)  
Dim pkcs1Encrypted() As Byte = rsa.Encrypt(data, RSAEncryptionPadding.Pkcs1)
```

- **Support for converting dates and times to or from Unix time**

The following new methods have been added to the [DateTimeOffset](#) structure to support converting date and time values to or from Unix

time:

- `DateTimeOffset.FromUnixTimeSeconds`
- `DateTimeOffset.FromUnixTimeMilliseconds`
- `DateTimeOffset.ToUnixTimeSeconds`
- `DateTimeOffset.ToUnixTimeMilliseconds`

- **Compatibility switches**

The new [AppContext](#) class adds a new compatibility feature that enables library writers to provide a uniform opt-out mechanism for new functionality for their users. It establishes a loosely-coupled contract between components in order to communicate an opt-out request. This capability is typically important when a change is made to existing functionality. Conversely, there is already an implicit opt-in for new functionality.

With [AppContext](#), libraries define and expose compatibility switches, while code that depends on them can set those switches to affect the library behavior. By default, libraries provide the new functionality, and they only alter it (that is, they provide the previous functionality) if the switch is set.

An application (or a library) can declare the value of a switch (which is always a [Boolean](#) value) that a dependent library defines. The switch is always implicitly `false`. Setting the switch to `true` enables it. Explicitly setting the switch to `false` provides the new behavior.

```
AppContext.SetSwitch("Switch.AmazingLib.ThrowOnException", true);
```

The library must check if a consumer has declared the value of the switch and then appropriately act on it.

```
if (!AppContext.TryGetSwitch("Switch.AmazingLib.ThrowOnException", out shouldThrow))
{
    // This is the case where the switch value was not set by the application.
    // The library can choose to get the value of shouldThrow by other means.
    // If no overrides nor default values are specified, the value should be 'false'.
    // A false value implies the latest behavior.
}

// The library can use the value of shouldThrow to throw exceptions or not.
if (shouldThrow)
{
    // old code
}
else {
    // new code
}
```

It's beneficial to use a consistent format for switches, since they are a formal contract exposed by a library. The following are two obvious formats.

- `Switch.namespace.switchname`
- `Switch.library.switchname`

- **Changes to the task-based asynchronous pattern (TAP)**

For apps that target the .NET Framework 4.6, [Task](#) and [Task<TResult>](#) objects inherit the culture and UI culture of the calling thread. The behavior of apps that target previous versions of the .NET Framework, or that do not target a specific version of the .NET Framework, is unaffected. For more information, see the "Culture and task-based asynchronous operations" section of the [CultureInfo](#) class topic.

The [System.Threading.AsyncLocal<T>](#) class allows you to represent ambient data that is local to a given asynchronous control flow, such as an `async` method. It can be used to persist data across threads. You can also define a callback method that is notified whenever the ambient data changes either because the [AsyncLocal<T>.Value](#) property was explicitly changed, or because the thread encountered a context transition.

Three convenience methods, [Task.CompletedTask](#), [Task.FromCanceled](#), and [Task.FromException](#), have been added to the task-based asynchronous pattern (TAP) to return completed tasks in a particular state.

The [NamedPipeClientStream](#) class now supports asynchronous communication with its new [ConnectAsync](#) method.

- **EventSource now supports writing to the Event log**

You now can use the [EventSource](#) class to log administrative or operational messages to the event log, in addition to any existing ETW sessions created on the machine. In the past, you had to use the [Microsoft.Diagnostics.Tracing.EventSource](#) NuGet package for this functionality. This functionality is now built-into the .NET Framework 4.6.

Both the NuGet package and the .NET Framework 4.6 have been updated with the following features:

- **Dynamic events**

Allows events defined "on the fly" without creating event methods.

- **Rich payloads**

Allows specially attributed classes and arrays as well as primitive types to be passed as a payload

- **Activity tracking**

Causes Start and Stop events to tag events between them with an ID that represents all currently active activities.

To support these features, the overloaded [Write](#) method has been added to the [EventSource](#) class.

- **Windows Presentation Foundation (WPF)**

- **HDPI improvements**

HDPI support in WPF is now better in the .NET Framework 4.6. Changes have been made to layout rounding to reduce instances of clipping in controls with borders. By default, this feature is enabled only if your [TargetFrameworkAttribute](#) is set to .NET 4.6. Applications that target earlier versions of the framework but are running on the .NET Framework 4.6 can opt in to the new behavior by adding the following line to the `<runtime>` section of the app.config file:

```
<AppContextSwitchOverrides  
value="Switch.MS.Internal.DoNotApplyLayoutRoundingToMarginsAndBorderThickness=false"  
/>
```

WPF windows straddling multiple monitors with different DPI settings (Multi-DPI setup) are now completely rendered without blacked-out regions. You can opt out of this behavior by adding the following line to the `<appSettings>` section of the app.config file to disable this new behavior:

```
<add key="EnableMultiMonitorDisplayClipping" value="true"/>
```

Support for automatically loading the right cursor based on DPI setting has been added to [System.Windows.Input.Cursor](#).

- **Touch is better**

Customer reports on [Connect](#) that touch produces unpredictable behavior have been addressed in the .NET Framework 4.6. The double tap threshold for Windows Store applications and WPF applications is now the same in Windows 8.1 and above.

- **Transparent child window support**

WPF in the .NET Framework 4.6 supports transparent child windows in Windows 8.1 and above. This allows you to create non-rectangular and transparent child windows in your top-level windows. You can enable this feature by setting the [HwndSourceParameters.UsesPerPixelTransparency](#) property to `true`.

- **Windows Communication Foundation (WCF)**

- **SSL support**

WCF now supports SSL version TLS 1.1 and TLS 1.2, in addition to SSL 3.0 and TLS 1.0, when using NetTcp with transport security and client authentication. It is now possible to select which protocol to use, or to disable old lesser secure protocols. This can be done either by setting the [SslProtocols](#) property or by adding the following to a configuration file.

```
<netTcpBinding>  
  <binding>  
    <security mode= "None|Transport|Message|TransportWithMessageCredential" >  
      <transport clientCredentialType="None|Windows|Certificate"  
        protectionLevel="None|Sign|EncryptAndSign"  
        sslProtocols="Ssl3|Tls1|Tls11|Tls12">  
        </transport>  
      </security>  
    </binding>  
  </netTcpBinding>
```

- **Sending messages using different HTTP connections**

WCF now allows users to ensure certain messages are sent using different underlying HTTP connections. There are two ways to do this:

- **Using a connection group name prefix**

Users can specify a string that WCF will use as a prefix for the connection group name. Two messages with different prefixes are sent using different underlying HTTP connections. You set the prefix by adding a key/value pair to the message's [Message.Properties](#) property. The key is "HttpTransportConnectionGroupNamePrefix"; the value is the desired prefix.

- **Using different channel factories**

Users can also enable a feature that ensures that messages sent using channels created by different channel factories will use different underlying HTTP connections. To enable this feature, users must set the following `appSetting` to `true`:

```
<appSettings>
  <add key="wcf:httpTransportBinding:useUniqueConnectionPoolPerFactory" value="true" />
</appSettings>
```

• Windows Workflow Foundation (WWF)

You can now specify the number of seconds a workflow service will hold on to an out-of-order operation request when there is an outstanding "non-protocol" bookmark before timing out the request. A "non-protocol" bookmark is a bookmark that is not related to outstanding Receive activities. Some activities create non-protocol bookmarks within their implementation, so it may not be obvious that a non-protocol bookmark exists. These include State and Pick. So if you have a workflow service implemented with a state machine or containing a Pick activity, you will most likely have non-protocol bookmarks. You specify the interval by adding a line like the following to the `appSettings` section of your app.config file:

```
<add key="microsoft:WorkflowServices:FilterResumeTimeoutInSeconds" value="60"/>
```

The default value is 60 seconds. If `value` is set to 0, out-of-order requests are immediately rejected with a fault with text that looks like this:

```
Operation 'Request3|{http://tempuri.org/}IService' on service instance with identifier '2b0667b6-09c8-4093-9d02-f6c67d534292' cannot be performed at this time. Please ensure that the operations are performed in the correct order and that the binding in use provides ordered delivery guarantees.
```

This is the same message that you receive if an out-of-order operation message is received and there are no non-protocol bookmarks.

If the value of the `FilterResumeTimeoutInSeconds` element is non-zero, there are non-protocol bookmarks, and the timeout interval expires, the operation fails with a timeout message.

• Transactions

You can now include the distributed transaction identifier for the transaction that has caused an exception derived from `TransactionException` to be thrown. You do this by adding the following key to the `appSettings` section of your app.config file:

```
<add key="Transactions:IncludeDistributedTransactionIdInExceptionMessage" value="true"/>
```

The default value is `false`.

• Networking

○ Socket reuse

Windows 10 includes a new high-scalability networking algorithm that makes better use of machine resources by reusing local ports for outbound TCP connections. The .NET Framework 4.6 supports the new algorithm, enabling .NET apps to take advantage of the new behavior. In previous versions of Windows, there was an artificial concurrent connection limit (typically 16,384, the default size of the dynamic port range), which could limit the scalability of a service by causing port exhaustion when under load.

In the .NET Framework 4.6, two new APIs have been added to enable port reuse, which effectively removes the 64K limit on concurrent connections:

- The `System.Net.Sockets.SocketOptionName` enumeration value.
- The `ServicePointManager.ReusePort` property.

By default, the `ServicePointManager.ReusePort` property is `false` unless the `HWRPortReuseOnSocketBind` value of the `HKEY_LOCAL_MACHINE\Software\Microsoft\NETFramework\v4.0.30319` registry key is set to 0x1. To enable local port reuse on HTTP connections, set the `ServicePointManager.ReusePort` property to `true`. This causes all outgoing TCP socket connections from `HttpClient` and `HttpWebRequest` to use a new Windows 10 socket option, `SO_REUSE_UNICASTPORT`, that enables local port reuse.

Developers writing a sockets-only application can specify the `System.Net.Sockets.SocketOptionName` option when calling a method such as `Socket.SetSocketOption` so that outbound sockets reuse local ports during binding.

○ Support for international domain names and PunyCode

A new property, `IdnHost`, has been added to the `Uri` class to better support international domain names and PunyCode.

• Resizing in Windows Forms controls.

This feature has been expanded in .NET Framework 4.6 to include the `DomainUpDown`, `NumericUpDown`, `DataGridViewComboBoxColumn`, `DataGridViewColumn` and `ToolStripSplitButton` types and the rectangle specified by the `Bounds` property used when drawing a `UITypeEditor`.

This is an opt-in feature. To enable it, set the `EnableWindowsFormsHighDpiAutoResizing` element to `true` in the application configuration (app.config) file:

```
<appSettings>
  <add key="EnableWindowsFormsHighDpiAutoResizing" value="true" />
</appSettings>
```

- **Support for code page encodings**

.NET Core primarily supports the Unicode encodings and by default provides limited support for code page encodings. You can add support for code page encodings available in the .NET Framework but unsupported in .NET Core by registering code page encodings with the [Encoding.RegisterProvider](#) method. For more information, see [System.Text.CodePagesEncodingProvider](#).

- **.NET Native**

Windows apps for Windows 10 that target .NET Core and are written in C# or Visual Basic can take advantage of a new technology that compiles apps to native code rather than IL. They produce apps characterized by faster startup and execution times. For more information, see [Compiling Apps with .NET Native](#). For an overview of .NET Native that examines how it differs from both JIT compilation and NGEN and what that means for your code, see [.NET Native and Compilation](#).

Your apps are compiled to native code by default when you compile them with Visual Studio 2015 or later. For more information, see [Getting Started with .NET Native](#).

To support debugging .NET Native apps, a number of new interfaces and enumerations have been added to the unmanaged debugging API. For more information, see the [Debugging \(Unmanaged API Reference\)](#) topic.

- **Open-source .NET Framework packages**

.NET Core packages such as the immutable collections, [SIMD APIs](#), and networking APIs such as those found in the [System.Net.Http](#) namespace are now available as open source packages on [GitHub](#). To access the code, see [CoreFx on GitHub](#). For more information and how to contribute to these packages, see [.NET Core and Open-Source](#), [.NET Home Page on GitHub](#).

What's new in the .NET Framework 4.5.2

- **New APIs for ASP.NET apps.** The new [HttpResponse.AddOnSendingHeaders](#) and [HttpResponseBase.AddOnSendingHeaders](#) methods let you inspect and modify response headers and status code as the response is being flushed to the client app. Consider using these methods instead of the [PreSendRequestHeaders](#) and [PreSendRequestContent](#) events; they are more efficient and reliable.

The [HostingEnvironment.QueueBackgroundWorkItem](#) method lets you schedule small background work items. ASP.NET tracks these items and prevents IIS from abruptly terminating the worker process until all background work items have completed. This method can't be called outside an ASP.NET managed app domain.

The new [HttpResponse.HeadersWritten](#) and [HttpResponseBase.HeadersWritten](#) properties return Boolean values that indicate whether the response headers have been written. You can use these properties to make sure that calls to APIs such as [HttpResponse.StatusCode](#) (which throw exceptions if the headers have been written) will succeed.

- **Resizing in Windows Forms controls.** This feature has been expanded. You can now use the system DPI setting to resize components of the following additional controls (for example, the drop-down arrow in combo boxes):

- [ComboBox](#)
- [ToolStripComboBox](#)
- [ToolStripMenuItem](#)
- [Cursor](#)
- [DataGridView](#)
- [DataGridViewComboBoxColumn](#)

This is an opt-in feature. To enable it, set the `<appSettings>` element to `true` in the application configuration (app.config) file:

```
<appSettings>
  <add key="EnableWindowsFormsHighDpiAutoResizing" value="true" />
</appSettings>
```

- **New workflow feature.** A resource manager that's using the [EnlistPromotableSinglePhase](#) method (and therefore implementing the [IPromotableSinglePhaseNotification](#) interface) can use the new [Transaction.PromoteAndEnlistDurable](#) method to request the following:

- Promote the transaction to a Microsoft Distributed Transaction Coordinator (MS DTC) transaction.
- Replace [IPromotableSinglePhaseNotification](#) with an [ISinglePhaseNotification](#), which is a durable enlistment that supports single phase commits.

This can be done within the same app domain, and doesn't require any extra unmanaged code to interact with MSDTC to perform the promotion. The new method can be called only when there's an outstanding call from [System.Transactions](#) to the [IPromotableSinglePhaseNotification Promote](#) method that's implemented by the promotable enlistment.

- **Profiling improvements.** The following new unmanaged profiling APIs provide more robust profiling:

- [COR_PRF_ASSEMBLY_REFERENCE_INFO Structure](#)
- [COR_PRF_HIGH_MONITOR Enumeration](#)
- [GetAssemblyReferences Method](#)
- [GetEventMask2 Method](#)
- [SetEventMask2 Method](#)

- [AddAssemblyReference Method](#)

Previous `ICorProfiler` implementations supported lazy loading of dependent assemblies. The new profiling APIs require dependent assemblies that are injected by the profiler to be loadable immediately, instead of being loaded after the app is fully initialized. This change doesn't affect users of the existing `ICorProfiler` APIs.

- **Debugging improvements.** The following new unmanaged debugging APIs provide better integration with a profiler. You can now access metadata inserted by the profiler as well as local variables and code produced by compiler ReJIT requests when dump debugging.

- [SetWritableDatabaseUpdateMode Method](#)
- [EnumerateLocalVariablesEx Method](#)
- [GetLocalVariableEx Method](#)
- [GetCodeEx Method](#)
- [GetActiveReJitRequestILCode Method](#)
- [GetInstrumentedILMap Method](#)

- **Event tracing changes.** The .NET Framework 4.5.2 enables out-of-process, Event Tracing for Windows (ETW)-based activity tracing for a larger surface area. This enables Advanced Power Management (APM) vendors to provide lightweight tools that accurately track the costs of individual requests and activities that cross threads. These events are raised only when ETW controllers enable them; therefore, the changes don't affect previously written ETW code or code that runs with ETW disabled.

- **Promoting a transaction and converting it to a durable enlistment**

`Transaction.PromoteAndEnlistDurable` is a new API added to the .NET Framework 4.5.2 and 4.6:

```
[System.Security.Permissions.PermissionSetAttribute(System.Security.Permissions.SecurityAction.LinkDemand, Name = "FullTrust")]
public Enlistment PromoteAndEnlistDurable(Guid resourceManagerIdentifier,
                                             IPromotableSinglePhaseNotification promotableNotification,
                                             ISinglePhaseNotification enlistmentNotification,
                                             EnlistmentOptions enlistmentOptions)
```

The method may be used by an enlistment that was previously created by `Transaction.EnlistPromotableSinglePhase` in response to the `ITransactionPromoter.Promote` method. It asks `System.Transactions` to promote the transaction to an MSDTC transaction and to "convert" the promotable enlistment to a durable enlistment. After this method completes successfully, the `IPromotableSinglePhaseNotification` interface will no longer be referenced by `System.Transactions`, and any future notifications will arrive on the provided `ISinglePhaseNotification` interface. The enlistment in question must act as a durable enlistment, supporting transaction logging and recovery. Refer to `Transaction.EnlistDurable` for details. In addition, the enlistment must support `ISinglePhaseNotification`. This method can *only* be called while processing an `ITransactionPromoter.Promote` call. If that is not the case, a `TransactionException` exception is thrown.

What's new in the .NET Framework 4.5.1

April 2014 updates:

- [Visual Studio 2013 Update 2](#) includes updates to the Portable Class Library templates to support these scenarios:
 - You can use Windows Runtime APIs in portable libraries that target Windows 8.1, Windows Phone 8.1, and Windows Phone Silverlight 8.1.
 - You can include XAML (Windows.UI.Xaml types) in portable libraries when you target Windows 8.1 or Windows Phone 8.1. The following XAML templates are supported: Blank Page, Resource Dictionary, Templated Control, and User Control.
 - You can create a portable Windows Runtime component (.winmd file) for use in Store apps that target Windows 8.1 and Windows Phone 8.1.
 - You can retarget a Windows Store or Windows Phone Store class library like a Portable Class Library.

For more information about these changes, see [Portable Class Library](#).

- The .NET Framework content set now includes documentation for .NET Native, which is a precompilation technology for building and deploying Windows apps. .NET Native compiles your apps directly to native code, rather than to intermediate language (IL), for better performance. For details, see [Compiling Apps with .NET Native](#).
- The [.NET Framework Reference Source](#) provides a new browsing experience and enhanced functionality. You can now browse through the .NET Framework source code online, [download the reference](#) for offline viewing, and step through the sources (including patches and updates) during debugging. For more information, see the blog entry [A new look for .NET Reference Source](#).

Core new features and enhancements in the .NET Framework 4.5.1 include:

- Automatic binding redirection for assemblies. Starting with Visual Studio 2013, when you compile an app that targets the .NET Framework 4.5.1, binding redirects may be added to the app configuration file if your app or its components reference multiple versions of the same assembly. You can also enable this feature for projects that target older versions of the .NET Framework. For more information, see [How to: Enable and Disable Automatic Binding Redirection](#).
- Ability to collect diagnostics information to help developers improve the performance of server and cloud applications. For more information, see the `WriteEventWithRelatedActivityId` and `WriteEventWithRelatedActivityIdCore` methods in the `EventSource` class.
- Ability to explicitly compact the large object heap (LOH) during garbage collection. For more information, see the

`GCSettings.LargeObjectHeapCompactionMode` property.

- Additional performance improvements such as ASP.NET app suspension, multi-core JIT improvements, and faster app startup after a .NET Framework update. For details, see the [.NET Framework 4.5.1 announcement](#) and the [ASP.NET app suspend](#) blog post.

Improvements to Windows Forms include:

- Resizing in Windows Forms controls. You can use the system DPI setting to resize components of controls (for example, the icons that appear in a property grid) by opting in with an entry in the application configuration file (app.config) for your app. This feature is currently supported in the following Windows Forms controls:
 - [PropertyGrid](#)
 - [TreeView](#)
 - Some aspects of the [DataGridView](#) (see new features in 4.5.2 for additional controls supported)

To enable this feature, add a new `<appSettings>` element to the configuration file (app.config) and set the `EnableWindowsFormsHighDpiAutoResizing` element to `true`:

```
<appSettings>
  <add key="EnableWindowsFormsHighDpiAutoResizing" value="true" />
</appSettings>
```

Improvements when debugging your .NET Framework apps in Visual Studio 2013 include:

- Return values in the Visual Studio debugger. When you debug a managed app in Visual Studio 2013, the Autos window displays return types and values for methods. This information is available for desktop, Windows Store, and Windows Phone apps. For more information, see [Examine return values of method calls](#).
- Edit and Continue for 64-bit apps. Visual Studio 2013 supports the Edit and Continue feature for 64-bit managed apps for desktop, Windows Store, and Windows Phone. The existing limitations remain in effect for both 32-bit and 64-bit apps (see the last section of the [Supported Code Changes \(C#\)](#) article).
- Async-aware debugging. To make it easier to debug asynchronous apps in Visual Studio 2013, the call stack hides the infrastructure code provided by compilers to support asynchronous programming, and also chains in logical parent frames so you can follow logical program execution more clearly. A Tasks window replaces the Parallel Tasks window and displays tasks that relate to a particular breakpoint, and also displays any other tasks that are currently active or scheduled in the app. You can read about this feature in the "Async-aware debugging" section of the [.NET Framework 4.5.1 announcement](#).
- Better exception support for Windows Runtime components. In Windows 8.1, exceptions that arise from Windows Store apps preserve information about the error that caused the exception, even across language boundaries. You can read about this feature in the "Windows Store app development" section of the [.NET Framework 4.5.1 announcement](#).

Starting with Visual Studio 2013, you can use the [Managed Profile Guided Optimization Tool \(Mpg0.exe\)](#) to optimize Windows 8.x Store apps as well as desktop apps.

For new features in ASP.NET 4.5.1, see [ASP.NET and Web Tools for Visual Studio 2013 Release Notes](#).

What's new in the .NET Framework 4.5

Core new features and improvements

- Ability to reduce system restarts by detecting and closing .NET Framework 4 applications during deployment. See [Reducing System Restarts During .NET Framework 4.5 Installations](#).
- Support for arrays that are larger than 2 gigabytes (GB) on 64-bit platforms. This feature can be enabled in the application configuration file. See the `<gcAllowVeryLargeObjects>` element, which also lists other restrictions on object size and array size.
- Better performance through background garbage collection for servers. When you use server garbage collection in the .NET Framework 4.5, background garbage collection is automatically enabled. See the Background Server Garbage Collection section of the [Fundamentals of Garbage Collection](#) topic.
- Background just-in-time (JIT) compilation, which is optionally available on multi-core processors to improve application performance. See [ProfileOptimization](#).
- Ability to limit how long the regular expression engine will attempt to resolve a regular expression before it times out. See the `Regex.MatchTimeout` property.
- Ability to define the default culture for an application domain. See the `CultureInfo` class.
- Console support for Unicode (UTF-16) encoding. See the `Console` class.
- Support for versioning of cultural string ordering and comparison data. See the `SortVersion` class.
- Better performance when retrieving resources. See [Packaging and Deploying Resources](#).
- Zip compression improvements to reduce the size of a compressed file. See the `System.IO.Compression` namespace.
- Ability to customize a reflection context to override default reflection behavior through the `CustomReflectionContext` class.

- Support for the 2008 version of the Internationalized Domain Names in Applications (IDNA) standard when the [System.Globalization.IdnMapping](#) class is used on Windows 8.
- Delegation of string comparison to the operating system, which implements Unicode 6.0, when the .NET Framework is used on Windows 8. When running on other platforms, the .NET Framework includes its own string comparison data, which implements Unicode 5.x. See the [String](#) class and the Remarks section of the [SortVersion](#) class.
- Ability to compute the hash codes for strings on a per application domain basis. See [`<UseRandomizedStringHashAlgorithm>` Element](#).
- Type reflection support split between [Type](#) and [TypeInfo](#) classes. See [Reflection in the .NET Framework for Windows Store Apps](#).

Managed Extensibility Framework (MEF)

In the .NET Framework 4.5, the Managed Extensibility Framework (MEF) provides the following new features:

- Support for generic types.
- Convention-based programming model that enables you to create parts based on naming conventions rather than attributes.
- Multiple scopes.
- A subset of MEF that you can use when you create Windows 8.x Store apps. This subset is available as a [downloadable package](#) from the NuGet Gallery. To install the package, open your project in Visual Studio, choose **Manage NuGet Packages** from the **Project** menu, and search online for the [Microsoft.Composition](#) package.

For more information, see [Managed Extensibility Framework \(MEF\)](#).

Asynchronous file operations

In the .NET Framework 4.5, new asynchronous features were added to the C# and Visual Basic languages. These features add a task-based model for performing asynchronous operations. To use this new model, use the asynchronous methods in the I/O classes. See [Asynchronous File I/O](#).

Tools

In the .NET Framework 4.5, Resource File Generator (Resgen.exe) enables you to create a .resw file for use in Windows 8.x Store apps from a .resources file embedded in a .NET Framework assembly. For more information, see [Resgen.exe \(Resource File Generator\)](#).

Managed Profile Guided Optimization (Mpgc.exe) enables you to improve application startup time, memory utilization (working set size), and throughput by optimizing native image assemblies. The command-line tool generates profile data for native image application assemblies. See [Mpgc.exe \(Managed Profile Guided Optimization Tool\)](#). Starting with Visual Studio 2013, you can use Mpgc.exe to optimize Windows 8.x Store apps as well as desktop apps.

Parallel computing

The .NET Framework 4.5 provides several new features and improvements for parallel computing. These include improved performance, increased control, improved support for asynchronous programming, a new dataflow library, and improved support for parallel debugging and performance analysis. See the entry [What's New for Parallelism in .NET 4.5](#) in the Parallel Programming with .NET blog.

Web

ASP.NET 4.5 and 4.5.1 add model binding for Web Forms, WebSocket support, asynchronous handlers, performance enhancements, and many other features. For more information, see the following resources:

- [ASP.NET 4.5 and Visual Studio 2012](#)
- [ASP.NET and Web Tools for Visual Studio 2013 Release Notes](#)

Networking

The .NET Framework 4.5 provides a new programming interface for HTTP applications. For more information, see the new [System.Net.Http](#) and [System.Net.Http.Headers](#) namespaces.

Support is also included for a new programming interface for accepting and interacting with a WebSocket connection by using the existing [HttpListener](#) and related classes. For more information, see the new [System.Net.WebSockets](#) namespace and the [HttpListener](#) class.

In addition, the .NET Framework 4.5 includes the following networking improvements:

- RFC-compliant URI support. For more information, see [Uri](#) and related classes.
- Support for Internationalized Domain Name (IDN) parsing. For more information, see [Uri](#) and related classes.
- Support for Email Address Internationalization (EAI). For more information, see the [System.Net.Mail](#) namespace.
- Improved IPv6 support. For more information, see the [System.Net.NetworkInformation](#) namespace.
- Dual-mode socket support. For more information, see the [Socket](#) and [TcpListener](#) classes.

Windows Presentation Foundation (WPF)

In the .NET Framework 4.5, Windows Presentation Foundation (WPF) contains changes and improvements in the following areas:

- The new [Ribbon](#) control, which enables you to implement a ribbon user interface that hosts a Quick Access Toolbar, Application Menu, and tabs.
- The new [INotifyDataErrorInfo](#) interface, which supports synchronous and asynchronous data validation.
- New features for the [VirtualizingPanel](#) and [Dispatcher](#) classes.

- Improved performance when displaying large sets of grouped data, and by accessing collections on non-UI threads.
- Data binding to static properties, data binding to custom types that implement the [ICustomTypeProvider](#) interface, and retrieval of data binding information from a binding expression.
- Repositioning of data as the values change (live shaping).
- Ability to check whether the data context for an item container is disconnected.
- Ability to set the amount of time that should elapse between property changes and data source updates.
- Improved support for implementing weak event patterns. Also, events can now accept markup extensions.

Windows Communication Foundation (WCF)

In the .NET Framework 4.5, the following features have been added to make it simpler to write and maintain Windows Communication Foundation (WCF) applications:

- Simplification of generated configuration files.
- Support for contract-first development.
- Ability to configure ASP.NET compatibility mode more easily.
- Changes in default transport property values to reduce the likelihood that you will have to set them.
- Updates to the [XmlDictionaryReaderQuotas](#) class to reduce the likelihood that you will have to manually configure quotas for XML dictionary readers.
- Validation of WCF configuration files by Visual Studio as part of the build process, so you can detect configuration errors before you run your application.
- New asynchronous streaming support.
- New HTTPS protocol mapping to make it easier to expose an endpoint over HTTPS with Internet Information Services (IIS).
- Ability to generate metadata in a single WSDL document by appending `?singleWSDL` to the service URL.
- Websockets support to enable true bidirectional communication over ports 80 and 443 with performance characteristics similar to the TCP transport.
- Support for configuring services in code.
- XML Editor tooltips.
- [ChannelFactory](#) caching support.
- Binary encoder compression support.
- Support for a UDP transport that enables developers to write services that use "fire and forget" messaging. A client sends a message to a service and expects no response from the service.
- Ability to support multiple authentication modes on a single WCF endpoint when using the HTTP transport and transport security.
- Support for WCF services that use internationalized domain names (IDNs).

For more information, see [What's New in Windows Communication Foundation](#).

Windows Workflow Foundation (WF)

In the .NET Framework 4.5, several new features were added to Windows Workflow Foundation (WF), including:

- State machine workflows, which were first introduced as part of the .NET Framework 4.0.1 ([.NET Framework 4 Platform Update 1](#)). This update included several new classes and activities that enabled developers to create state machine workflows. These classes and activities were updated for the .NET Framework 4.5 to include:
 - The ability to set breakpoints on states.
 - The ability to copy and paste transitions in the workflow designer.
 - Designer support for shared trigger transition creation.
 - Activities for creating state machine workflows, including: [StateMachine](#), [State](#), and [Transition](#).
- Enhanced Workflow Designer features such as the following:
 - Enhanced workflow search capabilities in Visual Studio, including **Quick Find** and **Find in Files**.
 - Ability to automatically create a Sequence activity when a second child activity is added to a container activity, and to include both activities in the Sequence activity.
 - Panning support, which enables the visible portion of a workflow to be changed without using the scroll bars.
 - A new **Document Outline** view that shows the components of a workflow in a tree-style outline view and lets you select a component in the **Document Outline** view.

- Ability to add annotations to activities.
- Ability to define and consume activity delegates by using the workflow designer.
- Auto-connect and auto-insert for activities and transitions in state machine and flowchart workflows.
- Storage of the view state information for a workflow in a single element in the XAML file, so you can easily locate and edit the view state information.
- A NoPersistScope container activity to prevent child activities from persisting.
- Support for C# expressions:
 - Workflow projects that use Visual Basic will use Visual Basic expressions, and C# workflow projects will use C# expressions.
 - C# workflow projects that were created in Visual Studio 2010 and that have Visual Basic expressions are compatible with C# workflow projects that use C# expressions.
- Versioning enhancements:
 - The new [WorkflowIdentity](#) class, which provides a mapping between a persisted workflow instance and its workflow definition.
 - Side-by-side execution of multiple workflow versions in the same host, including [WorkflowServiceHost](#).
 - In Dynamic Update, the ability to modify the definition of a persisted workflow instance.
- Contract-first workflow service development, which provides support for automatically generating activities to match an existing service contract.

For more information, see [What's New in Windows Workflow Foundation](#).

.NET for Windows 8.x Store apps

Windows 8.x Store apps are designed for specific form factors and leverage the power of the Windows operating system. A subset of the .NET Framework 4.5 or 4.5.1 is available for building Windows 8.x Store apps for Windows by using C# or Visual Basic. This subset is called .NET for Windows 8.x Store apps and is discussed in an [overview](#) in the Windows Dev Center.

Portable Class Libraries

The Portable Class Library project in Visual Studio 2012 (and later versions) enables you to write and build managed assemblies that work on multiple .NET Framework platforms. Using a Portable Class Library project, you choose the platforms (such as Windows Phone and .NET for Windows 8.x Store apps) to target. The available types and members in your project are automatically restricted to the common types and members across these platforms. For more information, see [Portable Class Library](#).

Get started with the .NET Framework

2/15/2019 • 6 minutes to read • [Edit Online](#)

The .NET Framework is a runtime execution environment that manages apps that target the .NET Framework. It consists of the common language runtime, which provides memory management and other system services, and an extensive class library, which enables programmers to take advantage of robust, reliable code for all major areas of app development.

NOTE

The .NET Framework is available on Windows systems only. You can use [.NET Core](#) to run apps on Windows, MacOS, and Linux.

What is the .NET Framework?

The .NET Framework is a managed execution environment for Windows that provides a variety of services to its running apps. It consists of two major components: the common language runtime (CLR), which is the execution engine that handles running apps, and the .NET Framework Class Library, which provides a library of tested, reusable code that developers can call from their own apps. The services that the .NET Framework provides to running apps include the following:

- Memory management. In many programming languages, programmers are responsible for allocating and releasing memory and for handling object lifetimes. In .NET Framework apps, the CLR provides these services on behalf of the app.
- A common type system. In traditional programming languages, basic types are defined by the compiler, which complicates cross-language interoperability. In the .NET Framework, basic types are defined by the .NET Framework type system and are common to all languages that target the .NET Framework.
- An extensive class library. Instead of having to write vast amounts of code to handle common low-level programming operations, programmers use a readily accessible library of types and their members from the .NET Framework Class Library.
- Development frameworks and technologies. The .NET Framework includes libraries for specific areas of app development, such as ASP.NET for web apps, ADO.NET for data access, Windows Communication Foundation for service-oriented apps, and Windows Presentation Foundation for Windows desktop apps.
- Language interoperability. Language compilers that target the .NET Framework emit an intermediate code named Common Intermediate Language (CIL), which, in turn, is compiled at runtime by the common language runtime. With this feature, routines written in one language are accessible to other languages, and programmers focus on creating apps in their preferred languages.
- Version compatibility. With rare exceptions, apps that are developed by using a particular version of the .NET Framework run without modification on a later version.
- Side-by-side execution. The .NET Framework helps resolve version conflicts by allowing multiple versions of the common language runtime to exist on the same computer. This means that multiple versions of apps can coexist and that an app can run on the version of the .NET Framework with which it was built. Side-by-side execution applies to the .NET Framework version groups 1.0/1.1, 2.0/3.0/3.5, and 4/4.5.x/4.6.x/4.7.x.
- Multitargeting. By targeting [.NET Standard](#), developers create class libraries that work on multiple .NET Framework platforms supported by that version of the standard. For example, libraries that target the .NET

Standard 2.0 can be used by apps that target the .NET Framework 4.6.1, .NET Core 2.0, and UWP 10.0.16299.

The .NET Framework for users

If you don't develop .NET Framework apps, but you use them, you aren't required to have specific knowledge about the .NET Framework or its operation. For the most part, the .NET Framework is completely transparent to users.

If you're using the Windows operating system, the .NET Framework may already be installed on your computer. In addition, if you install an app that requires the .NET Framework, the app's setup program might install a specific version of the .NET Framework on your computer. In some cases, you may see a dialog box that asks you to install the .NET Framework. If you've just tried to run an app when this dialog box appears and if your computer has Internet access, you can go to a webpage that lets you install the missing version of the .NET Framework. For more information, see the [Installation guide](#).

In general, you shouldn't uninstall versions of the .NET Framework that are installed on your computer. There are two reasons for this:

- If an app that you use depends on a specific version of the .NET Framework, that app may break if that version is removed.
- Some versions of the .NET Framework are in-place updates to earlier versions. For example, the .NET Framework 3.5 is an in-place update to version 2.0, and the .NET Framework 4.7.2 is an in-place update to versions 4 through 4.7.1. For more information, see [.NET Framework Versions and Dependencies](#).

On Windows versions before Windows 8, if you do choose to remove the .NET Framework, always use **Programs and Features** from Control Panel to uninstall it. Never remove a version of the .NET Framework manually. On Windows 8 and above, the .NET Framework is an operating system component and cannot be independently uninstalled.

Note that multiple versions of the .NET Framework can coexist on a single computer at the same time. This means that you don't have to uninstall previous versions in order to install a later version.

The .NET Framework for developers

If you're a developer, choose any programming language that supports the .NET Framework to create your apps. Because the .NET Framework provides language independence and interoperability, you interact with other .NET Framework apps and components regardless of the language with which they were developed.

To develop .NET Framework apps or components, do the following:

1. If it's not preinstalled on your operating system, install the version of the .NET Framework that your app will target. The most recent production version is the .NET Framework 4.7.2. It is preinstalled on Windows 10 April 2018 Update and Windows 10 October 2018 Update, and it is available for download on earlier versions of the Windows operating system. For .NET Framework system requirements, see [System Requirements](#). For information on installing other versions of the .NET Framework, see [Installation Guide](#). Additional .NET Framework packages are released out of band, which means that they're released on a rolling basis outside of any regular or scheduled release cycle. For information about these packages, see [The .NET Framework and Out-of-Band Releases](#).
2. Select the language or languages supported by the .NET Framework that you intend to use to develop your apps. A number of languages are available, including [Visual Basic](#), [C#](#), [F#](#), and [C++/CLI](#) from Microsoft. (A programming language that allows you to develop apps for the .NET Framework adheres to the [Common Language Infrastructure \(CLI\) specification](#).)
3. Select and install the development environment to use to create your apps and that supports your selected

programming language or languages. The Microsoft integrated development environment (IDE) for .NET Framework apps is [Visual Studio](#). It's available in a number of editions.

For more information on developing apps that target the .NET Framework, see the [Development Guide](#).

Migration Guide to the .NET Framework 4.7, 4.6, and 4.5

1/11/2019 • 2 minutes to read • [Edit Online](#)

If you created your app using an earlier version of the .NET Framework, you can generally upgrade it to the .NET Framework 4.5 and its point releases (4.5.1 and 4.5.2), the .NET Framework 4.6 and its point releases (4.6.1 and 4.6.2), or the .NET Framework 4.7 and its point releases (4.7.1 and 4.7.2) easily. Open your project in Visual Studio.

If your project was created in an earlier version of Visual Studio, the **Project Compatibility** dialog box automatically opens. For more information about upgrading a project in Visual Studio, see [Port, Migrate, and Upgrade Visual Studio Projects](#) and [Visual Studio 2017 Platform Targeting and Compatibility](#).

However, some changes in the .NET Framework require changes to your code. You may also want to take advantage of functionality that is new in the .NET Framework 4.5 and its point releases, in the .NET Framework 4.6 and its point releases, or in the .NET Framework 4.7 and its point releases. Making these types of changes to your app for a new version of the .NET Framework is typically referred to as *migration*. If your app doesn't have to be migrated, you can run it in the .NET Framework 4.5 or a later version without recompiling it.

Migration resources

Review the following documents before you migrate your app from earlier versions of the .NET Framework to version 4.5, 4.5.1, 4.5.2, 4.6, 4.6.1, 4.6.2, 4.7, 4.7.1, or 4.7.2:

- See [Versions and Dependencies](#) to understand the CLR version underlying each version of the .NET Framework and to review guidelines for targeting your apps successfully.
- Review [Application Compatibility](#) to find out about runtime and retargeting changes that might affect your app and how to handle them.
- Review [What's Obsolete in the Class Library](#) to determine any types or members in your code that have been made obsolete, and the recommended alternatives.
- See [What's New](#) for descriptions of new features that you may want to add to your app.

Deploying .NET Framework applications with Docker

12/22/2018 • 2 minutes to read • [Edit Online](#)

You can deploy .NET Framework application with Docker, using Windows Containers. You can learn the requirements for using [Windows Containers](#) and how to [Get Started with Docker for Windows](#).

You can begin by [running a console application with Docker](#). For running web applications in Docker, you can read [ASP.NET MVC applications in Docker](#).

Running console applications in Windows containers

3/16/2019 • 5 minutes to read • [Edit Online](#)

Console applications are used for many purposes; from simple querying of a status to long running document image processing tasks. In any case, the ability to start up and scale these applications are met with limitations of hardware acquisitions, startup times or running multiple instances.

Moving your console applications to use Docker and Windows Server containers allows for starting these applications from a clean state, enabling them to perform the operation and then shutdown cleanly. This topic will show the steps needed to move a console application to a Windows based container and start it using a PowerShell script.

The sample console application is a simple example which takes an argument, a question in this case, and returns a random answer. This could take a `customer_id` and process their taxes, or create a thumbnail for an `image_url` argument.

In addition to the answer, the `Environment.MachineName` has been added to the response to show the difference between running the application locally and in a Windows container. When running the application locally, your local machine name should be returned and when running in a Windows Container; the container session id is returned.

The [complete example](#) is available in the dotnet/samples repository on GitHub. For download instructions, see [Samples and Tutorials](#).

You need to be familiar with some Docker terms before you begin working on moving your application to a container.

A *Docker image* is a read-only template that defines the environment for a running container, including the operating system (OS), system components, and application(s).

One important feature of Docker images is that images are composed from a base image. Each new image adds a small set of features to an existing image.

A *Docker container* is a running instance of an image.

You scale an application by running the same image in many containers. Conceptually, this is similar to running the same application in multiple hosts.

You can learn more about the Docker architecture by reading the [Docker Overview](#) on the Docker site.

Moving your console application is a matter of a few steps.

1. [Build the application](#)
2. [Creating a Dockerfile for the image](#)
3. [Process to build and run the Docker container](#)

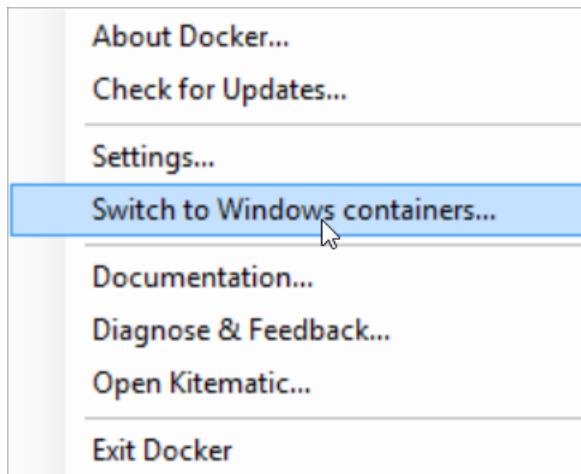

Prerequisites

Windows containers are supported on [Windows 10 Anniversary Update](#) or [Windows Server 2016](#).

NOTE

If you are using Windows Server 2016, you must enable containers manually since the Docker for Windows installer will not enable the feature. Make sure all updates have run for the OS and then follow the instructions from the [Container Host Deployment](#) article to install the containers and Docker features.

You need to have Docker for Windows, version 1.12 Beta 26 or higher to support Windows containers. By default, Docker enables Linux based containers; switch to Windows containers by right clicking the Docker icon in the system tray and select **Switch to Windows containers**. Docker will run the process to change and a restart may be required.

Building the application

Typically console applications are distributed through an installer, FTP, or File Share deployment. When deploying to a container, the assets need to be compiled and staged to a location that can be used when the Docker image is created.

In *build.ps1*, the script uses [MSBuild](#) to compile the application to complete the task of building the assets. There are a few parameters passed to MSBuild to finalize the needed assets. The name of the project file or solution to be compiled, the location for the output and finally the configuration (Release or Debug).

In the call to `Invoke-MSBuild` the `OutputPath` is set to **publish** and `Configuration` set to **Release**.

```
function Invoke-MSBuild ([string]$MSBuildPath, [string]$MSBuildParameters) {
    Invoke-Expression "$MSBuildPath $MSBuildParameters"
}

Invoke-MSBuild -MSBuildPath "MSBuild.exe" -MSBuildParameters ".\ConsoleRandomAnswerGenerator.csproj" -p:OutputPath=.\\publish -p:Configuration=Release"
```

Creating the Dockerfile

The base image used for a console .NET Framework application is `microsoft/windowsservercore`, publicly available on [Docker Hub](#). The base image contains a minimal installation of Windows Server 2016, .NET Framework 4.6.2 and serves as the base OS image for Windows Containers.

```
FROM microsoft/windowsservercore
ADD publish/
ENTRYPOINT ConsoleRandomAnswerGenerator.exe
```

The first line in the Dockerfile designates the base image using the `FROM` instruction. Next, `ADD` in the file copies the application assets from the **publish** folder to root folder of the container and last; setting the `ENTRYPOINT` of the image states that this is the command or application that will run when the container starts.

Creating the image

In order to create the Docker image, the following code is added to the `build.ps1` script. When the script is run, the `console-random-answer-generator` image is created using the assets compiled from MSBuild defined in the [Building the application](#) section.

```
$ImageName="console-random-answer-generator"

function Invoke-Docker-Build ([string]$ImageName, [string]$ImagePath, [string]$DockerBuildArgs = "") {
    echo "docker build -t $ImageName $ImagePath $DockerBuildArgs"
    Invoke-Expression "docker build -t $ImageName $ImagePath $DockerBuildArgs"
}

Invoke-Docker-Build -ImageName $ImageName -ImagePath ".."
```

Run the script using `.\build.ps1` from the PowerShell command prompt.

When the build is complete, using the `docker images` command from a command line or PowerShell prompt; you'll see that the image is created and ready to be run.

REPOSITORY	TAG	IMAGE ID	CREATED	SIZE
console-random-answer-generator	latest	8f7c807db1b5	8 seconds ago	7.33 GB

Running the container

You can start the container from the command line using the Docker commands.

```
docker run console-random-answer-generator "Are you a square container?"
```

The output is

```
The answer to your question: 'Are you a square container?' is Concentrate and ask again on (70C3D48F4343)
```

If you run the `docker ps -a` command from PowerShell, you can see that the container still exists.

CONTAINER ID	IMAGE	COMMAND	CREATED	STATUS
70c3d48f4343	console-random-answer-generator	"cmd /S /C ConsoleRan"	2 minutes ago	Exited (0)

The STATUS column shows at "About a minute ago", the application was complete and could be shut down. If the command was run a hundred times, there would be a hundred containers left static with no work to do. In the beginning scenario the ideal operation was to do the work and shutdown or cleanup. To accomplish that workflow, adding the `--rm` option to the `docker run` command will remove the container as soon as the `Exited` signal is received.

```
docker run --rm console-random-answer-generator "Are you a square container?"
```

Running the command with this option and then looking at the output of `docker ps -a` command; notice that the container id (the `Environment.MachineName`) is not in the list.

Running the container using PowerShell

In the sample project files there is also a `run.ps1` which is an example of how to use PowerShell to run the application accepting the arguments.

To run, open PowerShell and use the following command:

```
.\run.ps1 "Is this easy or what?"
```

Summary

Just by adding a Dockerfile and publishing the application, you can containerize your .NET Framework console applications and now take the advantage of running multiple instances, clean start and stop and more Windows Server 2016 capabilities without making any changes to the application code at all.

.NET Framework Development Guide

2/12/2019 • 2 minutes to read • [Edit Online](#)

This section explains how to create, configure, debug, secure, and deploy your .NET Framework apps. The section also provides information about technology areas such as dynamic programming, interoperability, extensibility, memory management, and threading.

In This Section

[Application Essentials](#)

Provides information about basic app development tasks, such as programming with app domains and assemblies, using attributes, formatting and parsing base types, using collections, handling events and exceptions, using files and data streams, and using generics.

[Data and Modeling](#)

Provides information about how to access data using ADO.NET, Language Integrated Query (LINQ), WCF Data Services, and XML.

[Client Applications](#)

Explains how to create Windows-based apps by using Windows Presentation Foundation (WPF) or Windows Forms.

[Web Applications with ASP.NET](#)

Provides links to information about using ASP.NET to build enterprise-class web apps with a minimum of coding.

[Service-Oriented Applications with WCF](#)

Describes how to use Windows Communication Foundation (WCF) to build service-oriented apps that are secure and reliable.

[Building workflows with Windows Workflow Foundation](#)

Provides information about the programming model, samples, and tools for using Windows Workflow Foundation (WF).

[Windows Service Applications](#)

Explains how you can use Visual Studio and the .NET Framework to create an app that is installed as a service, and start, stop, and otherwise control its behavior.

[Parallel Processing, Concurrency, and Async Programming in .NET](#)

Provides information about managed threading, parallel programming, and asynchronous programming design patterns.

[Network Programming in the .NET Framework](#)

Describes the layered, extensible, and managed implementation of Internet services that you can quickly and easily integrate into your apps.

[Configuring .NET Framework Apps](#)

Explains how you can use configuration files to change settings without having to recompile your .NET Framework apps.

[Compiling Apps with .NET Native](#)

Explains how you can use the .NET Native precompilation technology to build and deploy Windows Store apps. .NET Native compiles apps that are written in managed code (C#) and that target the .NET Framework to native

code.

[Security](#)

Provides information about the classes and services in the .NET Framework that facilitate secure app development.

[Debugging, Tracing, and Profiling](#)

Explains how to test, optimize, and profile .NET Framework apps and the app environment. This section includes information for administrators as well as developers.

[Developing for Multiple Platforms](#)

Provides information about how you can use the .NET Framework to build assemblies that can be shared across multiple platforms and multiple devices such as phones, desktop, and web.

[Deployment](#)

Explains how to package and distribute your .NET Framework app, and includes deployment guides for both developers and administrators.

[Performance](#)

Provides information about caching, lazy initialization, reliability, and ETW events.

Reference

[.NET Framework Class Library](#)

Supplies syntax, code examples, and usage information for each class that is contained in the .NET Framework namespaces.

Related Sections

[Getting Started](#)

Provides a comprehensive overview of the .NET Framework and links to additional resources.

[What's New](#)

Describes key new features and changes in the latest version of the .NET Framework. Includes lists of new and obsolete types and members, and provides a guide for migrating your apps from the previous version of the .NET Framework.

[Tools](#)

Describes the tools that help you develop, configure, and deploy apps by using .NET Framework technologies.

[.NET samples and tutorials](#)

Provides links to samples and tutorials that help you learn about .NET.

Programming with Application Domains and Assemblies

5/2/2018 • 2 minutes to read • [Edit Online](#)

Hosts such as Microsoft Internet Explorer, ASP.NET, and the Windows shell load the common language runtime into a process, create an [application domain](#) in that process, and then load and execute user code in that application domain when running a .NET Framework application. In most cases, you do not have to worry about creating application domains and loading assemblies into them because the runtime host performs those tasks.

However, if you are creating an application that will host the common language runtime, creating tools or code you want to unload programmatically, or creating pluggable components that can be unloaded and reloaded on the fly, you will be creating your own application domains. Even if you are not creating a runtime host, this section provides important information on how to work with application domains and assemblies loaded in these application domains.

In This Section

[Application Domains and Assemblies How-to Topics](#)

Provides links to all How-to topics found in the conceptual documentation for programming with application domains and assemblies.

[Using Application Domains](#)

Provides examples of creating, configuring, and using application domains.

[Programming with Assemblies](#)

Describes how to create, sign, and set attributes on assemblies.

Related Sections

[Emitting Dynamic Methods and Assemblies](#)

Describes how to create dynamic assemblies.

[Assemblies in the Common Language Runtime](#)

Provides a conceptual overview of assemblies.

[Reflection Overview](#)

Describes how to use the **Reflection** class to obtain information about an assembly.

Resources in .NET Apps

3/1/2019 • 3 minutes to read • [Edit Online](#)

Nearly every production-quality app has to use resources. A resource is any nonexecutable data that is logically deployed with an app. A resource might be displayed in an app as error messages or as part of the user interface. Resources can contain data in a number of forms, including strings, images, and persisted objects. (To write persisted objects to a resource file, the objects must be serializable.) Storing your data in a resource file enables you to change the data without recompiling your entire app. It also enables you to store data in a single location, and eliminates the need to rely on hard-coded data that is stored in multiple locations.

The .NET Framework and .NET Core provide comprehensive support for the creation and localization of resources. In addition, .NET supports a simple model for packaging and deploying localized resources.

For information about resources in ASP.NET, see [ASP.NET Web Page Resources Overview](#).

Creating and Localizing Resources

In a non-localized app, you can use resource files as a repository for app data, particularly for strings that might otherwise be hard-coded in multiple locations in source code. Most commonly, you create resources as either text (.txt) or XML (.resx) files, and use [Resgen.exe \(Resource File Generator\)](#) to compile them into binary .resources files. These files can then be embedded in the app's executable file by a language compiler. For more information about creating resources, see [Creating Resource Files](#).

You can also localize your app's resources for specific cultures. This enables you to build localized (translated) versions of your apps. When you develop an app that uses localized resources, you designate a culture that serves as the neutral or fallback culture whose resources are used if no suitable resources are available. Typically, the resources of the neutral culture are stored in the app's executable. The remaining resources for individual localized cultures are stored in standalone satellite assemblies. For more information, see [Creating Satellite Assemblies](#).

Packaging and Deploying Resources

You deploy localized app resources in [satellite assemblies](#). A satellite assembly contains the resources of a single culture; it does not contain any app code. In the satellite assembly deployment model, you create an app with one default assembly (which is typically the main assembly) and one satellite assembly for each culture that the app supports. Because the satellite assemblies are not part of the main assembly, you can easily replace or update resources corresponding to a specific culture without replacing the app's main assembly.

Carefully determine which resources will make up your app's default resource assembly. Because it is a part of the main assembly, any changes to it will require you to replace the main assembly. If you do not provide a default resource, an exception will be thrown when the [resource fallback process](#) attempts to find it. In a well-designed app, using resources should never throw an exception.

For more information, see the [Packaging and Deploying Resources](#) article.

Retrieving Resources

At run time, an app loads the appropriate localized resources on a per-thread basis, based on the culture specified by the [CultureInfo.CurrentCulture](#) property. This property value is derived as follows:

- By directly assigning a [CultureInfo](#) object that represents the localized culture to the [Thread.CurrentCulture](#) property.

- If a culture is not explicitly assigned, by retrieving the default thread UI culture from the [CultureInfo.DefaultThreadCurrentUICulture](#) property.
- If a default thread UI culture is not explicitly assigned, by retrieving the culture for the current user on the local computer. .NET implementations running on Windows do this by calling the Windows [GetUserDefaultUILanguage](#) function.

For more information about how the current UI culture is set, see the [CultureInfo](#) and [CultureInfo.CurrentUICulture](#) reference pages.

You can then retrieve resources for the current UI culture or for a specific culture by using the [System.Resources.ResourceManager](#) class. Although the [ResourceManager](#) class is most commonly used for retrieving resources, the [System.Resources](#) namespace contains additional types that you can use to retrieve resources. These include:

- The [ResourceReader](#) class, which enables you to enumerate resources embedded in an assembly or stored in a standalone binary .resources file. It is useful when you don't know the precise names of the resources that are available at run time.
- The [ResXResourceReader](#) class, which enables you to retrieve resources from an XML (.resx) file.
- The [ResourceSet](#) class, which enables you to retrieve the resources of a specific culture without observing fallback rules. The resources can be stored in an assembly or a standalone binary .resources file. You can also develop an [IResourceReader](#) implementation that enables you to use the [ResourceSet](#) class to retrieve resources from some other source.
- The [ResXResourceSet](#) class, which enables you to retrieve all the items in an XML resource file into memory.

Windows Forms

3/9/2019 • 2 minutes to read • [Edit Online](#)

As forms are the base unit of your application, it is essential that you give some thought to their function and design. A form is ultimately a blank slate that you, as a developer, enhance with controls to create a user interface and with code to manipulate data. To that end, Visual Studio provides you with an integrated development environment (IDE) to aid in writing code, as well as a rich control set written with the .NET Framework. By complementing the functionality of these controls with your code, you can easily and quickly develop the solutions you need.

In This Section

[Getting Started with Windows Forms](#)

Develop Windows service apps

2/20/2019 • 2 minutes to read • [Edit Online](#)

Using Visual Studio or the .NET Framework SDK, you can easily create services by creating an application that is installed as a service. This type of application is called a Windows service. With framework features, you can create services, install them, and start, stop, and otherwise control their behavior.

NOTE

In Visual Studio you can create a service in managed code in Visual C# or Visual Basic, which can interoperate with existing C++ code if required. Or, you can create a Windows service in native C++ by using the [ATL Project Wizard](#).

In this section

[Introduction to Windows Service Applications](#)

Provides an overview of Windows service applications, the lifetime of a service, and how service applications differ from other common project types.

[Walkthrough: Creating a Windows Service Application in the Component Designer](#)

Provides an example of creating a service in Visual Basic and Visual C#.

[Service Application Programming Architecture](#)

Explains the language elements used in service programming.

[How to: Create Windows Services](#)

Describes the process of creating and configuring Windows services using the Windows service project template.

Related sections

[Create Projects from Templates](#) - Describes the projects types used in this chapter and how to choose between them.

64-bit Applications

2/3/2019 • 3 minutes to read • [Edit Online](#)

When you compile an application, you can specify that it should run on a Windows 64-bit operating system either as a native application or under WOW64 (Windows 32-bit on Windows 64-bit). WOW64 is a compatibility environment that enables a 32-bit application to run on a 64-bit system. WOW64 is included in all 64-bit versions of the Windows operating system.

Running 32-bit vs. 64-bit Applications on Windows

All applications that are built on the .NET Framework 1.0 or 1.1 are treated as 32-bit applications on a 64-bit operating system and are always executed under WOW64 and the 32-bit common language runtime (CLR). 32-bit applications that are built on the .NET Framework 4 or later versions also run under WOW64 on 64-bit systems.

Visual Studio installs the 32-bit version of the CLR on an x86 computer, and both the 32-bit version and the appropriate 64-bit version of the CLR on a 64-bit Windows computer. (Because Visual Studio is a 32-bit application, when it is installed on a 64-bit system, it runs under WOW64.)

NOTE

Because of the design of x86 emulation and the WOW64 subsystem for the Itanium processor family, applications are restricted to execution on one processor. These factors reduce the performance and scalability of 32-bit .NET Framework applications that run on Itanium-based systems. We recommend that you use the .NET Framework 4, which includes native 64-bit support for Itanium-based systems, for increased performance and scalability.

By default, when you run a 64-bit managed application on a 64-bit Windows operating system, you can create an object of no more than 2 gigabytes (GB). However, in the .NET Framework 4.5, you can increase this limit. For more information, see the [`<gcAllowVeryLargeObjects>`](#) element.

Many assemblies run identically on both the 32-bit CLR and the 64-bit CLR. However, some programs may behave differently, depending on the CLR, if they contain one or more of the following:

- Structures that contain members that change size depending on the platform (for example, any pointer type).
- Pointer arithmetic that includes constant sizes.
- Incorrect platform invoke or COM declarations that use `Int32` for handles instead of `IntPtr`.
- Code that casts `IntPtr` to `Int32`.

For more information about how to port a 32-bit application to run on the 64-bit CLR, see [Migrating 32-bit Managed Code to 64-bit](#).

General 64-Bit Programming Information

For general information about 64-bit programming, see the following documents:

- For more information about the 64-bit version of the CLR on a 64-bit Windows computer, see the [.NET Framework Developer Center](#) on the MSDN website.
- In the Windows SDK documentation, see [Programming Guide for 64-bit Windows](#).

- For information about how to download a 64-bit version of the CLR, see [.NET Framework Developer Center Downloads](#) on the MSDN website.
- For information about Visual Studio support for creating 64-bit applications, see [Visual Studio IDE 64-Bit Support](#).

Compiler Support for Creating 64-Bit Applications

By default, when you use the .NET Framework to build an application on either a 32-bit or a 64-bit computer, the application will run on a 64-bit computer as a native application (that is, not under WOW64). The following table lists documents that explain how to use Visual Studio compilers to create 64-bit applications that will run as native, under WOW64, or both.

COMPILER	COMPILER OPTION
Visual Basic	/platform (Visual Basic)
Visual C#	/platform (C# Compiler Options)
Visual C++	<p>You can create platform-agnostic, Microsoft intermediate language (MSIL) applications by using /clr:safe. For more information, see /clr (Common Language Runtime Compilation).</p> <p>Visual C++ includes a separate compiler for each 64-bit operating system. For more information about how to use Visual C++ to create native applications that run on a 64-bit Windows operating system, see 64-bit Programming.</p>

Determining the Status of an .exe File or .dll File

To determine whether an .exe file or .dll file is meant to run only on a specific platform or under WOW64, use [CorFlags.exe \(CorFlags Conversion Tool\)](#) with no options. You can also use CorFlags.exe to change the platform status of an .exe file or .dll file. The CLR header of a Visual Studio assembly has the major runtime version number set to 2 and the minor runtime version number set to 5. Applications that have the minor runtime version set to 0 are treated as legacy applications and are always executed under WOW64.

To programmatically query an .exe or .dll to see whether it is meant to run only on a specific platform or under WOW64, use the [Module.GetPEKind](#) method.

Developing Web apps with ASP.NET

1/23/2019 • 2 minutes to read • [Edit Online](#)

ASP.NET is a .NET Framework technology for creating web apps. For more information on ASP.NET, see:

- [ASP.NET documentation](#)
- [ASP.NET MVC](#)
- [ASP.NET Web Pages](#)
- [ASP.NET Web API](#)
- [Create an ASP.NET Framework web app in Azure](#)

Developing Web apps with ASP.NET Core

ASP.NET Core is a redesign of ASP.NET 4.x. Some of the benefits ASP.NET Core provides over ASP.NET:

- Cross platform.
- Leaner and more modular.
- A unified story for building web UI and web APIs.

See [Why use ASP.NET Core?](#) for an expanded list of benefits.

For more information on ASP.NET Core](/aspnet/core), see:

- [Get started with Razor Pages](#)
- [Create a Web API](#)
- [Create an ASP.NET Core web app in Azure](#)

Network Programming in the .NET Framework

1/23/2019 • 4 minutes to read • [Edit Online](#)

The Microsoft .NET Framework provides a layered, extensible, and managed implementation of Internet services that can be quickly and easily integrated into your applications. Your network applications can build on pluggable protocols to automatically take advantage of new Internet protocols, or they can use a managed implementation of the Windows socket interface to work with the network on the socket level.

In This Section

[Introducing Pluggable Protocols](#)

Describes how to access an Internet resource without regard to the access protocol that it requires.

[Requesting Data](#)

Explains how to use pluggable protocols to upload and download data from Internet resources.

[Programming Pluggable Protocols](#)

Explains how to derive protocol-specific classes to implement pluggable protocols.

[Using Application Protocols](#)

Describes programming applications that take advantage of network protocols such as TCP, UDP, and HTTP.

[Internet Protocol Version 6](#)

Describes the advantages of Internet Protocol version 6 (IPv6) over the current version of the Internet Protocol suite (IPv4), describes IPv6 addressing, routing and auto-configuration, and how to enable and disable IPv6.

[Configuring Internet Applications](#)

Explains how to use the .NET Framework configuration files to configure Internet applications.

[Network Tracing in the .NET Framework](#)

Explains how to use network tracing to get information about method invocations and network traffic generated by a managed application.

[Cache Management for Network Applications](#)

Describes how to use caching for applications that use the `System.Net.WebClient`, `System.Net.WebRequest`, and `System.Net.HttpWebRequest` classes.

[Security in Network Programming](#)

Describes how to use standard Internet security and authentication techniques.

[Best Practices for System.Net Classes](#)

Provides tips and tricks for getting the most out of your Internet applications.

[Accessing the Internet Through a Proxy](#)

Describes how to configure proxies.

[NetworkInformation](#)

Describes how to gather information about network events, changes, statistics, and properties and also explains how to determine whether a remote host is reachable by using the `System.Net.NetworkInformation.Ping` class.

[Changes to the System.Uri namespace in Version 2.0](#)

Describes several changes made to the `System.Uri` class in Version 2.0 to fix incorrect behavior, enhance usability, and enhance security.

[International Resource Identifier Support in System.Uri](#)

Describes enhancements to the [System.Uri](#) class in Version 3.5, 3.0 SP1, and 2.0 SP1 for International Resource Identifier (IRI) and Internationalized Domain Name (IDN) support.

[Socket Performance Enhancements in Version 3.5](#)

Describes a set of enhancements to the [System.Net.Sockets.Socket](#) class in Version 3.5, 3.0 SP1, and 2.0 SP1 that provide an alternative asynchronous pattern that can be used by specialized high-performance socket applications.

[Peer Name Resolution Protocol](#)

Describes support added in Version 3.5 to support the Peer Name Resolution Protocol (PNRP), a serverless and dynamic name registration and name resolution protocol. These new features are supported by the [System.Net.PeerToPeer](#) namespace.

[Peer-to-Peer Collaboration](#)

Describes support added in Version 3.5 to support the Peer-to-Peer Collaboration that builds on PNRP. These new features are supported by the [System.Net.PeerToPeer.Collaboration](#) namespace.

[Changes to NTLM authentication for HttpWebRequest in Version 3.5 SP1](#)

Describes security changes made in Version 3.5 SP1 that affect how integrated Windows authentication is handled by the [System.Net.HttpWebRequest](#), [System.Net.HttpListener](#), [System.Net.Security.NegotiateStream](#), and related classes in the [System.Net](#) namespace.

[Integrated Windows Authentication with Extended Protection](#)

Describes enhancements for extended protection that affect how integrated Windows authentication is handled by the [System.Net.HttpWebRequest](#), [System.Net.HttpListener](#), [System.Net.Mail.SmtpClient](#), [System.Net.Security.SslStream](#), [System.Net.Security.NegotiateStream](#), and related classes in the [System.Net](#) and related namespaces.

[NAT Traversal using IPv6 and Teredo](#)

Describes enhancements added to the [System.Net](#), [System.Net.NetworkInformation](#), and [System.Net.Sockets](#) namespaces to support NAT traversal using IPv6 and Teredo.

[Network Isolation for Windows Store Apps](#)

Describes the impact of network isolation when classes in the [System.Net](#), [System.Net.Http](#), and [System.Net.Http.Headers](#) namespaces are used in Windows 8.x Store apps.

[Network Programming Samples](#)

Links to downloadable network programming samples that use classes in the [System.Net](#), [System.Net.Cache](#), [System.Net.Configuration](#), [System.Net.Mail](#), [System.Net.Mime](#), [System.Net.NetworkInformation](#), [System.Net.PeerToPeer](#), [System.Net.Security](#), [System.Net.Sockets](#) namespaces.

Reference

[System.Net](#)

Provides a simple programming interface for many of the protocols used on networks today. The [System.Net.WebRequest](#) and [System.Net.WebResponse](#) classes in this namespace are the basis for pluggable protocols.

[System.Net.Cache](#)

Defines the types and enumerations used to define cache policies for resources obtained using the [System.Net.WebRequest](#) and [System.Net.HttpWebRequest](#) classes.

[System.Net.Configuration](#)

Classes that applications use to programmatically access and update configuration settings for the [System.Net](#) namespaces.

[System.Net.Http](#)

Classes that provides a programming interface for modern HTTP applications.

[System.Net.Http.Headers](#)

Provides support for collections of HTTP headers used by the [System.Net.Http](#) namespace

[System.Net.Mail](#)

Classes to compose and send mail using the SMTP protocol.

[System.Net.Mime](#)

Defines types that are used to represent Multipurpose Internet Mail Exchange (MIME) headers used by classes in the [System.Net.Mail](#) namespace.

[System.Net.NetworkInformation](#)

Classes to programmatically gather information about network events, changes, statistics, and properties.

[System.Net.PeerToPeer](#)

Provides a managed implementation of the Peer Name Resolution Protocol (PNRP) for developers.

[System.Net.PeerToPeer.Collaboration](#)

Provides a managed implementation of the Peer-to-Peer Collaboration interface for developers.

[System.Net.Security](#)

Classes to provide network streams for secure communications between hosts.

[System.Net.Sockets](#)

Provides a managed implementation of the Windows Sockets (Winsock) interface for developers who need to help control access to the network.

[System.Net.WebSockets](#)

Provides a managed implementation of the WebSocket interface for developers.

[System.Uri](#)

Provides an object representation of a uniform resource identifier (URI) and easy access to the parts of the URI.

[System.Security.Authentication.ExtendedProtection](#)

Provides support for authentication using extended protection for applications.

[System.Security.Authentication.ExtendedProtection.Configuration](#)

Provides support for configuration of authentication using extended protection for applications.

Configuring Apps by using Configuration Files

2/7/2019 • 4 minutes to read • [Edit Online](#)

The .NET Framework, through configuration files, gives developers and administrators control and flexibility over the way applications run. Configuration files are XML files that can be changed as needed. An administrator can control which protected resources an application can access, which versions of assemblies an application will use, and where remote applications and objects are located. Developers can put settings in configuration files, eliminating the need to recompile an application every time a setting changes. This section describes what can be configured and why configuring an application might be useful.

NOTE

Managed code can use the classes in the [System.Configuration](#) namespace to read settings from the configuration files, but not to write settings to those files.

This topic describes the syntax of configuration files and provides information about the three types of configuration files: machine, application, and security.

Configuration File Format

Configuration files contain elements, which are logical data structures that set configuration information. Within a configuration file, you use tags to mark the beginning and end of an element. For example, the `<runtime>` element consists of `<runtime> child elements </runtime>`. An empty element would be written as `<runtime/>` or `<runtime></runtime>`.

As with all XML files, the syntax in configuration files is case-sensitive.

You specify configuration settings using predefined attributes, which are name/value pairs inside an element's start tag. The following example specifies two attributes (`version` and `href`) for the `<codeBase>` element, which specifies where the runtime can locate an assembly (for more information, see [Specifying an Assembly's Location](#)).

```
<codeBase version="2.0.0.0"
          href="http://www.litwareinc.com/myAssembly.dll"/>
```

Machine Configuration Files

The machine configuration file, `Machine.config`, contains settings that apply to an entire computer. This file is located in the `%runtime install path%\Config` directory. `Machine.config` contains configuration settings for machine-wide assembly binding, built-in [remoting channels](#), and ASP.NET.

The configuration system first looks in the machine configuration file for the `<appSettings>` element and other configuration sections that a developer might define. It then looks in the application configuration file. To keep the machine configuration file manageable, it is best to put these settings in the application configuration file.

However, putting the settings in the machine configuration file can make your system more maintainable. For example, if you have a third-party component that both your client and server application uses, it is easier to put the settings for that component in one place. In this case, the machine configuration file is the appropriate place for the settings, so you don't have the same settings in two different files.

NOTE

Deploying an application using XCOPY will not copy the settings in the machine configuration file.

For more information about how the common language runtime uses the machine configuration file for assembly binding, see [How the Runtime Locates Assemblies](#).

Application Configuration Files

An application configuration file contains settings that are specific to an app. This file includes configuration settings that the common language runtime reads (such as assembly binding policy, remoting objects, and so on), and settings that the app can read.

The name and location of the application configuration file depend on the app's host, which can be one of the following:

- Executable-hosted app.

These apps have two configuration files: a source configuration file, which is modified by the developer during development, and an output file that is distributed with the app.

When you develop in Visual Studio, place the source configuration file for your app in the project directory and set its **Copy To Output Directory** property to **Copy always** or **Copy if newer**. The name of the configuration file is the name of the app with a .config extension. For example, an app called myApp.exe should have a source configuration file called myApp.exe.config.

Visual Studio automatically copies the source configuration file to the directory where the compiled assembly is placed to create the output configuration file, which is deployed with the app. In some cases, Visual Studio may modify the output configuration file; for more information, see the [Redirecting assembly versions at the app level](#) section of the [Redirecting Assembly Versions](#) article.

- ASP.NET-hosted app.

For more information about ASP.NET configuration files, see [ASP.NET Configuration Settings](#).

- Internet Explorer-hosted app.

If an app hosted in Internet Explorer has a configuration file, the location of this file is specified in a `<link>` tag with the following syntax:

```
<link rel="ConfigurationFileName" href="location">
```

In this tag, `location` is a URL to the configuration file. This sets the app base. The configuration file must be located on the same website as the app.

Security Configuration Files

Security configuration files contain information about the code group hierarchy and permission sets associated with a policy level. We strongly recommend that you use the [Code Access Security Policy tool \(Caspol.exe\)](#) to modify security policy to ensure that policy changes do not corrupt the security configuration files.

NOTE

Starting with the .NET Framework 4, the security configuration files are present only if security policy has been changed.

The security configuration files are in the following locations:

- Enterprise policy configuration file: %*runtime-install-path*\Config\Enterprisesec.config
- Machine policy configuration file: %*runtime-install-path*\Config\Security.config
- User policy configuration file: %USERPROFILE%\Application data\Microsoft\CLR security config\vxx.xx\Security.config

Compiling Apps with .NET Native

5/22/2018 • 2 minutes to read • [Edit Online](#)

.NET Native is a precompilation technology for building and deploying Windows apps that is included with Visual Studio 2015 and later versions. It automatically compiles the release version of apps that are written in managed code (C# or Visual Basic) and that target the .NET Framework and Windows 10 to native code.

Typically, apps that target the .NET Framework are compiled to intermediate language (IL). At run time, the just-in-time (JIT) compiler translates the IL to native code. In contrast, .NET Native compiles Windows apps directly to native code. For developers, this means:

- Your apps feature the performance of native code. Usually, performance will be superior to code that is first compiled to IL and then compiled to native code by the JIT compiler.
- You can continue to program in C# or Visual Basic.
- You can continue to take advantage of the resources provided by the .NET Framework, including its class library, automatic memory management and garbage collection, and exception handling.

For users of your apps, .NET Native offers these advantages:

- Faster execution times for the majority of apps and scenarios.
- Faster startup times for the majority of apps and scenarios.
- Low deployment and update costs.
- Optimized app memory usage.

IMPORTANT

For the vast majority of apps and scenarios, .NET Native offers significantly faster startup times and superior performance when compared to an app compiled to IL or to an NGEN image. However, your results may vary. To ensure that your app has benefited from the performance enhancements of .NET Native, you should compare its performance with that of the non-.NET Native version of your app. For more information, see [Performance Session Overview](#).

But .NET Native involves more than a compilation to native code. It transforms the way that .NET Framework apps are built and executed. In particular:

- During precompilation, required portions of the .NET Framework are statically linked into your app. This allows the app to run with app-local libraries of the .NET Framework, and the compiler to perform global analysis to deliver performance wins. As a result, apps launch consistently faster even after .NET Framework updates.
- The .NET Native runtime is optimized for static precompilation and in the vast majority of cases offers superior performance. At the same time, it retains the core reflection features that developers find so productive.
- .NET Native uses the same back end as the C++ compiler, which is optimized for static precompilation scenarios.

.NET Native is able to bring the performance benefits of C++ to managed code developers because it uses the same or similar tools as C++ under the hood, as shown in this table.

	.NET NATIVE	C++
Libraries	The .NET Framework + Windows Runtime	Win32 + Windows Runtime
Compiler	UTC optimizing compiler	UTC optimizing compiler
Deployed	Ready-to-run binaries	Ready-to-run binaries (ASM)
Runtime	MRT.dll (Minimal CLR Runtime)	CRT.dll (C Runtime)

For Windows apps for Windows 10, you upload .NET Native Code Compilation binaries in app packages (.appx files) to the Windows Store.

In This Section

Debugging, Tracing, and Profiling

2/12/2019 • 2 minutes to read • [Edit Online](#)

To debug a .NET Framework application, the compiler and runtime environment must be configured to enable a debugger to attach to the application and to produce both symbols and line maps, if possible, for the application and its corresponding Microsoft intermediate language (MSIL). After a managed application has been debugged, it can be profiled to boost performance. Profiling evaluates and describes the lines of source code that generate the most frequently executed code, and how much time it takes to execute them.

.NET Framework applications are easily debugged by using Visual Studio, which handles many of the configuration details. If Visual Studio is not installed, you can examine and improve the performance of .NET Framework applications by using the debugging classes in the .NET Framework [System.Diagnostics](#) namespace. This namespace includes the [Trace](#), [Debug](#), and [TraceSource](#) classes for tracing execution flow, and the [Process](#), [EventLog](#), and [PerformanceCounter](#) classes for profiling code.

In This Section

[Enabling JIT-Attach Debugging](#)

Shows how to configure the registry to JIT-attach a debug engine to a .NET Framework application.

[Making an Image Easier to Debug](#)

Shows how to turn JIT tracking on and optimization off to make an assembly easier to debug.

[Tracing and Instrumenting Applications](#)

Describes how to monitor the execution of your application while it is running, and how to instrument it to display how well it is performing or whether something has gone wrong.

[Diagnosing Errors with Managed Debugging Assistants](#)

Describes managed debugging assistants (MDAs), which are debugging aids that work in conjunction with the common language runtime (CLR) to provide information on runtime state.

[Enhancing Debugging with the Debugger Display Attributes](#)

Describes how the developer of a type can specify what that type will look like when it is displayed in a debugger.

Servicing

- For general information, see the [.NET Framework blog](#)
- [Detecting versions](#)
- [Detecting service packs and updates](#)

Features That Simplify Deployment

The .NET Framework provides a number of basic features that make it easier to deploy your applications:

- No-impact applications.

This feature provides application isolation and eliminates DLL conflicts. By default, components do not affect other applications.

- Private components by default.

By default, components are deployed to the application directory and are visible only to the containing application.

- Controlled code sharing.

Code sharing requires you to explicitly make code available for sharing instead of being the default behavior.

- Side-by-side versioning.

Multiple versions of a component or application can coexist, you can choose which versions to use, and the common language runtime enforces versioning policy.

- XCOPY deployment and replication.

Self-described and self-contained components and applications can be deployed without registry entries or dependencies.

- On-the-fly updates.

Administrators can use hosts, such as ASP.NET, to update program DLLs, even on remote computers.

- Integration with the Windows Installer.

Advertisement, publishing, repair, and install-on-demand are all available when deploying your application.

- Enterprise deployment.

This feature provides easy software distribution, including using Active Directory.

- Downloading and caching.

Incremental downloads keep downloads smaller, and components can be isolated for use only by the application for low-impact deployment.

- Partially trusted code.

Identity is based on the code instead of the user, and no certificate dialog boxes appear.

Packaging and Distributing .NET Framework Applications

Some of the packaging and deployment information for the .NET Framework is described in other sections of the documentation. Those sections provide information about the self-describing units called [assemblies](#), which require no registry entries, [strong-named assemblies](#), which ensure name uniqueness and prevent name spoofing, and [assembly versioning](#), which addresses many of the problems associated with DLL conflicts. The following sections provide information about packaging and distributing .NET Framework applications.

Packaging

The .NET Framework provides the following options for packaging applications:

- As a single assembly or as a collection of assemblies.

With this option, you simply use the .dll or .exe files as they were built.

- As cabinet (CAB) files.

With this option, you compress files into .cab files to make distribution or download less time consuming.

- As a Windows Installer package or in other installer formats.

With this option, you create .msi files for use with the Windows Installer, or you package your application for use with some other installer.

Distribution

The .NET Framework provides the following options for distributing applications:

- Use XCOPY or FTP.

Because common language runtime applications are self-describing and require no registry entries, you can use XCOPY or FTP to simply copy the application to an appropriate directory. The application can then be run from that directory.

- Use code download.

If you are distributing your application over the Internet or through a corporate intranet, you can simply download the code to a computer and run the application there.

- Use an installer program such as Windows Installer 2.0.

Windows Installer 2.0 can install, repair, or remove .NET Framework assemblies in the global assembly cache and in private directories.

Installation Location

To determine where to deploy your application's assemblies so they can be found by the runtime, see [How the Runtime Locates Assemblies](#).

Security considerations can also affect how you deploy your application. Security permissions are granted to managed code according to where the code is located. Deploying an application or component to a location where it receives little trust, such as the Internet, limits what the application or component can do. For more information about deployment and security considerations, see [Code Access Security Basics](#).

.NET Framework Performance

3/5/2019 • 4 minutes to read • [Edit Online](#)

If you want to create apps with great performance, you should design and plan for performance just as you would design any other feature of your app. You can use the tools provided by Microsoft to measure your app's performance, and, if needed, make improvements to memory use, code throughput, and responsiveness. This topic lists the performance analysis tools that Microsoft provides, and provides links to other topics that cover performance for specific areas of app development.

Designing and planning for performance

If you want a great performing app, you must design performance into your app just as you would design any other feature. You should determine the performance-critical scenarios in your app, set performance goals, and measure performance for these app scenarios early and often. Because each app is different and has different performance-critical execution paths, determining those paths early and focusing your efforts enable you to maximize your productivity.

You don't have to be completely familiar with your target platform to create a high-performance app. However, you should develop an understanding of which parts of your target platform are costly in terms of performance. You can do this by measuring performance early in your development process.

To determine the areas that are crucial to performance and to establish your performance goals, always consider the user experience. Startup time and responsiveness are two key areas that will affect the user's perception of your app. If your app uses a lot of memory, it may appear sluggish to the user or affect other apps running on the system, or, in some cases, it could fail the Windows Store or Windows Phone Store submission process. Also, if you determine which parts of your code execute more frequently, you can make sure that these portions of your code are well optimized.

Analyzing performance

As part of your overall development plan, set points during development where you will measure the performance of your app and compare the results with the goals you set previously. Measure your app in the environment and hardware that you expect your users to have. By analyzing your app's performance early and often you can change architectural decisions that would be costly and expensive to fix later in the development cycle. The following sections describe performance tools you can use to analyze your apps and discuss event tracing, which is used by these tools.

Performance tools

Here are some of the performance tools you can use with your .NET Framework apps.

TOOL	DESCRIPTION
Visual Studio Performance Analysis	<p>Use to analyze the CPU usage of your .NET Framework apps that will be deployed to computers that are running the Windows operating system.</p> <p>This tool is available from the Debug menu in Visual Studio after you open a project. For more information, see Performance Explorer. Note: Use Windows Phone Application Analysis (see next row) when targeting Windows Phone.</p>

Tool	Description
Windows Phone Application Analysis	<p>Use to analyze the CPU and memory, network data transfer rate, app responsiveness, and battery consumption in your Windows Phone apps.</p> <p>This tool is available from the Debug menu for a Windows Phone project in Visual Studio after you install the Windows Phone SDK. For more information, see App profiling for Windows Phone 8.</p>
PerfView	<p>Use to identify CPU and memory-related performance issues. This tool uses event tracing for Windows (ETW) and CLR profiling APIs to provide advanced memory and CPU investigations as well as information about garbage collection and JIT compilation. For more information about how to use PerfView, see the tutorial and help files that are included with the app, Channel 9 video tutorials, and blog posts.</p> <p>For memory-specific issues, see Using PerfView for Memory Investigations.</p>
Windows Performance Analyzer	<p>Use to determine overall system performance such as your app's memory and storage use when multiple apps are running on the same computer. This tool is available from the download center as part of the Windows Assessment and Deployment Kit (ADK) for Windows 8. For more information, see Windows Performance Analyzer.</p>

Event tracing for Windows (ETW)

ETW is a technique that lets you obtain diagnostic information about running code and is essential for many of the performance tools mentioned previously. ETW creates logs when particular events are raised by .NET Framework apps and Windows. With ETW, you can enable and disable logging dynamically, so that you can perform detailed tracing in a production environment without restarting your app. The .NET Framework offers support for ETW events, and ETW is used by many profiling and performance tools to generate performance data. These tools often enable and disable ETW events, so familiarity with them is helpful. You can use specific ETW events to collect performance information about particular components of your app. For more information about ETW support in the .NET Framework, see [ETW Events in the Common Language Runtime](#) and [ETW Events in Task Parallel Library and PLINQ](#).

Performance by app type

Each type of .NET Framework app has its own best practices, considerations, and tools for evaluating performance. The following table links to performance topics for specific .NET Framework app types.

App Type	See
.NET Framework apps for all platforms	Garbage Collection and Performance Performance Tips

Managed Extensibility Framework (MEF)

10/13/2018 • 16 minutes to read • [Edit Online](#)

This topic provides an overview of the Managed Extensibility Framework that was introduced in the .NET Framework 4.

What is MEF?

The Managed Extensibility Framework or MEF is a library for creating lightweight, extensible applications. It allows application developers to discover and use extensions with no configuration required. It also lets extension developers easily encapsulate code and avoid fragile hard dependencies. MEF not only allows extensions to be reused within applications, but across applications as well.

The Problem of Extensibility

Imagine that you are the architect of a large application that must provide support for extensibility. Your application has to include a potentially large number of smaller components, and is responsible for creating and running them.

The simplest approach to the problem is to include the components as source code in your application, and call them directly from your code. This has a number of obvious drawbacks. Most importantly, you cannot add new components without modifying the source code, a restriction that might be acceptable in, for example, a Web application, but is unworkable in a client application. Equally problematic, you may not have access to the source code for the components, because they might be developed by third parties, and for the same reason you cannot allow them to access yours.

A slightly more sophisticated approach would be to provide an extension point or interface, to permit decoupling between the application and its components. Under this model, you might provide an interface that a component can implement, and an API to enable it to interact with your application. This solves the problem of requiring source code access, but it still has its own difficulties.

Because the application lacks any capacity for discovering components on its own, it must still be explicitly told which components are available and should be loaded. This is typically accomplished by explicitly registering the available components in a configuration file. This means that assuring that the components are correct becomes a maintenance issue, particularly if it is the end user and not the developer who is expected to do the updating.

In addition, components are incapable of communicating with one another, except through the rigidly defined channels of the application itself. If the application architect has not anticipated the need for a particular communication, it is usually impossible.

Finally, the component developers must accept a hard dependency on what assembly contains the interface they implement. This makes it difficult for a component to be used in more than one application, and can also create problems when you create a test framework for components.

What MEF Provides

Instead of this explicit registration of available components, MEF provides a way to discover them implicitly, via *composition*. A MEF component, called a *part*, declaratively specifies both its dependencies (known as *imports*) and what capabilities (known as *exports*) it makes available. When a part is created, the MEF composition engine satisfies its imports with what is available from other parts.

This approach solves the problems discussed in the previous section. Because MEF parts declaratively specify their

capabilities, they are discoverable at runtime, which means an application can make use of parts without either hard-coded references or fragile configuration files. MEF allows applications to discover and examine parts by their metadata, without instantiating them or even loading their assemblies. As a result, there is no need to carefully specify when and how extensions should be loaded.

In addition to its provided exports, a part can specify its imports, which will be filled by other parts. This makes communication among parts not only possible, but easy, and allows for good factoring of code. For example, services common to many components can be factored into a separate part and easily modified or replaced.

Because the MEF model requires no hard dependency on a particular application assembly, it allows extensions to be reused from application to application. This also makes it easy to develop a test harness, independent of the application, to test extension components.

An extensible application written by using MEF declares an import that can be filled by extension components, and may also declare exports in order to expose application services to extensions. Each extension component declares an export, and may also declare imports. In this way, extension components themselves are automatically extensible.

Where Is MEF Available?

MEF is an integral part of the .NET Framework 4, and is available wherever the .NET Framework is used. You can use MEF in your client applications, whether they use Windows Forms, WPF, or any other technology, or in server applications that use ASP.NET.

MEF and MAF

Previous versions of the .NET Framework introduced the Managed Add-in Framework (MAF), designed to allow applications to isolate and manage extensions. The focus of MAF is slightly higher-level than MEF, concentrating on extension isolation and assembly loading and unloading, while MEF's focus is on discoverability, extensibility, and portability. The two frameworks interoperate smoothly, and a single application can take advantage of both.

SimpleCalculator: An Example Application

The simplest way to see what MEF can do is to build a simple MEF application. In this example, you build a very simple calculator named SimpleCalculator. The goal of SimpleCalculator is to create a console application that accepts basic arithmetic commands, in the form "5+3" or "6-2", and returns the correct answers. Using MEF, you'll be able to add new operators without changing the application code.

To download the complete code for this example, see the [SimpleCalculator sample](#).

NOTE

The purpose of SimpleCalculator is to demonstrate the concepts and syntax of MEF, rather than to necessarily provide a realistic scenario for its use. Many of the applications that would benefit most from the power of MEF are more complex than SimpleCalculator. For more extensive examples, see the [Managed Extensibility Framework](#) on GitHub.

- To start, in Visual Studio, create a new Console Application project and name it `SimpleCalculator`.
- Add a reference to the `System.ComponentModel.Composition` assembly, where MEF resides.
- Open `Module1.vb` or `Program.cs` and add `Imports` or `using` statements for `System.ComponentModel.Composition` and `System.ComponentModel.Composition.Hosting`. These two namespaces contain MEF types you will need to develop an extensible application.
- If you're using Visual Basic, add the `Public` keyword to the line that declares the `Module1` module.

Composition Container and Catalogs

The core of the MEF composition model is the *composition container*, which contains all the parts available and performs composition. Composition is the matching up of imports to exports. The most common type of composition container is [CompositionContainer](#), and you'll use this for SimpleCalculator.

If you're using Visual Basic, in Module1.vb, add a public class named `Program`.

Add the following line to the `Program` class in Module1.vb or Program.cs:

```
Dim _container As CompositionContainer
```

```
private CompositionContainer _container;
```

In order to discover the parts available to it, the composition containers makes use of a *catalog*. A catalog is an object that makes available parts discovered from some source. MEF provides catalogs to discover parts from a provided type, an assembly, or a directory. Application developers can easily create new catalogs to discover parts from other sources, such as a Web service.

Add the following constructor to the `Program` class:

```
Public Sub New()
    'An aggregate catalog that combines multiple catalogs
    Dim catalog = New AggregateCatalog()

    'Adds all the parts found in the same assembly as the Program class
    catalog.Catalogs.Add(New AssemblyCatalog(GetType(Program).Assembly))

    'Create the CompositionContainer with the parts in the catalog
    _container = New CompositionContainer(catalog)

    'Fill the imports of this object
    Try
        _container.ComposeParts(Me)
    Catch ex As Exception
        Console.WriteLine(ex.ToString())
    End Try
End Sub
```

```
private Program()
{
    //An aggregate catalog that combines multiple catalogs
    var catalog = new AggregateCatalog();
    //Adds all the parts found in the same assembly as the Program class
    catalog.Catalogs.Add(new AssemblyCatalog(typeof(Program).Assembly));

    //Create the CompositionContainer with the parts in the catalog
    _container = new CompositionContainer(catalog);

    //Fill the imports of this object
    try
    {
        this._container.ComposeParts(this);
    }
    catch (CompositionException compositionException)
    {
        Console.WriteLine(compositionException.ToString());
    }
}
```

The call to `ComposeParts` tells the composition container to compose a specific set of parts, in this case the current instance of `Program`. At this point, however, nothing will happen, since `Program` has no imports to fill.

Imports and Exports with Attributes

First, you have `Program` import a calculator. This allows the separation of user interface concerns, such as the console input and output that will go into `Program`, from the logic of the calculator.

Add the following code to the `Program` class:

```
<Import(GetType(ICalculator))>
Public Property calculator As ICalculator
```

```
[Import(typeof(ICalculator))]
public ICalculator calculator;
```

Notice that the declaration of the `calculator` object is not unusual, but that it is decorated with the `ImportAttribute` attribute. This attribute declares something to be an import; that is, it will be filled by the composition engine when the object is composed.

Every import has a *contract*, which determines what exports it will be matched with. The contract can be an explicitly specified string, or it can be automatically generated by MEF from a given type, in this case the interface `ICalculator`. Any export declared with a matching contract will fulfill this import. Note that while the type of the `calculator` object is in fact `ICalculator`, this is not required. The contract is independent from the type of the importing object. (In this case, you could leave out the `typeof(ICalculator)`. MEF will automatically assume the contract to be based on the type of the import unless you specify it explicitly.)

Add this very simple interface to the module or `SimpleCalculator` namespace:

```
Public Interface ICalculator
    Function Calculate(ByVal input As String) As String
End Interface
```

```
public interface ICalculator
{
    String Calculate(String input);
}
```

Now that you have defined `ICalculator`, you need a class that implements it. Add the following class to the module or `SimpleCalculator` namespace:

```
<Export(GetType(ICalculator))>
Public Class MySimpleCalculator
    Implements ICalculator
End Class
```

```
[Export(typeof(ICalculator))]
class MySimpleCalculator : ICalculator
{}
```

Here is the export that will match the import in `Program`. In order for the export to match the import, the export must have the same contract. Exporting under a contract based on `typeof(MySimpleCalculator)` would produce a mismatch, and the import would not be filled; the contract needs to match exactly.

Since the composition container will be populated with all the parts available in this assembly, the `MySimpleCalculator` part will be available. When the constructor for `Program` performs composition on the `Program` object, its import will be filled with a `MySimpleCalculator` object, which will be created for that purpose.

The user interface layer (`Program`) does not need to know anything else. You can therefore fill in the rest of the user interface logic in the `Main` method.

Add the following code to the `Main` method:

```
Sub Main()
    Dim p As New Program()
    Dim s As String
    Console.WriteLine("Enter Command:")
    While (True)
        s = Console.ReadLine()
        Console.WriteLine(p.calculator.Calculate(s))
    End While
End Sub
```

```
static void Main(string[] args)
{
    Program p = new Program(); //Composition is performed in the constructor
    String s;
    Console.WriteLine("Enter Command:");
    while (true)
    {
        s = Console.ReadLine();
        Console.WriteLine(p.calculator.Calculate(s));
    }
}
```

This code simply reads a line of input and calls the `Calculate` function of `ICalculator` on the result, which it writes back to the console. That is all the code you need in `Program`. All the rest of the work will happen in the parts.

Further Imports and ImportMany

In order for SimpleCalculator to be extensible, it needs to import a list of operations. An ordinary `ImportAttribute` attribute is filled by one and only one `ExportAttribute`. If more than one is available, the composition engine produces an error. To create an import that can be filled by any number of exports, you can use the `ImportManyAttribute` attribute.

Add the following operations property to the `MySimpleCalculator` class:

```
<ImportMany()
Public Property operations As IEnumerable(Of Lazy(Of IOperation, IOperationData))
```

```
[ImportMany]
IEnumerable<Lazy<IOperation, IOperationData>> operations;
```

`Lazy<T,TMetadata>` is a type provided by MEF to hold indirect references to exports. Here, in addition to the exported object itself, you also get *export metadata*, or information that describes the exported object. Each

`Lazy<T, TMetadata>` contains an `IOperation` object, representing an actual operation, and an `IOperationData` object, representing its metadata.

Add the following simple interfaces to the module or `SimpleCalculator` namespace:

```
Public Interface IOperation
    Function Operate(ByVal left As Integer, ByVal right As Integer) As Integer
End Interface

Public Interface IOperationData
    ReadOnly Property Symbol As Char
End Interface
```

```
public interface IOperation
{
    int Operate(int left, int right);
}

public interface IOperationData
{
    Char Symbol { get; }
}
```

In this case, the metadata for each operation is the symbol that represents that operation, such as `+`, `-`, `*`, and so on. To make the addition operation available, add the following class to the module or `SimpleCalculator` namespace:

```
<Export(GetType(IOperation))>
<ExportMetadata("Symbol", "+c")>
Public Class Add
    Implements IOperation

    Public Function Operate(ByVal left As Integer, ByVal right As Integer) As Integer Implements
IOperation.Operate
        Return left + right
    End Function
End Class
```

```
[Export(typeof(IOperation))]
[ExportMetadata("Symbol", '+')]
class Add: IOperation
{
    public int Operate(int left, int right)
    {
        return left + right;
    }
}
```

The `ExportAttribute` attribute functions as it did before. The `ExportMetadataAttribute` attribute attaches metadata, in the form of a name-value pair, to that export. While the `Add` class implements `IOperation`, a class that implements `IOperationData` is not explicitly defined. Instead, a class is implicitly created by MEF with properties based on the names of the metadata provided. (This is one of several ways to access metadata in MEF.)

Composition in MEF is *recursive*. You explicitly composed the `Program` object, which imported an `ICalculator` that turned out to be of type `MySimpleCalculator`. `MySimpleCalculator`, in turn, imports a collection of `IOperation` objects, and that import will be filled when `MySimpleCalculator` is created, at the same time as the imports of `Program`. If the `Add` class declared a further import, that too would have to be filled, and so on. Any import left unfilled results in a composition error. (It is possible, however, to declare imports to be optional or to assign them

default values.)

Calculator Logic

With these parts in place, all that remains is the calculator logic itself. Add the following code in the `MySimpleCalculator` class to implement the `Calculate` method:

```
Public Function Calculate(ByVal input As String) As String Implements ICalculator.Calculate
    Dim left, right As Integer
    Dim operation As Char
    Dim fn = FindFirstNonDigit(input) 'Finds the operator
    If fn < 0 Then
        Return "Could not parse command."
    End If
    operation = input(fn)
    Try
        left = Integer.Parse(input.Substring(0, fn))
        right = Integer.Parse(input.Substring(fn + 1))
    Catch ex As Exception
        Return "Could not parse command."
    End Try
    For Each i As Lazy(Of IOperation, IOperationData) In operations
        If i.Metadata.symbol = operation Then
            Return i.Value.Operate(left, right).ToString()
        End If
    Next
    Return "Operation not found!"
End Function
```

```
public String Calculate(String input)
{
    int left;
    int right;
    Char operation;
    int fn = FindFirstNonDigit(input); //finds the operator
    if (fn < 0) return "Could not parse command.";

    try
    {
        //separate out the operands
        left = int.Parse(input.Substring(0, fn));
        right = int.Parse(input.Substring(fn + 1));
    }
    catch
    {
        return "Could not parse command.";
    }

    operation = input[fn];

    foreach (Lazy<IOperation, IOperationData> i in operations)
    {
        if (i.Metadata.Symbol.Equals(operation)) return i.Value.Operate(left, right).ToString();
    }
    return "Operation Not Found!";
}
```

The initial steps parse the input string into left and right operands and an operator character. In the `foreach` loop, every member of the `operations` collection is examined. These objects are of type `Lazy<T,TMetadata>`, and their metadata values and exported object can be accessed with the `Metadata` property and the `Value` property respectively. In this case, if the `Symbol` property of the `IOperationData` object is discovered to be a match, the calculator calls the `Operate` method of the `IOperation` object and returns the result.

To complete the calculator, you also need a helper method that returns the position of the first non-digit character in a string. Add the following helper method to the `MySimpleCalculator` class:

```
Private Function FindFirstNonDigit(ByVal s As String) As Integer
    For i = 0 To s.Length
        If (Not (Char.IsDigit(s(i)))) Then Return i
    Next
    Return -1
End Function
```

```
private int FindFirstNonDigit(String s)
{
    for (int i = 0; i < s.Length; i++)
    {
        if (!(Char.IsDigit(s[i]))) return i;
    }
    return -1;
}
```

You should now be able to compile and run the project. In Visual Basic, make sure that you added the `Public` keyword to `Module1`. In the console window, type an addition operation, such as "5+3", and the calculator returns the results. Any other operator results in the "Operation Not Found!" message.

Extending SimpleCalculator Using A New Class

Now that the calculator works, adding a new operation is easy. Add the following class to the module or `SimpleCalculator` namespace:

```
<Export(GetType(IOperation))>
<ExportMetadata("Symbol", "-c")>
Public Class Subtract
    Implements IOperation

    Public Function Operate(ByVal left As Integer, ByVal right As Integer) As Integer Implements
IOperation.Operate
        Return left - right
    End Function
End Class
```

```
[Export(typeof(IOperation))]
[ExportMetadata("Symbol", '-')]
class Subtract : IOperation
{
    public int Operate(int left, int right)
    {
        return left - right;
    }
}
```

Compile and run the project. Type a subtraction operation, such as "5-3". The calculator now supports subtraction as well as addition.

Extending SimpleCalculator Using A New Assembly

Adding classes to the source code is simple enough, but MEF provides the ability to look outside an application's own source for parts. To demonstrate this, you will need to modify SimpleCalculator to search a directory, as well as its own assembly, for parts, by adding a [DirectoryCatalog](#).

Add a new directory named `Extensions` to the SimpleCalculator project. Make sure to add it at the project level, and not at the solution level. Then add a new Class Library project to the solution, named `ExtendedOperations`. The new project will compile into a separate assembly.

Open the Project Properties Designer for the ExtendedOperations project and click the **Compile** or **Build** tab. Change the **Build output path** or **Output path** to point to the Extensions directory in the SimpleCalculator project directory (`..\SimpleCalculator\Extensions`).

In Module1.vb or Program.cs, add the following line to the `Program` constructor:

```
catalog.Catalogs.Add(New DirectoryCatalog("C:\SimpleCalculator\SimpleCalculator\Extensions"))
```

```
catalog.Catalogs.Add(new DirectoryCatalog("C:\\SimpleCalculator\\SimpleCalculator\\\\Extensions"));
```

Replace the example path with the path to your Extensions directory. (This absolute path is for debugging purposes only. In a production application, you would use a relative path.) The [DirectoryCatalog](#) will now add any parts found in any assemblies in the Extensions directory to the composition container.

In the ExtendedOperations project, add references to SimpleCalculator and System.ComponentModel.Composition. In the ExtendedOperations class file, add an `Imports` or a `using` statement for System.ComponentModel.Composition. In Visual Basic, also add an `Imports` statement for SimpleCalculator. Then add the following class to the ExtendedOperations class file:

```
<Export(GetType(SimpleCalculator.IOperation))>
<ExportMetadata("Symbol", "%c")>
Public Class Modulo
    Implements IOperation

    Public Function Operate(ByVal left As Integer, ByVal right As Integer) As Integer Implements
        IOperation.Operate
        Return left Mod right
    End Function
End Class
```

```
[Export(typeof(SimpleCalculator.IOperation))]
[ExportMetadata("Symbol", '%')]
public class Mod : SimpleCalculator.IOperation
{
    public int Operate(int left, int right)
    {
        return left % right;
    }
}
```

Note that in order for the contract to match, the [ExportAttribute](#) attribute must have the same type as the [ImportAttribute](#).

Compile and run the project. Test the new Mod (%) operator.

Conclusion

This topic covered the basic concepts of MEF.

- Parts, catalogs, and the composition container

Parts and the composition container are the basic building blocks of a MEF application. A part is any object

that imports or exports a value, up to and including itself. A catalog provides a collection of parts from a particular source. The composition container uses the parts provided by a catalog to perform composition, the binding of imports to exports.

- Imports and exports

Imports and exports are the way by which components communicate. With an import, the component specifies a need for a particular value or object, and with an export it specifies the availability of a value. Each import is matched with a list of exports by way of its contract.

Where Do I Go Now?

To download the complete code for this example, see the [SimpleCalculator sample](#).

For more information and code examples, see [Managed Extensibility Framework](#). For a list of the MEF types, see the [System.ComponentModel.Composition](#) namespace.

Interoperating with unmanaged code

3/25/2019 • 2 minutes to read • [Edit Online](#)

The .NET Framework promotes interaction with COM components, COM+ services, external type libraries, and many operating system services. Data types, method signatures, and error-handling mechanisms vary between managed and unmanaged object models. To simplify interoperation between .NET Framework components and unmanaged code and to ease the migration path, the common language runtime conceals from both clients and servers the differences in these object models.

Code that executes under the control of the runtime is called managed code. Conversely, code that runs outside the runtime is called unmanaged code. COM components, ActiveX interfaces, and Windows API functions are examples of unmanaged code.

[Interop Marshaling](#)

Describes marshaling for COM interop and platform invoke.

[How to: Map HRESULTs and Exceptions](#)

Describes the mapping between exceptions and HRESULTs.

[COM Wrappers](#)

Describes the wrappers provided by COM interop.

[Type Equivalence and Embedded Interop Types](#)

Describes how type information for COM types is embedded in assemblies, and how the common language runtime determines the equivalence of embedded COM types.

[How to: Generate Primary Interop Assemblies Using Tlbimp.exe](#)

Describes how to produce primary interop assemblies using *Tlbimp.exe* (Type Library Importer).

[How to: Register Primary Interop Assemblies](#)

Describes how to register the primary interop assemblies before you can reference them in your projects.

[Registration-Free COM Interop](#)

Describes how COM interop can activate components without using the Windows registry.

[How to: Configure .NET Framework-Based COM Components for Registration-Free Activation](#)

Describes how to create an application manifest and how to create and embed a component manifest.

Unmanaged API Reference

2/15/2019 • 2 minutes to read • [Edit Online](#)

This section includes information on unmanaged APIs that can be used by managed-code-related applications, such as runtime hosts, compilers, disassemblers, obfuscators, debuggers, and profilers.

In This Section

[Common Data Types](#)

Lists the common data types that are used, particularly in the unmanaged profiling and debugging APIs.

[ALink](#)

Describes the ALink API, which supports the creation of .NET Framework assemblies and unbound modules.

[Authenticode](#)

Supports the Authenticode XrML license creation and verification module.

[Constants](#)

Describes the constants that are defined in CorSym.idl.

[Custom Interface Attributes](#)

Describes component object model (COM) custom interface attributes.

[Debugging](#)

Describes the debugging API, which enables a debugger to debug code that runs in the common language runtime (CLR) environment.

[Diagnostics Symbol Store](#)

Describes the diagnostics symbol store API, which enables a compiler to generate symbol information for use by a debugger.

[Fusion](#)

Describes the fusion API, which enables a runtime host to access the properties of an application's resources in order to locate the correct versions of those resources for the application.

[Hosting](#)

Describes the hosting API, which enables unmanaged hosts to integrate the CLR into their applications.

[Metadata](#)

Describes the metadata API, which enables a client such as a compiler to generate or access a component's metadata without the types being loaded by the CLR.

[Profiling](#)

Describes the profiling API, which enables a profiler to monitor a program's execution by the CLR.

[Strong Naming](#)

Describes the strong naming API, which enables a client to administer strong name signing for assemblies.

[WMI and Performance Counters](#)

Describes the APIs that wrap calls to Windows Management Instrumentation (WMI) libraries.

[Tlbexp Helper Functions](#)

Describes the two helper functions and interface used by the Type Library Exporter (Tlbexp.exe) during the assembly-to-type-library conversion process.

XAML Services

3/15/2019 • 8 minutes to read • [Edit Online](#)

This topic describes the capabilities of a technology set known as .NET Framework XAML Services. The majority of the services and APIs described are located in the assembly System.Xaml, which is an assembly introduced with the .NET Framework 4 set of .NET core assemblies. Services include readers and writers, schema classes and schema support, factories, attributing of classes, XAML language intrinsic support, and other XAML language features.

About This Documentation

Conceptual documentation for .NET Framework XAML Services assumes that you have previous experience with the XAML language and how it might apply to a specific framework, for example Windows Presentation Foundation (WPF) or Windows Workflow Foundation, or a specific technology feature area, for example the build customization features in [Microsoft.Build.Framework.XamlTypes](#). This documentation does not attempt to explain the basics of XAML as a markup language, XAML syntax terminology, or other introductory material. Instead, this documentation focuses on specifically using the .NET Framework XAML Services that are enabled in the System.Xaml assembly library. Most of these APIs are for scenarios of XAML language integration and extensibility. This might include any of the following:

- Extending the capabilities of the base XAML readers or XAML writers (processing the XAML node stream directly; deriving your own XAML reader or XAML writer).
- Defining XAML-usable custom types that do not have specific framework dependencies, and attributing the types to convey their XAML type system characteristics to .NET Framework XAML Services.
- Hosting XAML readers or XAML writers as a component of an application, such as a visual designer or interactive editor for XAML markup sources.
- Writing XAML value converters (markup extensions; type converters for custom types).
- Defining a custom XAML schema context (using alternate assembly-loading techniques for backing type sources; using known-types lookup techniques instead of always reflecting assemblies; using loaded assembly concepts that do not use the CLR `AppDomain` and its associated security model).
- Extending the base XAML type system.
- Using the `Lookup` or `Invoker` techniques to influence the XAML type system and how type backings are evaluated.

If you are looking for introductory material on XAML as a language, you might try [XAML Overview \(WPF\)](#). That topic discusses XAML for an audience that is new both to Windows Presentation Foundation (WPF) and also to using XAML markup and XAML language features. Another useful document is the introductory material in the [XAML language specification](#).

.NET Framework XAML Services and System.Xaml in the .NET Architecture

In previous versions of Microsoft .NET Framework, support for XAML language features was implemented by frameworks that built on Microsoft .NET Framework (Windows Presentation Foundation (WPF), Windows Workflow Foundation and Windows Communication Foundation (WCF)), and therefore varied in its behavior and the API used depending on which specific framework you were using. This included the XAML parser and its object

graph creation mechanism, XAML language intrinsics, serialization support, and so on.

In .NET Framework 4, .NET Framework XAML Services and the System.Xaml assembly define much of what is needed for supporting XAML language features. This includes base classes for XAML readers and XAML writers. The most important feature added to .NET Framework XAML Services that was not present in any of the framework-specific XAML implementations is a type system representation for XAML. The type system representation presents XAML in an object-oriented way that centers on XAML capabilities without taking dependencies on specific capabilities of frameworks.

The XAML type system is not limited by the markup form or run-time specifics of the XAML origin; nor is it limited by any specific backing type system. The XAML type system includes object representations for types, members, XAML schema contexts, XML-level concepts, and other XAML language concepts or XAML intrinsics. Using or extending the XAML type system makes it possible to derive from classes like XAML readers and XAML writers, and extend the functionality of XAML representations into specific features enabled by a framework, a technology, or an application that consumes or emits XAML. The concept of a XAML schema context enables practical object graph write operations from the combination of a XAML object writer implementation, a technology's backing type system as communicated through assembly information in the context, and the XAML node source. For more information on the XAML schema concept, see [Default XAML Schema Context](#) and [WPF XAML Schema Context](#).

XAML Node Streams, XAML Readers, and XAML Writers

To understand the role that .NET Framework XAML Services plays in the relationship between the XAML language and specific technologies that use XAML as a language, it is helpful to understand the concept of a XAML node stream and how that concept shapes the API and terminology. The XAML node stream is a conceptual intermediate between a XAML language representation and the object graph that the XAML represents or defines.

- A XAML reader is an entity that processes XAML in some form, and produces a XAML node stream. In the API, a XAML reader is represented by the base class [XamlReader](#).
- A XAML writer is an entity that processes a XAML node stream and produces something else. In the API, a XAML writer is represented by the base class [XamlWriter](#).

The two most common scenarios involving XAML are loading XAML to instantiate an object graph, and saving an object graph from an application or tool and producing a XAML representation (typically in markup form saved as text file). Loading XAML and creating an object graph is often referred to in this documentation as the load path. Saving or serializing an existing object graph to XAML is often referred to in this documentation as the save path.

The most common type of load path can be described as follows:

- Start with a XAML representation, in UTF-encoded XML format and saved as a text file.
- Load that XAML into [XamlXmlReader](#). [XamlXmlReader](#) is a [XamlReader](#) subclass.
- The result is a XAML node stream. You can access individual nodes of the XAML node stream using [XamlXmlReader](#) / [XamlReader](#) API. The most typical operation here is to advance through the XAML node stream, processing each node using a "current record" metaphor.
- Pass the resulting nodes from the XAML node stream to a [XamlObjectWriter](#) API. [XamlObjectWriter](#) is a [XamlWriter](#) subclass.
- The [XamlObjectWriter](#) writes an object graph, one object at a time, in accordance to progress through the source XAML node stream. This is done with the assistance of a XAML schema context and an implementation that can access the assemblies and types of a backing type system and framework.
- Call [Result](#) at the end of the XAML node stream to obtain the root object of the object graph.

The most common type of save path can be described as follows:

- Start with the object graph of an entire application run time, the UI content and state of a run time, or a smaller segment of an overall application's object representation at run time.
- From a logical start object, such as an application root or document root, load the objects into [XamlObjectReader](#). [XamlObjectReader](#) is a [XamlReader](#) subclass.
- The result is a XAML node stream. You can access individual nodes of the XAML node stream using [XamlObjectReader](#) and [XamlReader](#) API. The most typical operation here is to advance through the XAML node stream, processing each node using a "current record" metaphor.
- Pass the resulting nodes from the XAML node stream to a [XamlXmlWriter](#) API. [XamlXmlWriter](#) is a [XamlWriter](#) subclass.
- The [XamlXmlWriter](#) writes XAML in an XML UTF encoding. You can save this as a text file, as a stream, or in other forms.
- Call [Flush](#) to obtain the final output.

For more information about XAML node stream concepts, see [Understanding XAML Node Stream Structures and Concepts](#).

The [XamlServices](#) Class

It is not always necessary to deal with a XAML node stream. If you want a basic load path or a basic save path, you can use APIs in the [XamlServices](#) class.

- Various signatures of [Load](#) implement a load path. You can either load a file or stream, or can load an [XmlReader](#), [TextReader](#) or [XamlReader](#) that wrap your XAML input by loading with that reader's APIs.
- Various signatures of [Save](#) save an object graph and produce output as a stream, file, or [XmlWriter/TextWriter](#) instance.
- [Transform](#) converts XAML by linking a load path and a save path as a single operation. A different schema context or different backing type system could be used for [XamlReader](#) and [XamlWriter](#), which is what influences how the resulting XAML is transformed.

For more information about how to use [XamlServices](#), see [XAMLservices Class and Basic XAML Reading or Writing](#).

XAML Type System

The XAML type system provides the APIs that are required to work with a given individual node of a XAML node stream.

[XamlType](#) is the representation for an object - what you are processing between a start object node and end object node.

[XamlMember](#) is the representation for a member of an object - what you are processing between a start member node and end member node.

APIs such as [GetAllMembers](#) and [GetMember](#) and [DeclaringType](#) report the relationships between a [XamlType](#) and [XamlMember](#).

The default behavior of the XAML type system as implemented by .NET Framework XAML Services is based on the common language runtime (CLR), and static analysis of CLR types in assemblies by using reflection. Therefore, for a specific CLR type, the default implementation of the XAML type system can expose the XAML schema of that type and its members and report it in terms of the XAML type system. In the default XAML type system, the concept of assignability of types is mapped onto CLR inheritance, and the concepts of instances, value types and so on are also mapped to the supporting behaviors and features of the CLR.

Reference for XAML Language Features

To support XAML, .NET Framework XAML Services provides specific implementation of XAML language concepts as defined for the XAML language XAML namespace. These are documented as specific reference pages. The language features are documented from the perspective of how these language features behave when they are processed by a XAML reader or XAML writer that is defined by .NET Framework XAML Services. For more information, see [XAML Namespace \(x:\) Language Features](#).

.NET Framework Tools

2/13/2019 • 5 minutes to read • [Edit Online](#)

The .NET Framework tools make it easier for you to create, deploy, and manage applications and components that target the .NET Framework.

Most of the .NET Framework tools described in this section are automatically installed with Visual Studio. To download Visual Studio, visit the [Visual Studio Downloads](#) page.

You can run all the tools from the command line with the exception of the Assembly Cache Viewer (Shfusion.dll). You must access Shfusion.dll from File Explorer.

The best way to run the command-line tools is by using the Developer Command Prompt for Visual Studio. These utilities enable you to run the tools easily, without navigating to the installation folder. For more information, see [Command Prompts](#).

NOTE

Some tools are specific to either 32-bit computers or 64-bit computers. Be sure to run the appropriate version of the tool for your computer.

In This Section

[Al.exe \(Assembly Linker\)](#)

Generates a file that has an assembly manifest from modules or resource files.

[Aximp.exe \(Windows Forms ActiveX Control Importer\)](#)

Converts type definitions in a COM type library for an ActiveX control into a Windows Forms control.

[Caspol.exe \(Code Access Security Policy Tool\)](#)

Enables you to view and configure security policy for the machine policy level, the user policy level, and the enterprise policy level. In the .NET Framework 4 and later, this tool does not affect code access security (CAS) policy unless the `<legacyCasPolicy>` element is set to `true`. For more information, see [Security Changes](#).

[Cert2spc.exe \(Software Publisher Certificate Test Tool\)](#)

Creates a Software Publisher's Certificate (SPC) from one or more X.509 certificates. This tool is for testing purposes only.

[Certmgr.exe \(Certificate Manager Tool\)](#)

Manages certificates, certificate trust lists (CTLs), and certificate revocation lists (CRLs).

[Clrver.exe \(CLR Version Tool\)](#)

Reports all the installed versions of the common language runtime (CLR) on the computer.

[CorFlags.exe \(CorFlags Conversion Tool\)](#)

Lets you configure the CorFlags section of the header of a portable executable (PE) image.

[Fuslogvw.exe \(Assembly Binding Log Viewer\)](#)

Displays information about assembly binds to help you diagnose why the .NET Framework cannot locate an assembly at run time.

[Gacutil.exe \(Global Assembly Cache Tool\)](#)

Lets you view and manipulate the contents of the global assembly cache and download cache.

[Ilasm.exe \(IL Assembler\)](#)

Generates a portable executable (PE) file from intermediate language (IL). You can run the resulting executable to determine whether the IL performs as expected.

[Ildasm.exe \(IL Disassembler\)](#)

Takes a portable executable (PE) file that contains intermediate language (IL) code and creates a text file that can be input to the IL Assembler (Ilasm.exe).

[Installutil.exe \(Installer Tool\)](#)

Enables you to install and uninstall server resources by executing the installer components in a specified assembly. (Works with classes in the [System.Configuration.Install](#) namespace.) Enables you to install and uninstall server resources by executing the installer components in a specified assembly. (Works with classes in the [System.Configuration.Install](#) namespace.)

[Lc.exe \(License Compiler\)](#)

Reads text files that contain licensing information and produces a .licenses file that can be embedded in a common language runtime executable as a resource. Reads text files that contain licensing information and produces a .licenses file that can be embedded in a common language runtime executable as a resource.

[Mage.exe \(Manifest Generation and Editing Tool\)](#)

Lets you create, edit, and sign application and deployment manifests. As a command-line tool, Mage.exe can be run from both batch scripts and other Windows-based applications, including ASP.NET applications.

[MageUI.exe \(Manifest Generation and Editing Tool, Graphical Client\)](#)

Supports the same functionality as the command-line tool Mage.exe, but uses a Windows-based user interface (UI). Supports the same functionality as the command-line tool Mage.exe, but uses a Windows-based user interface (UI).

[MDbg.exe \(.NET Framework Command-Line Debugger\)](#)

Helps tools vendors and application developers find and fix bugs in programs that target the .NET Framework common language runtime. This tool uses the runtime debugging API to provide debugging services.

[Mgmtclassgen.exe \(Management Strongly Typed Class Generator\)](#)

Enables you to generate an early-bound managed class for a specified Windows Management Instrumentation (WMI) class.

[Mpgo.exe \(Managed Profile Guided Optimization Tool\)](#)

Enables you to tune native image assemblies using common end-user scenarios. Mpgo.exe allows the generation and consumption of profile data for native image application assemblies (not the .NET Framework assemblies) using training scenarios selected by the application developer.

[Ngen.exe \(Native Image Generator\)](#)

Improves the performance of managed applications through the use of native images (files containing compiled processor-specific machine code). The runtime can use native images from the cache instead of using the just-in-time (JIT) compiler to compile the original assembly.

[Peverify.exe \(PEVerify Tool\)](#)

Helps you verify whether your Microsoft intermediate language (MSIL) code and associated metadata meet type safety requirements. Helps you verify whether your Microsoft intermediate language (MSIL) code and associated metadata meet type safety requirements.

[Regasm.exe \(Assembly Registration Tool\)](#)

Reads the metadata within an assembly and adds the necessary entries to the registry. This enables COM clients to appear as .NET Framework classes.

[Regsvcs.exe \(.NET Services Installation Tool\)](#)

Loads and registers an assembly, generates and installs a type library into a specified COM+ version 1.0

application, and configures services that you have added programmatically to a class.

[Resgen.exe \(Resource File Generator\)](#)

Converts text (.txt or .restext) files and XML-based resource format (.resx) files to common language runtime binary (.resources) files that can be embedded in a runtime binary executable or compiled into satellite assemblies.

[SecAnnotate.exe \(.NET Security Annotator Tool\)](#)

Identifies the `SecurityCritical` and `SecuritySafeCritical` portions of an assembly. Identifies the `SecurityCritical` and `SecuritySafeCritical` portions of an assembly.

[SignTool.exe \(Sign Tool\)](#)

Digitally signs files, verifies signatures in files, and time-stamps files.

[Sn.exe \(Strong Name Tool\)](#)

Helps create assemblies with strong names. This tool provides options for key management, signature generation, and signature verification.

[SOS.dll \(SOS Debugging Extension\)](#)

Helps you debug managed programs in the WinDbg.exe debugger and in Visual Studio by providing information about the internal common language runtime environment.

[SqlMetal.exe \(Code Generation Tool\)](#)

Generates code and mapping for the LINQ to SQL component of the .NET Framework.

[Storeadm.exe \(Isolated Storage Tool\)](#)

Manages isolated storage; provides options for listing the user's stores and deleting them.

[Tlbexp.exe \(Type Library Exporter\)](#)

Generates a type library that describes the types that are defined in a common language runtime assembly.

[Tlbimp.exe \(Type Library Importer\)](#)

Converts the type definitions found in a COM type library into equivalent definitions in a common language runtime assembly.

[Winmdexp.exe \(Windows Runtime Metadata Export Tool\)](#)

Exports a .NET Framework assembly that is compiled as a .winmdobj file into a Windows Runtime component, which is packaged as a .winmd file that contains both Windows Runtime metadata and implementation information.

[Winres.exe \(Windows Forms Resource Editor\)](#)

Helps you localize user interface (UI) resources (.resx or .resources files) that are used by Windows Forms. You can translate strings, and then size, move, and hide controls to accommodate the localized strings.

Additional class libraries and APIs

2/3/2019 • 2 minutes to read • [Edit Online](#)

The .NET Framework is constantly evolving. To improve cross-platform development and introduce new functionality early, new features are released out of band (OOB). This topic lists the OOB projects that we provide documentation for.

In addition, some libraries target specific platforms or implementations of the .NET Framework. For example, the [CodePagesEncodingProvider](#) class makes code page encodings available to UWP apps developed using the .NET Framework. This topic lists these libraries as well.

OOB projects

PROJECT	DESCRIPTION
System.Collections.Immutable	Provides collections that are thread safe and guaranteed to never change their contents.
WinHttpHandler	Provides a message handler for HttpClient based on the WinHTTP interface of Windows.
System.Numerics	Provides a library of vector types that can take advantage of SIMD hardware-based acceleration.
System.Threading.Tasks.Dataflow	The TPL Dataflow Library provides dataflow components to help increase the robustness of concurrency-enabled applications.

Platform-specific libraries

PROJECT	DESCRIPTION
CodePagesEncodingProvider	Extends the EncodingProvider class to make code page encodings available to apps that target the Universal Windows Platform.

Private APIs

These APIs support the product infrastructure and are not intended/supported to be used directly from your code.

API NAME

C# Guide

1/23/2019 • 3 minutes to read • [Edit Online](#)

The C# guide provides many resources about the C# language. This site has many different audiences. Depending on your experience with programming, or with the C# language and .NET, you may wish to explore different sections of this guide.

- For brand-new developers:
 - Start with the [Introduction to C# tutorials](#). These tutorials let you explore the C# language interactively in your browser. From there, you can move on to other [tutorials](#). These tutorials show you how to create C# programs from scratch. The tutorials provide a step-by-step process to create programs. They show the language concepts and how to build C# programs on your own. If you prefer reading overview information first, try the [tour of the C# language](#). It explains the concepts of the C# language. After reading this, you'll have a basic understanding of the language, and be ready to try the tutorials, or build something on your own.
- For developers new to C#:
 - If you've done development before, but are new to C#, read the [tour of the C# language](#). It covers the basic syntax and structure for the language, and you can use the language tour to contrast C# with other languages you've used. You can also browse the [tutorials](#) to try basic C# programs.
- Experienced C# developers:
 - If you've used C# before, you should start by reading what's in the latest version of the language. Check out [What's new in C#](#) for the new features in the current version.

How the C# guide is organized

There are several sections in the C# Guide. You can read them in order, or jump directly to what interests you the most. Some of the sections are heavily focused on the language. Others provide end-to-end scenarios that demonstrate a few of the types of programs you can create using C# and the .NET Framework.

- [Get Started](#)
 - This section covers what you need to install for a C# development environment on your preferred platform. The different topics under this section explain how to create your first C# program in different supported environments.
- [Introduction to C# tutorials](#):
 - Introduction to C# tutorials presents interactive tutorials for brand-new developers to explore and learn the C# language in the browser using a Read-Eval-Print Loop (REPL) interface. After you finish the interactive lessons, you can improve your coding skills by practicing the same lessons on your machine.
- [Tutorials](#)
 - This section provides a variety of end-to-end scenarios, including descriptions and code. It shows why certain idioms are preferred, what C# features work best in different situations, and reference implementations for common tasks. If you learn best by seeing code, start in this section. You can also download all the code and experiment in your own environment.
- [Tour of C#](#)
 - This section provides an overview of the language. It covers the elements that make up C# programs and the capabilities of the language. It shows small samples of all the syntax elements of C# and

discussions of the major C# language topics.

- [What's new in C#](#)
 - Provides overviews of new features added in the latest language releases and of the history of the C# language.
- [C# Programming Guide](#)
 - Provides information and practical examples about how to use C# language constructs.
- [Walkthroughs](#)
 - Provides links to programming walkthroughs that use C# and a brief description of each walkthrough.
- [Language Reference](#)
 - This section contains the reference material on the C# language. This material helps you understand the syntax and semantics of C#. It also includes reference material on types, operators, attributes, preprocessor directives, compiler switches, compiler errors, and compiler warnings.
- [C# Language Specification](#)
 - Links to the latest versions of the C# language specification.

- [C# Samples](#)

Get started with C#

1/23/2019 • 2 minutes to read • [Edit Online](#)

This section provides short, simple tutorials that let you quickly build an application using C# and .NET Core. There are getting started topics for Visual Studio 2017 and Visual Studio Code. You can build either a simple Hello World application or, if you have Visual Studio 2017, a simple class library that can be used by other applications.

The following topics are available:

- [Introduction to the C# Language and the .NET Framework](#)

Provides an overview of the C# language and .NET.

- [Building a C# Hello World application with .NET Core in Visual Studio 2017](#)

Visual Studio 2017, the latest release of Visual Studio, lets you code, compile, run, debug, profile, and publish your applications from an integrated development environment for Windows.

The topic lets you create and run a simple Hello World application and then modify it to run a slightly more interactive Hello World application. Once you've finished building and running your application, you can also learn how to [debug it](#) and how to [publish it](#) so that it can be run on any platform supported by .NET Core.

- [Building a class library with C# and .NET Core in Visual Studio 2017](#)

A class library lets you define types and type members that can be called from another application. This topic lets you create a class library with a single method that determines whether a string begins with an uppercase character. Once you've finished building the library, you can develop a [unit test](#) to ensure that it works as expected, and then you can make it available to [applications that want to consume it](#).

- [Get started with C# and Visual Studio Code](#)

Visual Studio Code is a free code editor optimized for building and debugging modern web and cloud applications. It supports IntelliSense and is available for Linux, macOS, and Windows.

This topic shows you how to create and run a simple Hello World application with Visual Studio Code and .NET Core.

Related Sections

C# Tutorials

3/15/2019 • 3 minutes to read • [Edit Online](#)

Welcome to the C# tutorials. These start with interactive lessons that you can run in your browser. Later tutorials, and more advanced tutorials help you work with the .NET development tools to create C# programs on your machine.

Introduction to C# interactive tutorials

The first lessons explain C# concepts using small snippets of code. You'll learn the basics of C# syntax and how to work with data types like strings, numbers, and booleans. It's all interactive, and you'll be writing and running code within minutes. These first lessons assume no prior knowledge of programming or the C# language.

Hello world

In the [Hello world](#) tutorial, you'll create the most basic C# program. You'll explore the `string` type and how to work with text.

Numbers in C#

In the [Numbers in C#](#) tutorial, you'll learn how computers store numbers and how to perform calculations with different numeric types. You'll learn the basics of rounding, and how to perform mathematical calculations using C#. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the [Hello world](#) lesson.

Branches and loops

The [Branches and loops](#) tutorial teaches the basics of selecting different paths of code execution based on the values stored in variables. You'll learn the basics of control flow, which is the basis of how programs make decisions and choose different actions. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the [Hello world](#) and [Numbers in C#](#) lessons.

String interpolation

The [String interpolation](#) tutorial shows you how to insert values into a string. You'll learn how to create an interpolated string with embedded C# expressions and how to control the text appearance of the expression results in the result string. This tutorial is also available [to run locally on your machine](#).

List collection

The [List collection](#) lesson gives you a tour of the List collection type that stores sequences of data. You'll learn how to add and remove items, search for items, and sort the lists. You'll explore different kinds of lists. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the lessons listed above.

Introduction to C# -- work locally

All the introductory tutorials following the Hello World lesson are available in your own local development

environment. At the end of each tutorial, you decide if you want to continue with the next lesson online or on your own machine. There are links to help you setup your environment and continue with the next tutorial on your machine.

Explore new features in C#

- [Try new features in C# 6 interactively](#): Explore the features added in [C# 6](#) interactively in your browser.
- [String Interpolation](#): demonstrates how to use string interpolation to create formatted strings in C#.
- [Nullable reference types](#): demonstrates how to use nullable reference types to express your intent for null references.
- [Update a project to make use of Nullable reference types](#): demonstrates techniques to upgrade an existing project to make use of nullable reference types.
- [Extend data capabilities using pattern matching](#): demonstrates how to use pattern matching to extend types beyond their core features.

General Tutorials

The following tutorials enable you to build C# programs using [.NET Core](#):

- [Console Application](#): demonstrates Console I/O, the structure of a Console application, and the basics of the task-based asynchronous programming model.
- [REST Client](#): demonstrates web communications, JSON serialization, and object-oriented features in the C# language.
- [Inheritance in C# and .NET](#): demonstrates inheritance in C#, including the use of inheritance to define base classes, abstract base classes, and derived classes.
- [Working with LINQ](#): demonstrates many of the features of LINQ and the language elements that support it.
- [Using Attributes](#): demonstrates how to create and use attributes in C#.

Introduction to C#

2/28/2019 • 2 minutes to read • [Edit Online](#)

Welcome to the introduction to C# tutorials. These start with interactive lessons that you can run in your browser.

The first lessons explain C# concepts using small snippets of code. You'll learn the basics of C# syntax and how to work with data types like strings, numbers, and booleans. It's all interactive, and you'll be writing and running code within minutes. These first lessons assume no prior knowledge of programming or the C# language.

All the introductory tutorials following the Hello World lesson are available using the online browser experience or [in your own local development environment](#). At the end of each tutorial, you decide if you want to continue with the next lesson online or on your own machine. There are links to help you set up your environment and continue with the next tutorial on your machine.

Hello world

In the [Hello world](#) tutorial, you'll create the most basic C# program. You'll explore the `string` type and how to work with text.

Numbers in C#

In the [Numbers in C#](#) tutorial, you'll learn how computers store numbers and how to perform calculations with different numeric types. You'll learn the basics of rounding, and how to perform mathematical calculations using C#. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the [Hello world](#) lesson.

Branches and loops

The [Branches and loops](#) tutorial teaches the basics of selecting different paths of code execution based on the values stored in variables. You'll learn the basics of control flow, which is the basis of how programs make decisions and choose different actions. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the [Hello world](#) and [Numbers in C#](#) lessons.

String interpolation

The [String interpolation](#) tutorial shows you how to insert values into a string. You'll learn how to create an interpolated string with embedded C# expressions and how to control the formatting of the output string. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the [Hello world](#), [Numbers in C#](#), and [Branches and loops](#) lessons.

List collection

The [List collection](#) lesson gives you a tour of the List collection type that stores sequences of data. You'll learn how to add and remove items, search for items, and sort the lists. You'll explore different kinds of lists. This tutorial is also available [to run locally on your machine](#).

This tutorial assumes that you have finished the lessons listed above.

Introduction to classes

This final tutorial is only available to run on your machine, using your own local development environment and .NET Core. You'll build a console application and see the basic object-oriented features that are part of the C# language.

This tutorial assumes you've finished the online introductory tutorials, and you've installed [.NET Core SDK](#) and [Visual Studio Code](#).

Become familiar with the .NET development tools

12/2/2018 • 2 minutes to read • [Edit Online](#)

The first step in running a tutorial on your machine is to set up a development environment. The .NET topic [Get Started in 10 minutes](#) has instructions for setting up your local development environment on Mac, PC or Linux.

Alternatively, you can install the [.NET Core SDK](#) and [Visual Studio Code](#).

Basic application development flow

You'll create applications using the `dotnet new` command. This command generates the files and assets necessary for your application. The introduction to C# tutorials all use the `console` application type. Once you've got the basics, you can expand to other application types.

The other commands you'll use are `dotnet build` to build the executable, and `dotnet run` to run the executable.

Pick your tutorial

You can start with any of the following tutorials:

Numbers in C#

In the [Numbers in C#](#) tutorial, you'll learn how computers store numbers and how to perform calculations with different numeric types. You'll learn the basics of rounding and how to perform mathematical calculations using C#.

This tutorial assumes that you have finished the [Hello world](#) lesson.

Branches and loops

The [Branches and loops](#) tutorial teaches the basics of selecting different paths of code execution based on the values stored in variables. You'll learn the basics of control flow, which is the basis of how programs make decisions and choose different actions.

This tutorial assumes that you have finished the [Hello world](#) and [Numbers in C#](#) lessons.

String interpolation

The [String interpolation](#) tutorial shows you how to insert values into a string. You'll learn how to create an interpolated string with embedded C# expressions and how to control the formatting of the result string.

This tutorial assumes that you have finished the [Hello world](#), [Numbers in C#](#), and [Branches and loops](#) lessons.

List collection

The [List collection](#) lesson gives you a tour of the List collection type that stores sequences of data. You'll learn how to add and remove items, search for items, and sort the lists. You'll explore different kinds of lists.

This tutorial assumes that you have finished the lessons listed above.

Introduction to classes

This final introduction to C# tutorial is only available to run on your machine, using your own local development environment and .NET Core. You'll build a console application and see the basic object-oriented features that are part of the C# language.

Manipulate integral and floating point numbers in C#

3/8/2019 • 8 minutes to read • [Edit Online](#)

This tutorial teaches you about the numeric types in C# interactively. You'll write small amounts of code, then you'll compile and run that code. The tutorial contains a series of lessons that explore numbers and math operations in C#. These lessons teach you the fundamentals of the C# language.

This tutorial expects you to have a machine you can use for development. The .NET topic [Get Started in 10 minutes](#) has instructions for setting up your local development environment on Mac, PC or Linux. A quick overview of the commands you'll use is in the [Become familiar with the development tools](#) with links to more details.

Explore integer math

Create a directory named **numbers-quickstart**. Make that the current directory and run

```
dotnet new console -n NumbersInCSharp -o ..
```

Open **Program.cs** in your favorite editor, and replace the line `Console.WriteLine("Hello World!");` with the following:

```
int a = 18;
int b = 6;
int c = a + b;
Console.WriteLine(c);
```

Run this code by typing `dotnet run` in your command window.

You've just seen one of the fundamental math operations with integers. The `int` type represents an **integer**, a positive or negative whole number. You use the `+` symbol for addition. Other common mathematical operations for integers include:

- `-` for subtraction
- `*` for multiplication
- `/` for division

Start by exploring those different operations. Add these lines after the line that writes the value of `c`:

```
c = a - b;
Console.WriteLine(c);
c = a * b;
Console.WriteLine(c);
c = a / b;
Console.WriteLine(c);
```

Run this code by typing `dotnet run` in your command window.

You can also experiment by performing multiple mathematics operations in the same line, if you'd like. Try `c = a + b - 12 * 17;` for example. Mixing variables and constant numbers is allowed.

TIP

As you explore C# (or any programming language), you'll make mistakes when you write code. The **compiler** will find those errors and report them to you. When the output contains error messages, look closely at the example code and the code in your window to see what to fix. That exercise will help you learn the structure of C# code.

You've finished the first step. Before you start the next section, let's move the current code into a separate method. That makes it easier to start working with a new example. Rename your `Main` method to `WorkingWithIntegers` and write a new `Main` method that calls `WorkingWithIntegers`. When you have finished, your code should look like this:

```
using System;

namespace NumbersInCSharp
{
    class Program
    {
        static void WorkingWithIntegers()
        {
            int a = 18;
            int b = 6;
            int c = a + b;
            Console.WriteLine(c);
            c = a - b;
            Console.WriteLine(c);
            c = a * b;
            Console.WriteLine(c);
            c = a / b;
            Console.WriteLine(c);
        }

        static void Main(string[] args)
        {
            WorkingWithIntegers();
        }
    }
}
```

Explore order of operations

Comment out the call to `WorkingWithIntegers()`. It will make the output less cluttered as you work in this section:

```
//WorkingWithIntegers();
```

The `//` starts a **comment** in C#. Comments are any text you want to keep in your source code but not execute as code. The compiler does not generate any executable code from comments.

The C# language defines the precedence of different mathematics operations with rules consistent with the rules you learned in mathematics. Multiplication and division take precedence over addition and subtraction. Explore that by adding the following code to your `Main` method, and executing `dotnet run`:

```
int a = 5;
int b = 4;
int c = 2;
int d = a + b * c;
Console.WriteLine(d);
```

The output demonstrates that the multiplication is performed before the addition.

You can force a different order of operation by adding parentheses around the operation or operations you want performed first. Add the following lines and run again:

```
d = (a + b) * c;  
Console.WriteLine(d);
```

Explore more by combining many different operations. Add something like the following lines at the bottom of your `Main` method. Try `dotnet run` again.

```
d = (a + b) - 6 * c + (12 * 4) / 3 + 12;  
Console.WriteLine(d);
```

You may have noticed an interesting behavior for integers. Integer division always produces an integer result, even when you'd expect the result to include a decimal or fractional portion.

If you haven't seen this behavior, try the following code at the end of your `Main` method:

```
int e = 7;  
int f = 4;  
int g = 3;  
int h = (e + f) / g;  
Console.WriteLine(h);
```

Type `dotnet run` again to see the results.

Before moving on, let's take all the code you've written in this section and put it in a new method. Call that new method `OrderPrecedence`. You should end up with something like this:

```

using System;

namespace NumbersInCSharp
{
    class Program
    {
        static void WorkingWithIntegers()
        {
            int a = 18;
            int b = 6;
            int c = a + b;
            Console.WriteLine(c);
            c = a - b;
            Console.WriteLine(c);
            c = a * b;
            Console.WriteLine(c);
            c = a / b;
            Console.WriteLine(c);
        }

        static void OrderPrecedence()
        {
            int a = 5;
            int b = 4;
            int c = 2;
            int d = a + b * c;
            Console.WriteLine(d);

            d = (a + b) * c;
            Console.WriteLine(d);

            d = (a + b) - 6 * c + (12 * 4) / 3 + 12;
            Console.WriteLine(d);

            int e = 7;
            int f = 4;
            int g = 3;
            int h = (e + f) / g;
            Console.WriteLine(h);
        }

        static void Main(string[] args)
        {
            WorkingWithIntegers();

            OrderPrecedence();
        }
    }
}

```

Explore integer precision and limits

That last sample showed you that integer division truncates the result. You can get the **remainder** by using the **modulo** operator, the `%` character. Try the following code in your `Main` method:

```

int a = 7;
int b = 4;
int c = 3;
int d = (a + b) / c;
int e = (a + b) % c;
Console.WriteLine($"quotient: {d}");
Console.WriteLine($"remainder: {e}");

```

The C# integer type differs from mathematical integers in one other way: the `int` type has minimum and maximum limits. Add this code to your `Main` method to see those limits:

```
int max = int.MaxValue;
int min = int.MinValue;
Console.WriteLine($"The range of integers is {min} to {max}");
```

If a calculation produces a value that exceeds those limits, you have an **underflow** or **overflow** condition. The answer appears to wrap from one limit to the other. Add these two lines to your `Main` method to see an example:

```
int what = max + 3;
Console.WriteLine($"An example of overflow: {what}");
```

Notice that the answer is very close to the minimum (negative) integer. It's the same as `min + 2`. The addition operation **overflowed** the allowed values for integers. The answer is a very large negative number because an overflow "wraps around" from the largest possible integer value to the smallest.

There are other numeric types with different limits and precision that you would use when the `int` type doesn't meet your needs. Let's explore those next.

Once again, let's move the code you wrote in this section into a separate method. Name it `TestLimits`.

Work with the `double` type

The `double` numeric type represents a double-precision floating point number. Those terms may be new to you. A **floating point** number is useful to represent non-integral numbers that may be very large or small in magnitude. **Double-precision** means that these numbers are stored using greater precision than **single-precision**. On modern computers, it is more common to use double precision than single precision numbers. Let's explore. Add the following code and see the result:

```
double a = 5;
double b = 4;
double c = 2;
double d = (a + b) / c;
Console.WriteLine(d);
```

Notice that the answer includes the decimal portion of the quotient. Try a slightly more complicated expression with doubles:

```
double e = 19;
double f = 23;
double g = 8;
double h = (e + f) / g;
Console.WriteLine(h);
```

The range of a double value is much greater than integer values. Try the following code below what you've written so far:

```
double max = double.MaxValue;
double min = double.MinValue;
Console.WriteLine($"The range of double is {min} to {max}");
```

These values are printed out in scientific notation. The number to the left of the `E` is the significand. The number to the right is the exponent, as a power of 10.

Just like decimal numbers in math, doubles in C# can have rounding errors. Try this code:

```
double third = 1.0 / 3.0;
Console.WriteLine(third);
```

You know that `0.3` repeating is not exactly the same as `1/3`.

Challenge

Try other calculations with large numbers, small numbers, multiplication and division using the `double` type. Try more complicated calculations.

After you've spent some time with the challenge, take the code you've written and place it in a new method.

Name that new method `WorkWithDoubles`.

Work with fixed point types

You've seen the basic numeric types in C#: integers and doubles. There is one other type to learn: the `decimal` type. The `decimal` type has a smaller range but greater precision than `double`. The term **fixed point** means that the decimal point (or binary point) doesn't move. Let's take a look:

```
decimal min = decimal.MinValue;
decimal max = decimal.MaxValue;
Console.WriteLine($"The range of the decimal type is {min} to {max}");
```

Notice that the range is smaller than the `double` type. You can see the greater precision with the decimal type by trying the following code:

```
double a = 1.0;
double b = 3.0;
Console.WriteLine(a / b);

decimal c = 1.0M;
decimal d = 3.0M;
Console.WriteLine(c / d);
```

The `M` suffix on the numbers is how you indicate that a constant should use the `decimal` type.

Notice that the math using the decimal type has more digits to the right of the decimal point.

Challenge

Now that you've seen the different numeric types, write code that calculates the area of a circle whose radius is 2.50 centimeters. Remember that the area of a circle is the radius squared multiplied by PI. One hint: .NET contains a constant for PI, [Math.PI](#) that you can use for that value.

You should get an answer between 19 and 20. You can check your answer by [looking at the finished sample code on GitHub](#)

Try some other formulas if you'd like.

You've completed the "Numbers in C#" quickstart. You can continue with the [Branches and loops](#) quickstart in your own development environment.

You can learn more about numbers in C# in the following topics:

- [Integral Types Table](#)

- [Floating-Point Types Table](#)
- [Built-In Types Table](#)
- [Implicit Numeric Conversions Table](#)
- [Explicit Numeric Conversions Table](#)

Learn conditional logic with branch and loop statements

3/8/2019 • 8 minutes to read • [Edit Online](#)

This tutorial teaches you how to write code that examines variables and changes the execution path based on those variables. You write C# code and see the results of compiling and running it. The tutorial contains a series of lessons that explore branching and looping constructs in C#. These lessons teach you the fundamentals of the C# language.

This tutorial expects you to have a machine you can use for development. The .NET topic [Get Started in 10 minutes](#) has instructions for setting up your local development environment on Mac, PC or Linux. A quick overview of the commands you'll use is in the [Become familiar with the development tools](#) with links to more details.

Make decisions using the `if` statement

Create a directory named **branches-tutorial**. Make that the current directory and run `dotnet new console -n BranchesAndLoops -o .`. This command creates a new .NET Core console application in the current directory.

Open **Program.cs** in your favorite editor, and replace the line `Console.WriteLine("Hello World!");` with the following code:

```
int a = 5;
int b = 6;
if (a + b > 10)
    Console.WriteLine("The answer is greater than 10.");
```

Try this code by typing `dotnet run` in your console window. You should see the message "The answer is greater than 10." printed to your console.

Modify the declaration of `b` so that the sum is less than 10:

```
int b = 3;
```

Type `dotnet run` again. Because the answer is less than 10, nothing is printed. The **condition** you're testing is false. You don't have any code to execute because you've only written one of the possible branches for an `if` statement: the true branch.

TIP

As you explore C# (or any programming language), you'll make mistakes when you write code. The compiler will find and report the errors. Look closely at the error output and the code that generated the error. The compiler error can usually help you find the problem.

This first sample shows the power of `if` and Boolean types. A *Boolean* is a variable that can have one of two values: `true` or `false`. C# defines a special type, `bool` for Boolean variables. The `if` statement checks the value of a `bool`. When the value is `true`, the statement following the `if` executes. Otherwise, it is skipped.

This process of checking conditions and executing statements based on those conditions is very powerful.

Make if and else work together

To execute different code in both the true and false branches, you create an `else` branch that executes when the condition is false. Try this. Add the last two lines in the code below to your `Main` method (you should already have the first four):

```
int a = 5;
int b = 3;
if (a + b > 10)
    Console.WriteLine("The answer is greater than 10");
else
    Console.WriteLine("The answer is not greater than 10");
```

The statement following the `else` keyword executes only when the condition being tested is `false`. Combining `if` and `else` with Boolean conditions provides all the power you need to handle both a `true` and a `false` condition.

IMPORTANT

The indentation under the `if` and `else` statements is for human readers. The C# language doesn't treat indentation or white space as significant. The statement following the `if` or `else` keyword will be executed based on the condition. All the samples in this tutorial follow a common practice to indent lines based on the control flow of statements.

Because indentation is not significant, you need to use `{` and `}` to indicate when you want more than one statement to be part of the block that executes conditionally. C# programmers typically use those braces on all `if` and `else` clauses. The following example is the same as the one you just created. Modify your code above to match the following code:

```
int a = 5;
int b = 3;
if (a + b > 10)
{
    Console.WriteLine("The answer is greater than 10");
}
else
{
    Console.WriteLine("The answer is not greater than 10");
}
```

TIP

Through the rest of this tutorial, the code samples all include the braces, following accepted practices.

You can test more complicated conditions. Add the following code in your `Main` method after the code you've written so far:

```
int c = 4;
if ((a + b + c > 10) && (a > b))
{
    Console.WriteLine("The answer is greater than 10");
    Console.WriteLine("And the first number is greater than the second");
}
else
{
    Console.WriteLine("The answer is not greater than 10");
    Console.WriteLine("Or the first number is not greater than the second");
}
```

The `&&` represents "and". It means both conditions must be true to execute the statement in the true branch. These examples also show that you can have multiple statements in each conditional branch, provided you enclose them in `{` and `}`.

You can also use `||` to represent "or". Add the following code after what you've written so far:

```
if ((a + b + c > 10) || (a > b))
{
    Console.WriteLine("The answer is greater than 10");
    Console.WriteLine("Or the first number is greater than the second");
}
else
{
    Console.WriteLine("The answer is not greater than 10");
    Console.WriteLine("And the first number is not greater than the second");
}
```

You've finished the first step. Before you start the next section, let's move the current code into a separate method. That makes it easier to start working with a new example. Rename your `Main` method to `ExploreIf` and write a new `Main` method that calls `ExploreIf`. When you have finished, your code should look like this:

```

using System;

namespace BranchesAndLoops
{
    class Program
    {
        static void ExploreIf()
        {
            int a = 5;
            int b = 3;
            if (a + b > 10)
            {
                Console.WriteLine("The answer is greater than 10");
            }
            else
            {
                Console.WriteLine("The answer is not greater than 10");
            }

            if ((a + b + c > 10) && (a > b))
            {
                Console.WriteLine("The answer is greater than 10");
                Console.WriteLine("And the first number is greater than the second");
            }
            else
            {
                Console.WriteLine("The answer is not greater than 10");
                Console.WriteLine("Or the first number is not greater than the second");
            }

            if ((a + b + c > 10) || (a > b))
            {
                Console.WriteLine("The answer is greater than 10");
                Console.WriteLine("Or the first number is greater than the second");
            }
            else
            {
                Console.WriteLine("The answer is not greater than 10");
                Console.WriteLine("And the first number is not greater than the second");
            }
        }

        static void Main(string[] args)
        {
            ExploreIf();
        }
    }
}

```

Comment out the call to `ExploreIf()`. It will make the output less cluttered as you work in this section:

```
//ExploreIf();
```

The `//` starts a **comment** in C#. Comments are any text you want to keep in your source code but not execute as code. The compiler does not generate any executable code from comments.

Use loops to repeat operations

In this section you use **loops** to repeat statements. Try this code in your `Main` method:

```
int counter = 0;
while (counter < 10)
{
    Console.WriteLine($"Hello World! The counter is {counter}");
    counter++;
}
```

The `while` statement checks a condition and executes the statement or statement block following the `while`. It repeatedly checks the condition and executing those statements until the condition is false.

There's one other new operator in this example. The `++` after the `counter` variable is the **increment** operator. It adds 1 to the value of `counter` and stores that value in the `counter` variable.

IMPORTANT

Make sure that the `while` loop condition changes to false as you execute the code. Otherwise, you create an **infinite loop** where your program never ends. That is not demonstrated in this sample, because you have to force your program to quit using **CTRL-C** or other means.

The `while` loop tests the condition before executing the code following the `while`. The `do ... while` loop executes the code first, and then checks the condition. The do while loop is shown in the following code:

```
counter = 0;
do
{
    Console.WriteLine($"Hello World! The counter is {counter}");
    counter++;
} while (counter < 10);
```

This `do` loop and the earlier `while` loop produce the same output.

Work with the `for` loop

The `for` loop is commonly used in C#. Try this code in your `Main()` method:

```
for(int index = 0; index < 10; index++)
{
    Console.WriteLine($"Hello World! The index is {index}");
}
```

This does the same work as the `while` loop and the `do` loop you've already used. The `for` statement has three parts that control how it works.

The first part is the **for initializer**: `int index = 0;` declares that `index` is the loop variable, and sets its initial value to `0`.

The middle part is the **for condition**: `index < 10` declares that this `for` loop continues to execute as long as the value of counter is less than 10.

The final part is the **for iterator**: `index++` specifies how to modify the loop variable after executing the block following the `for` statement. Here, it specifies that `index` should be incremented by 1 each time the block executes.

Experiment with these yourself. Try each of the following:

- Change the initializer to start at a different value.

- Change the condition to stop at a different value.

When you're done, let's move on to write some code yourself to use what you've learned.

Combine branches and loops

Now that you've seen the `if` statement and the looping constructs in the C# language, see if you can write C# code to find the sum of all integers 1 through 20 that are divisible by 3. Here are a few hints:

- The `%` operator gives you the remainder of a division operation.
- The `if` statement gives you the condition to see if a number should be part of the sum.
- The `for` loop can help you repeat a series of steps for all the numbers 1 through 20.

Try it yourself. Then check how you did. You should get 63 for an answer. You can see one possible answer by [viewing the completed code on GitHub](#).

You've completed the "branches and loops" tutorial.

You can continue with the [String interpolation](#) tutorial in your own development environment.

You can learn more about these concepts in these topics:

- [If and else statement](#)
- [While statement](#)
- [Do statement](#)
- [For statement](#)

Use string interpolation to construct formatted strings

10/27/2018 • 7 minutes to read • [Edit Online](#)

This tutorial teaches you how to use C# [string interpolation](#) to insert values into a single result string. You write C# code and see the results of compiling and running it. The tutorial contains a series of lessons that show you how to insert values into a string and format those values in different ways.

This tutorial expects that you have a machine you can use for development. The .NET topic [Get Started in 10 minutes](#) has instructions for setting up your local development environment on Mac, PC or Linux. A quick overview of the commands you'll use is in [introduction to the local tutorials](#), with links to more details. You also can complete the [interactive version](#) of this tutorial in your browser.

Create an interpolated string

Create a directory named **interpolated**. Make it the current directory and run the following command from a console window:

```
dotnet new console
```

This command creates a new .NET Core console application in the current directory.

Open **Program.cs** in your favorite editor, and replace the line `Console.WriteLine("Hello World!");` with the following code, where you replace `<name>` with your name:

```
var name = "<name>";
Console.WriteLine($"Hello, {name}. It's a pleasure to meet you!");
```

Try this code by typing `dotnet run` in your console window. When you run the program, it displays a single string that includes your name in the greeting. The string included in the [WriteLine](#) method call is an *interpolated string*. It's a kind of template that lets you construct a single string (called the *result string*) from a string that includes embedded code. Interpolated strings are particularly useful for inserting values into a string or concatenating (joining together) strings.

This simple example contains the two elements that every interpolated string must have:

- A string literal that begins with the `$` character before its opening quotation mark character. There can't be any spaces between the `$` symbol and the quotation mark character. (If you'd like to see what happens if you include one, insert a space after the `$` character, save the file, and run the program again by typing `dotnet run` in the console window. The C# compiler displays an error message, "error CS1056: Unexpected character '\$'".)
- One or more *interpolated expressions*. An interpolated expression is indicated by an opening and closing brace (`{` and `}`). You can put any C# expression that returns a value (including `null`) inside the braces.

Let's try a few more string interpolation examples with some other data types.

Include different data types

In the previous section, you used string interpolation to insert one string inside of another. The result of an

interpolated expression can be of any data type, though. Let's include values of various data types in an interpolated string.

In the following example, we first define a `class` data type `Vegetable` that has a `Name` `property` and a `ToString` `method`, which `overrides` the behavior of the `Object.ToString()` method. The `public` `access modifier` makes that method available to any client code to get the string representation of a `Vegetable` instance. In the example the `Vegetable.ToString` method returns the value of the `Name` property that is initialized at the `Vegetable` `constructor`:

```
public Vegetable(string name) => Name = name;
```

Then we create an instance of the `Vegetable` class named `item` by using the `new` `keyword` and providing a name for the constructor `Vegetable`:

```
var item = new Vegetable("eggplant");
```

Finally, we include the `item` variable into an interpolated string that also contains a `DateTime` value, a `Decimal` value, and a `Unit` `enumeration` value. Replace all of the C# code in your editor with the following code, and then use the `dotnet run` command to run it:

```
using System;

public class Vegetable
{
    public Vegetable(string name) => Name = name;

    public string Name { get; }

    public override string ToString() => Name;
}

public class Program
{
    public enum Unit { item, kilogram, gram, dozen };

    public static void Main()
    {
        var item = new Vegetable("eggplant");
        var date = DateTime.Now;
        var price = 1.99m;
        var unit = Unit.item;
        Console.WriteLine($"On {date}, the price of {item} was {price} per {unit}.");
    }
}
```

Note that the interpolated expression `item` in the interpolated string resolves to the text "eggplant" in the result string. That's because, when the type of the expression result is not a string, the result is resolved to a string in the following way:

- If the interpolated expression evaluates to `null`, an empty string ("") or `String.Empty`) is used.
- If the interpolated expression doesn't evaluate to `null`, typically the `ToString` method of the result type is called. You can test this by updating the implementation of the `Vegetable.ToString` method. You might not even need to implement the `ToString` method since every type has some implementation of this method. To test this, comment out the definition of the `Vegetable.ToString` method in the example (to do that, put a comment symbol, `//`, in front of it). In the output, the string "eggplant" is replaced by the fully qualified type name ("Vegetable" in this example), which is the default behavior of the `Object.ToString()` method. The

default behavior of the `ToString` method for an enumeration value is to return the string representation of the value.

In the output from this example, the date is too precise (the price of eggplant doesn't change every second), and the price value doesn't indicate a unit of currency. In the next section, you'll learn how to fix those issues by controlling the format of string representations of the expression results.

Control the formatting of interpolated expressions

In the previous section, two poorly formatted strings were inserted into the result string. One was a date and time value for which only the date was appropriate. The second was a price that didn't indicate its unit of currency. Both issues are easy to address. String interpolation lets you specify *format strings* that control the formatting of particular types. Modify the call to `Console.WriteLine` from the previous example to include the format strings for the date and price expressions as shown in the following line:

```
Console.WriteLine($"On {date:d}, the price of {item} was {price:C2} per {unit}.");
```

You specify a format string by following the interpolated expression with a colon (":") and the format string. "d" is a [standard date and time format string](#) that represents the short date format. "C2" is a [standard numeric format string](#) that represents a number as a currency value with two digits after the decimal point.

A number of types in the .NET libraries support a predefined set of format strings. These include all the numeric types and the date and time types. For a complete list of types that support format strings, see [Format Strings and .NET Class Library Types](#) in the [Formatting Types in .NET](#) article.

Try modifying the format strings in your text editor and, each time you make a change, rerun the program to see how the changes affect the formatting of the date and time and the numeric value. Change the "d" in `{date:d}` to "t" (to display the short time format), "y" (to display the year and month), and "yyyy" (to display the year as a four-digit number). Change the "C2" in `{price:C2}` to "e" (for exponential notation) and "F3" (for a numeric value with three digits after the decimal point).

In addition to controlling formatting, you can also control the field width and alignment of the formatted strings that are included in the result string. In the next section, you'll learn how to do this.

Control the field width and alignment of interpolated expressions

Ordinarily, when the result of an interpolated expression is formatted to string, that string is included in a result string without leading or trailing spaces. Particularly when you work with a set of data, being able to control a field width and text alignment helps to produce a more readable output. To see this, replace all the code in your text editor with the following code, then type `dotnet run` to execute the program:

```

using System;
using System.Collections.Generic;

public class Example
{
    public static void Main()
    {
        var titles = new Dictionary<string, string>()
        {
            ["Doyle, Arthur Conan"] = "Hound of the Baskervilles, The",
            ["London, Jack"] = "Call of the Wild, The",
            ["Shakespeare, William"] = "Tempest, The"
        };

        Console.WriteLine("Author and Title List");
        Console.WriteLine();
        Console.WriteLine($"|{\"Author\", -25}|{\"Title\", 30}|");
        foreach (var title in titles)
            Console.WriteLine($"|{title.Key, -25}|{title.Value, 30}|");
    }
}

```

The names of authors are left-aligned, and the titles they wrote are right-aligned. You specify the alignment by adding a comma (",") after an interpolated expression and designating the *minimum* field width. If the specified value is a positive number, the field is right-aligned. If it is a negative number, the field is left-aligned.

Try removing the negative signs from the `{\"Author\", -25}` and `{title.Key, -25}` code and run the example again, as the following code does:

```

Console.WriteLine($"|{\"Author\", 25}|{\"Title\", 30}|");
foreach (var title in titles)
    Console.WriteLine($"|{title.Key, 25}|{title.Value, 30}|");

```

This time, the author information is right-aligned.

You can combine an alignment specifier and a format string for a single interpolated expression. To do that, specify the alignment first, followed by a colon and the format string. Replace all of the code inside the `Main` method with the following code, which displays three formatted strings with defined field widths. Then run the program by entering the `dotnet run` command.

```
Console.WriteLine($"[{DateTime.Now, -20:d}] Hour [{DateTime.Now, -10:HH}] [{1063.342, 15:N2}] feet");
```

The output looks something like the following:

[04/14/2018] Hour [16] [1,063.34] feet
-------------	------------	-----	----------------

You've completed the string interpolation tutorial.

You can continue with the [List collection](#) tutorial in your own development environment.

For more information, see the [String interpolation](#) topic and the [String interpolation in C#](#) tutorial.

Learn to manage data collections using the generic list type

2/14/2019 • 5 minutes to read • [Edit Online](#)

This introductory tutorial provides an introduction to the C# language and the basics of the `List<T>` class.

This tutorial expects you to have a machine you can use for development. The .NET topic [Get Started in 10 minutes](#) has instructions for setting up your local development environment on Mac, PC or Linux. A quick overview of the commands you'll use is in [Become familiar with the development tools](#), with links to more details.

A basic list example

Create a directory named **list-tutorial**. Make that the current directory and run `dotnet new console`.

Open **Program.cs** in your favorite editor, and replace the existing code with the following:

```
using System;
using System.Collections.Generic;

namespace list_tutorial
{
    class Program
    {
        static void Main(string[] args)
        {
            var names = new List<string> { "<name>", "Ana", "Felipe" };
            foreach (var name in names)
            {
                Console.WriteLine($"Hello {name.ToUpper()}!");
            }
        }
    }
}
```

Replace `<name>` with your name. Save **Program.cs**. Type `dotnet run` in your console window to try it.

You've just created a list of strings, added three names to that list, and printed out the names in all CAPS. You're using concepts that you've learned in earlier tutorials to loop through the list.

The code to display names makes use of the [string interpolation](#) feature. When you precede a `string` with the `$` character, you can embed C# code in the string declaration. The actual string replaces that C# code with the value it generates. In this example, it replaces the `{name.ToUpper()}` with each name, converted to capital letters, because you called the [ToUpper](#) method.

Let's keep exploring.

Modify list contents

The collection you created uses the `List<T>` type. This type stores sequences of elements. You specify the type of the elements between the angle brackets.

One important aspect of this `List<T>` type is that it can grow or shrink, enabling you to add or remove elements. Add this code before the closing `}` in the `Main` method:

```
Console.WriteLine();
names.Add("Maria");
names.Add("Bill");
names.Remove("Ana");
foreach (var name in names)
{
    Console.WriteLine($"Hello {name.ToUpper()}!");
}
```

You've added two more names to the end of the list. You've also removed one as well. Save the file, and type

`dotnet run` to try it.

The `List<T>` enables you to reference individual items by **index** as well. You place the index between `[` and `]` tokens following the list name. C# uses 0 for the first index. Add this code directly below the code you just added and try it:

```
Console.WriteLine($"My name is {names[0]}");
Console.WriteLine($"I've added {names[2]} and {names[3]} to the list");
```

You cannot access an index beyond the end of the list. Remember that indices start at 0, so the largest valid index is one less than the number of items in the list. You can check how long the list is using the `Count` property. Add the following code at the end of the `Main` method:

```
Console.WriteLine($"The list has {names.Count} people in it");
```

Save the file, and type `dotnet run` again to see the results.

Search and sort lists

Our samples use relatively small lists, but your applications may often create lists with many more elements, sometimes numbering in the thousands. To find elements in these larger collections, you need to search the list for different items. The `IndexOf` method searches for an item and returns the index of the item. Add this code to the bottom of your `Main` method:

```
var index = names.IndexOf("Felipe");
if (index == -1)
{
    Console.WriteLine($"When an item is not found, IndexOf returns {index}");
} else
{
    Console.WriteLine($"The name {names[index]} is at index {index}");
}

index = names.IndexOf("Not Found");
if (index == -1)
{
    Console.WriteLine($"When an item is not found, IndexOf returns {index}");
} else
{
    Console.WriteLine($"The name {names[index]} is at index {index}");
}
```

The items in your list can be sorted as well. The `Sort` method sorts all the items in the list in their normal order (alphabetically in the case of strings). Add this code to the bottom of our `Main` method:

```

names.Sort();
foreach (var name in names)
{
    Console.WriteLine($"Hello {name.ToUpper()}!");
}

```

Save the file and type `dotnet run` to try this latest version.

Before you start the next section, let's move the current code into a separate method. That makes it easier to start working with a new example. Rename your `Main` method to `WorkingWithStrings` and write a new `Main` method that calls `WorkingWithStrings`. When you have finished, your code should look like this:

```

using System;
using System.Collections.Generic;

namespace list_tutorial
{
    class Program
    {
        static void Main(string[] args)
        {
            WorkingWithStrings();
        }

        public static void WorkingWithStrings()
        {
            var names = new List<string> { "<name>", "Ana", "Felipe" };
            foreach (var name in names)
            {
                Console.WriteLine($"Hello {name.ToUpper()}!");
            }

            Console.WriteLine();
            names.Add("Maria");
            names.Add("Bill");
            names.Remove("Ana");
            foreach (var name in names)
            {
                Console.WriteLine($"Hello {name.ToUpper()}!");
            }

            Console.WriteLine($"My name is {names[0]}");
            Console.WriteLine($"I've added {names[2]} and {names[3]} to the list");

            Console.WriteLine($"The list has {names.Count} people in it");

            var index = names.IndexOf("Felipe");
            Console.WriteLine($"The name {names[index]} is at index {index}");

            var notFound = names.IndexOf("Not Found");
            Console.WriteLine($"When an item is not found, IndexOf returns {notFound}");

            names.Sort();
            foreach (var name in names)
            {
                Console.WriteLine($"Hello {name.ToUpper()}!");
            }
        }
    }
}

```

Lists of other types

You've been using the `string` type in lists so far. Let's make a `List<T>` using a different type. Let's build a set of numbers.

Add the following to the bottom of your new `Main` method:

```
var fibonacciNumbers = new List<int> {1, 1};
```

That creates a list of integers, and sets the first two integers to the value 1. These are the first two values of a *Fibonacci Sequence*, a sequence of numbers. Each next Fibonacci number is found by taking the sum of the previous two numbers. Add this code:

```
var previous = fibonacciNumbers[fibonacciNumbers.Count - 1];
var previous2 = fibonacciNumbers[fibonacciNumbers.Count - 2];

fibonacciNumbers.Add(previous + previous2);

foreach(var item in fibonacciNumbers)
    Console.WriteLine(item);
```

Save the file and type `dotnet run` to see the results.

TIP

To concentrate on just this section, you can comment out the code that calls `WorkingWithStrings();`. Just put two `/` characters in front of the call like this: `// WorkingWithStrings();`.

Challenge

See if you can put together some of the concepts from this and earlier lessons. Expand on what you've built so far with Fibonacci Numbers. Try to write the code to generate the first 20 numbers in the sequence. (As a hint, the 20th Fibonacci number is 6765.)

Complete challenge

You can see an example solution by [looking at the finished sample code on GitHub](#)

With each iteration of the loop, you're taking the last two integers in the list, summing them, and adding that value to the list. The loop repeats until you've added 20 items to the list.

Congratulations, you've completed the list tutorial. You can continue with the [Introduction to classes](#) tutorial in your own development environment.

You can learn more about working with the `List` type in the [.NET Guide](#) topic on [collections](#). You'll also learn about many other collection types.

Explore object oriented programming with classes and objects

1/29/2019 • 8 minutes to read • [Edit Online](#)

This tutorial expects that you have a machine you can use for development. The .NET topic [Get Started in 10 minutes](#) has instructions for setting up your local development environment on Mac, PC or Linux. A quick overview of the commands you'll use is in the [Become familiar with the development tools](#) with links to more details.

Create your application

Using a terminal window, create a directory named **classes**. You'll build your application there. Change to that directory and type `dotnet new console` in the console window. This command creates your application. Open **Program.cs**. It should look like this:

```
using System;

namespace classes
{
    class Program
    {
        static void Main(string[] args)
        {
            Console.WriteLine("Hello World!");
        }
    }
}
```

In this tutorial, you're going to create new types that represent a bank account. Typically developers define each class in a different text file. That makes it easier to manage as a program grows in size. Create a new file named **BankAccount.cs** in the **classes** directory.

This file will contain the definition of a **bank account**. Object Oriented programming organizes code by creating types in the form of **classes**. These classes contain the code that represents a specific entity. The `BankAccount` class represents a bank account. The code implements specific operations through methods and properties. In this tutorial, the bank account supports this behavior:

1. It has a 10-digit number that uniquely identifies the bank account.
2. It has a string that stores the name or names of the owners.
3. The balance can be retrieved.
4. It accepts deposits.
5. It accepts withdrawals.
6. The initial balance must be positive.
7. Withdrawals cannot result in a negative balance.

Define the bank account type

You can start by creating the basics of a class that defines that behavior. It would look like this:

```

using System;

namespace classes
{
    public class BankAccount
    {
        public string Number { get; }
        public string Owner { get; set; }
        public decimal Balance { get; }

        public void MakeDeposit(decimal amount, DateTime date, string note)
        {
        }

        public void MakeWithdrawal(decimal amount, DateTime date, string note)
        {
        }
    }
}

```

Before going on, let's take a look at what you've built. The `namespace` declaration provides a way to logically organize your code. This tutorial is relatively small, so you'll put all the code in one namespace.

`public class BankAccount` defines the class, or type, you are creating. Everything inside the `{` and `}` that follows the class declaration defines the behavior of the class. There are five **members** of the `BankAccount` class. The first three are **properties**. Properties are data elements and can have code that enforces validation or other rules. The last two are **methods**. Methods are blocks of code that perform a single function. Reading the names of each of the members should provide enough information for you or another developer to understand what the class does.

Open a new account

The first feature to implement is to open a bank account. When a customer opens an account, they must supply an initial balance, and information about the owner or owners of that account.

Creating a new object of the `BankAccount` type means defining a **constructor** that assigns those values. A **constructor** is a member that has the same name as the class. It is used to initialize objects of that class type. Add the following constructor to the `BankAccount` type:

```

public BankAccount(string name, decimal initialBalance)
{
    this.Owner = name;
    this.Balance = initialBalance;
}

```

Constructors are called when you create an object using `new`. Replace the line

`Console.WriteLine("Hello World!");` in `program.cs` with the following line (replace `<name>` with your name):

```

var account = new BankAccount("<name>", 1000);
Console.WriteLine($"Account {account.Number} was created for {account.Owner} with {account.Balance} initial
balance.");

```

Type `dotnet run` to see what happens.

Did you notice that the account number is blank? It's time to fix that. The account number should be assigned when the object is constructed. But it shouldn't be the responsibility of the caller to create it. The `BankAccount` class code should know how to assign new account numbers. A simple way to do this is to start with a 10-digit number. Increment it when each new account is created. Finally, store the current account number when an object is

constructed.

Add the following member declaration to the `BankAccount` class:

```
private static int accountNumberSeed = 1234567890;
```

This is a data member. It's `private`, which means it can only be accessed by code inside the `BankAccount` class. It's a way of separating the public responsibilities (like having an account number) from the private implementation (how account numbers are generated.) It is also `static`, which means it is shared by all of the `BankAccount` objects. The value of a non-static variable is unique to each instance of the `BankAccount` object. Add the following two lines to the constructor to assign the account number:

```
this.Number = accountNumberSeed.ToString();
accountNumberSeed++;
```

Type `dotnet run` to see the results.

Create deposits and withdrawals

Your bank account class needs to accept deposits and withdrawals to work correctly. Let's implement deposits and withdrawals by creating a journal of every transaction for the account. That has a few advantages over simply updating the balance on each transaction. The history can be used to audit all transactions and manage daily balances. By computing the balance from the history of all transactions when needed, any errors in a single transaction that are fixed will be correctly reflected in the balance on the next computation.

Let's start by creating a new type to represent a transaction. This is a simple type that doesn't have any responsibilities. It needs a few properties. Create a new file named `Transaction.cs`. Add the following code to it:

```
using System;

namespace classes
{
    public class Transaction
    {
        public decimal Amount { get; }
        public DateTime Date { get; }
        public string Notes { get; }

        public Transaction(decimal amount, DateTime date, string note)
        {
            this.Amount = amount;
            this.Date = date;
            this.Notes = note;
        }
    }
}
```

Now, let's add a `List<T>` of `Transaction` objects to the `BankAccount` class. Add the following declaration:

```
private List<Transaction> allTransactions = new List<Transaction>();
```

The `List<T>` class requires you to import a different namespace. Add the following at the beginning of `BankAccount.cs`:

```
using System.Collections.Generic;
```

Now, let's change how the `Balance` is reported. It can be found by summing the values of all transactions. Modify the declaration of `Balance` in the `BankAccount` class to the following:

```
public decimal Balance
{
    get
    {
        decimal balance = 0;
        foreach (var item in allTransactions)
        {
            balance += item.Amount;
        }

        return balance;
    }
}
```

This example shows an important aspect of **properties**. You're now computing the balance when another programmer asks for the value. Your computation enumerates all transactions, and provides the sum as the current balance.

Next, implement the `MakeDeposit` and `MakeWithdrawal` methods. These methods will enforce the final two rules: that the initial balance must be positive, and that any withdrawal must not create a negative balance.

This introduces the concept of **exceptions**. The standard way of indicating that a method cannot complete its work successfully is to throw an exception. The type of exception and the message associated with it describe the error. Here, the `MakeDeposit` method throws an exception if the amount of the deposit is negative. The `MakeWithdrawal` method throws an exception if the withdrawal amount is negative, or if applying the withdrawal results in a negative balance:

```
public void MakeDeposit(decimal amount, DateTime date, string note)
{
    if (amount <= 0)
    {
        throw new ArgumentOutOfRangeException(nameof(amount), "Amount of deposit must be positive");
    }
    var deposit = new Transaction(amount, date, note);
    allTransactions.Add(deposit);
}

public void MakeWithdrawal(decimal amount, DateTime date, string note)
{
    if (amount <= 0)
    {
        throw new ArgumentOutOfRangeException(nameof(amount), "Amount of withdrawal must be positive");
    }
    if (Balance - amount < 0)
    {
        throw new InvalidOperationException("Not sufficient funds for this withdrawal");
    }
    var withdrawal = new Transaction(-amount, date, note);
    allTransactions.Add(withdrawal);
}
```

The `throw` statement **throws** an exception. Execution of the current block ends, and control transfers to the first matching `catch` block found in the call stack. You'll add a `catch` block to test this code a little later on.

The constructor should get one change so that it adds an initial transaction, rather than updating the balance directly. Since you already wrote the `MakeDeposit` method, call it from your constructor. The finished constructor should look like this:

```

public BankAccount(string name, decimal initialBalance)
{
    this.Number = accountNumberSeed.ToString();
    accountNumberSeed++;

    this.Owner = name;
    MakeDeposit(initialBalance, DateTime.Now, "Initial balance");
}

```

`DateTime.Now` is a property that returns the current date and time. Test this by adding a few deposits and withdrawals in your `Main` method:

```

account.MakeWithdrawal(500, DateTime.Now, "Rent payment");
Console.WriteLine(account.Balance);
account.MakeDeposit(100, DateTime.Now, "Friend paid me back");
Console.WriteLine(account.Balance);

```

Next, test that you are catching error conditions by trying to create an account with a negative balance:

```

// Test that the initial balances must be positive.
try
{
    var invalidAccount = new BankAccount("invalid", -55);
}
catch (ArgumentOutOfRangeException e)
{
    Console.WriteLine("Exception caught creating account with negative balance");
    Console.WriteLine(e.ToString());
}

```

You use the `try` and `catch` statements to mark a block of code that may throw exceptions and to catch those errors that you expect. You can use the same technique to test the code that throws an exception for a negative balance:

```

// Test for a negative balance:
try
{
    account.MakeWithdrawal(750, DateTime.Now, "Attempt to overdraw");
}
catch (InvalidOperationException e)
{
    Console.WriteLine("Exception caught trying to overdraw");
    Console.WriteLine(e.ToString());
}

```

Save the file and type `dotnet run` to try it.

Challenge - log all transactions

To finish this tutorial, you can write the `GetAccountHistory` method that creates a `string` for the transaction history. Add this method to the `BankAccount` type:

```
public string GetAccountHistory()
{
    var report = new System.Text.StringBuilder();

    report.AppendLine("Date\tAmount\tNote");
    foreach (var item in allTransactions)
    {
        report.AppendLine($"{item.Date.ToShortDateString()}\t{item.Amount}\t{item.Notes}");
    }

    return report.ToString();
}
```

This uses the [StringBuilder](#) class to format a string that contains one line for each transaction. You've seen the string formatting code earlier in these tutorials. One new character is `\t`. That inserts a tab to format the output.

Add this line to test it in **Program.cs**:

```
Console.WriteLine(account.GetAccountHistory());
```

Type `dotnet run` to see the results.

Tutorial: Express your design intent more clearly with nullable and non-nullable reference types

3/14/2019 • 10 minutes to read • [Edit Online](#)

C# 8 introduces **nullable reference types**, which complement reference types the same way nullable value types complement value types. You declare a variable to be a **nullable reference type** by appending a `?` to the type. For example, `string?` represents a nullable `string`. You can use these new types to more clearly express your design intent: some variables *must always have a value*, others *may be missing a value*.

In this tutorial, you'll learn how to:

- Incorporate nullable and non-nullable reference types into your designs
- Enable nullable reference type checks throughout your code.
- Write code where the compiler enforces those design decisions.
- Use the nullable reference feature in your own designs

Prerequisites

You'll need to set up your machine to run .NET Core, including the C# 8.0 beta compiler. The C# 8 beta compiler is available with [Visual Studio 2019 preview 4](#), or [.NET Core 3.0 preview 3](#).

This tutorial assumes you're familiar with C# and .NET, including either Visual Studio or the .NET Core CLI.

Incorporate nullable reference types into your designs

In this tutorial, you'll build a library that models running a survey. The code uses both nullable reference types and non-nullable reference types to represent the real-world concepts. The survey questions can never be null. A respondent might prefer not to answer a question. The responses might be null in this case.

The code you'll write for this sample expresses that intent, and the compiler enforces that intent.

Create the application and enable nullable reference types

Create a new console application either in Visual Studio or from the command line using `dotnet new console`.

Name the application `NullableIntroduction`. Once you've created the application, you'll need to enable C# 8 beta features. Open the `csproj` file and add a `LangVersion` element to the `PropertyGroup` element. You must opt into the **nullable reference types** feature, even in C# 8 projects. That's because once the feature is turned on, existing reference variable declarations become **non-nullable reference types**. While that decision will help find issues where existing code may not have proper null-checks, it may not accurately reflect your original design intent. You turn on the feature by setting the `NullableContextOptions` element to `enable`:

```
<LangVersion>8.0</LangVersion>
<NullableContextOptions>enable</NullableContextOptions>
```

NOTE

When C# 8 is released (not in preview mode), the `NullableContextOptions` element will be added by new project templates. Until then, you'll need to add it manually.

Design the types for the application

This survey application requires creating a number of classes:

- A class that models the list of questions.
- A class that models a list of people contacted for the survey.
- A class that models the answers from a person that took the survey.

These types will make use of both nullable and non-nullable reference types to express which members are required and which members are optional. Nullable reference types communicate that design intent clearly:

- The questions that are part of the survey can never be null: It makes no sense to ask an empty question.
- The respondents can never be null. You'll want to track people you contacted, even respondents that declined to participate.
- Any response to a question may be null. Respondents can decline to answer some or all questions.

If you've programmed in C#, you may be so accustomed to reference types that allow null values that you may have missed other opportunities to declare non-nullable instances:

- The collection of questions should be non-nullable.
- The collection of respondents should be non-nullable.

As you write the code, you'll see that a non-nullable reference type as the default for references avoids common mistakes that could lead to null reference exceptions. One lesson from this tutorial is that you made decisions about which variables could or could not be null. The language didn't provide syntax to express those decisions. Now it does.

The app you'll build will do the following steps:

1. Create a survey and add questions to it.
2. Create a pseudo-random set of respondents for the survey.
3. Contact respondents until the completed survey size reaches the goal number.
4. Write out important statistics on the survey responses.

Build the survey with nullable and non-nullable types

The first code you'll write creates the survey. You'll write classes to model a survey question and a survey run. Your survey has three types of questions, distinguished by the format of the answer: Yes/No answers, number answers, and text answers. Create a `public` `SurveyQuestion` class:

```
namespace NullableIntroduction
{
    public class SurveyQuestion
    {
    }
}
```

The compiler interprets every reference type variable declaration as a **non-nullable** reference type for code in a nullable enabled context. You can see your first warning by adding properties for the question text and the type of question, as shown in the following code:

```

namespace NullableIntroduction
{
    public enum QuestionType
    {
        YesNo,
        Number,
        Text
    }

    public class SurveyQuestion
    {
        public string QuestionText { get; }
        public QuestionType TypeOfQuestion { get; }
    }
}

```

Because you haven't initialized `QuestionText`, the compiler issues a warning that a non-nullable property hasn't been initialized. Your design requires the question text to be non-null, so you add a constructor to initialize it and the `QuestionType` value as well. The finished class definition looks like the following code:

```

namespace NullableIntroduction
{
    public enum QuestionType
    {
        YesNo,
        Number,
        Text
    }

    public class SurveyQuestion
    {
        public string QuestionText { get; }
        public QuestionType TypeOfQuestion { get; }

        public SurveyQuestion(QuestionType typeOfQuestion, string text) =>
            (TypeOfQuestion, QuestionText) = (typeOfQuestion, text);
    }
}

```

Adding the constructor removes the warning. The constructor argument is also a non-nullable reference type, so the compiler doesn't issue any warnings.

Next, create a `public` class named `SurveyRun`. This class contains a list of `SurveyQuestion` objects and methods to add questions to the survey, as shown in the following code:

```

using System.Collections.Generic;

namespace NullableIntroduction
{
    public class SurveyRun
    {
        private List<SurveyQuestion> surveyQuestions = new List<SurveyQuestion>();

        public void AddQuestion(QuestionType type, string question) =>
            AddQuestion(new SurveyQuestion(type, question));
        public void AddQuestion(SurveyQuestion surveyQuestion) => surveyQuestions.Add(surveyQuestion);
    }
}

```

As before, you must initialize the list object to a non-null value or the compiler issues a warning. There are no null checks in the second overload of `AddQuestion` because they aren't needed: You've declared that variable to be non-

nullable. Its value can't be `null`.

Switch to `Program.cs` in your editor and replace the contents of `Main` with the following lines of code:

```
var surveyRun = new SurveyRun();
surveyRun.AddQuestion(QuestionType.YesNo, "Has your code ever thrown a NullReferenceException?");
surveyRun.AddQuestion(new SurveyQuestion(QuestionType.Number, "How many times (to the nearest 100) has that
happened?"));
surveyRun.AddQuestion(QuestionType.Text, "What is your favorite color?");
```

Because the entire project is in a nullable enabled context, you'll get warnings when you pass `null` to any method expecting a non-nullable reference type. Try it by adding the following line to `Main`:

```
surveyRun.AddQuestion(QuestionType.Text, default);
```

Create respondents and get answers to the survey

Next, write the code that generates answers to the survey. This process involves several small tasks:

1. Build a method that generates respondent objects. These represent people asked to fill out the survey.
2. Build logic to simulate asking the questions to a respondent and collecting answers or noting that a respondent didn't answer.
3. Repeat until enough respondents have answered the survey.

You'll need a class to represent a survey response, so add that now. Enable nullable support. Add an `Id` property and a constructor that initializes it, as shown in the following code:

```
namespace NullableIntroduction
{
    public class SurveyResponse
    {
        public int Id { get; }

        public SurveyResponse(int id) => Id = id;
    }
}
```

Next, add a `static` method to create new participants by generating a random ID:

```
private static readonly Random randomGenerator = new Random();
public static SurveyResponse GetRandomId() => new SurveyResponse(randomGenerator.Next());
```

The main responsibility of this class is to generate the responses for a participant to the questions in the survey. This responsibility has a few steps:

1. Ask for participation in the survey. If the person doesn't consent, return a missing (or null) response.
2. Ask each question and record the answer. Each answer may also be missing (or null).

Add the following code to your `SurveyResponse` class:

```

private Dictionary<int, string>? surveyResponses;
public bool AnswerSurvey(IEnumerable<SurveyQuestion> questions)
{
    if (ConsentToSurvey())
    {
        surveyResponses = new Dictionary<int, string>();
        int index = 0;
        foreach (var question in questions)
        {
            var answer = GenerateAnswer(question);
            if (answer != null)
            {
                surveyResponses.Add(index, answer);
            }
            index++;
        }
    }
    return surveyResponses != null;
}

private bool ConsentToSurvey() => randomGenerator.Next(0, 2) == 1;

private string? GenerateAnswer(SurveyQuestion question)
{
    switch (question.TypeOfQuestion)
    {
        case QuestionType.YesNo:
            int n = randomGenerator.Next(-1, 2);
            return (n == -1) ? default : (n == 0) ? "No" : "Yes";
        case QuestionType.Number:
            n = randomGenerator.Next(-30, 101);
            return (n < 0) ? default : n.ToString();
        case QuestionType.Text:
        default:
            switch (randomGenerator.Next(0, 5))
            {
                case 0:
                    return default;
                case 1:
                    return "Red";
                case 2:
                    return "Green";
                case 3:
                    return "Blue";
            }
            return "Red. No, Green. Wait.. Blue... AAARGGGGGHHH!";
    }
}

```

The storage for the survey answers is a `Dictionary<int, string>?`, indicating that it may be null. You're using the new language feature to declare your design intent, both to the compiler and to anyone reading your code later. If you ever dereference `surveyResponses` without checking for the null value first, you'll get a compiler warning. You don't get a warning in the `AnswerSurvey` method because the compiler can determine the `surveyResponses` variable was set to a non-null value above.

Using `null` for missing answers highlights a key point for working with nullable reference types: your goal isn't to remove all `null` values from your program. Rather, your goal is to ensure that the code you write expresses the intent of your design. Missing values are a necessary concept to express in your code. The `null` value is a clear way to express those missing values. Trying to remove all `null` values only leads to defining some other way to express those missing values without `null`.

Next, you need to write the `PerformSurvey` method in the `SurveyRun` class. Add the following code in the `SurveyRun` class:

```

private List<SurveyResponse>? respondents;
public void PerformSurvey(int numberOfRespondents)
{
    int respondentsConsenting = 0;
    respondents = new List<SurveyResponse>();
    while (respondentsConsenting < numberOfRespondents)
    {
        var respondent = SurveyResponse.GetRandomId();
        if (respondent.AnswerSurvey(surveyQuestions))
            respondentsConsenting++;
        respondents.Add(respondent);
    }
}

```

Here again, your choice of a nullable `List<SurveyResponse>?` indicates the response may be null. That indicates the survey hasn't been given to any respondents yet. Notice that respondents are added until enough have consented.

The last step to run the survey is to add a call to perform the survey at the end of the `Main` method:

```
surveyRun.PerformSurvey(50);
```

Examine survey responses

The last step is to display survey results. You'll add code to many of the classes you've written. This code demonstrates the value of distinguishing nullable and non-nullable reference types. Start by adding the following two expression-bodied members to the `SurveyResponse` class:

```

public bool AnsweredSurvey => surveyResponses != null;
public string Answer(int index) => surveyResponses.GetValueOrDefault(index, "No answer")!;

```

Because `surveyResponses` is a non-nullable reference type, no checks are necessary before de-referencing it. The `Answer` method returns a non-nullable string, so choose the overload of `GetValueOrDefault` that takes a second argument for the default value.

Next, add these three expression-bodied members to the `SurveyRun` class:

```

public IEnumerable<SurveyResponse> AllParticipants => (respondents ?? Enumerable.Empty<SurveyResponse>());
public ICollection<SurveyQuestion> Questions => surveyQuestions;
public SurveyQuestion GetQuestion(int index) => surveyQuestions[index];

```

The `AllParticipants` member must take into account that the `respondents` variable might be null, but the return value can't be null. If you change that expression by removing the `??` and the empty sequence that follows, the compiler warns you the method might return `null` and its return signature returns a non-nullable type.

Finally, add the following loop at the bottom of the `Main` method:

```
foreach (var participant in surveyRun.AllParticipants)
{
    Console.WriteLine($"Participant: {participant.Id}:");
    if (participant.AnsweredSurvey)
    {
        for (int i = 0; i < surveyRun.Questions.Count; i++)
        {
            var answer = participant.Answer(i);
            Console.WriteLine($"{surveyRun.GetQuestion(i)} : {answer}");
        }
    }
    else
        Console.WriteLine("\tNo responses");
}
```

You don't need any `null` checks in this code because you've designed the underlying interfaces so that they all return non-nullable reference types.

Get the code

You can get the code for the finished tutorial from our [samples](#) repository in the [csharp/NullableIntroduction](#) folder.

Experiment by changing the type declarations between nullable and non-nullable reference types. See how that generates different warnings to ensure you don't accidentally dereference a `null`.

Next steps

Learn more by migrating an existing application to use nullable reference types:

[Upgrade an application to use nullable reference types](#)

Tutorial: Migrate existing code with nullable reference types

2/20/2019 • 13 minutes to read • [Edit Online](#)

C# 8 introduces **nullable reference types**, which complement reference types the same way nullable value types complement value types. You declare a variable to be a **nullable reference type** by appending a `?` to the type. For example, `string?` represents a nullable `string`. You can use these new types to more clearly express your design intent: some variables *must always have a value*, others *may be missing a value*. Any existing variables of a reference type would be interpreted as a non-nullable reference type.

In this tutorial, you'll learn how to:

- Enable null reference checks as you work with code.
- Diagnose and correct different warnings related to null values.
- Manage the interface between nullable enabled and nullable disabled contexts.
- Control nullable annotation contexts.

Prerequisites

You'll need to set up your machine to run .NET Core, including the C# 8.0 beta compiler. The C# 8 beta compiler is available with [Visual Studio 2019 preview 2 and later](#), or [.NET Core 3.0 preview 2](#).

This tutorial assumes you're familiar with C# and .NET, including either Visual Studio or the .NET Core CLI.

Explore the sample application

The sample application that you'll migrate is an RSS feed reader web app. It reads from a single RSS feed and displays summaries for the most recent articles. You can click on any of the articles to visit the site. The application is relatively new but was written before nullable reference types were available. The design decisions for the application represented sound principles, but don't take advantage of this important language feature.

The sample application includes a unit test library that validates the major functionality of the app. That project will make it easier to upgrade safely, if you change any of the implementation based on the warnings generated. You can download the starter code from the [dotnet/samples](#) GitHub repository.

Your goal migrating a project should be to leverage the new language features so that you clearly express your intent on the nullability of variables, and do so in such a way that the compiler doesn't generate warnings when you have the nullable annotation context and nullable warning context set to `enabled`.

Upgrade the projects to C# 8

A good first step is to determine the scope of the migration task. Start by upgrading the project to C# 8.0 (or newer). Add the `LangVersion` element to both csproj files for the web project and the unit test project:

```
<LangVersion>8.0</LangVersion>
```

Upgrading the language version selects C# 8.0, but does not enable the nullable annotation context or the nullable warning context. Rebuild the project to ensure that it builds without warnings.

A good next step is to turn on the nullable annotation context and see how many warnings are generated. Add the

following element to both csproj files in the solution, directly under the `<LangVersion>` element:

```
<NullableContextOptions>enable</NullableContextOptions>
```

Do a test build, and notice the warning list. In this small application, the compiler generates five warnings, so it's likely you'd leave the nullable annotation context enabled and start fixing warnings for the entire project.

That strategy works only for smaller projects. For any larger projects, the number of warnings generated by enabling the nullable annotation context for the entire codebase makes it harder to fix the warnings systematically. For larger enterprise projects, you'll often want to migrate one project at a time. In each project, migrate one class or file at a time.

Warnings help discover original design intent

There are two classes that generate multiple warnings. Start with the `NewsStoryViewModel` class. Remove the `NullableContextOptions` element from both csproj files so that you can limit the scope of warnings to the sections of code you're working with. Open the `NewsStoryViewModel.cs` file and add the following directives to enable the nullable annotation context for the `NewsStoryViewModel` and restore it following that class definition:

```
#nullable enable
public class NewsStoryViewModel
{
    public DateTimeOffset Published { get; set; }
    public string Title { get; set; }
    public string Uri { get; set; }
}
#nullable restore
```

These two directives help you focus your migration efforts. The nullable warnings are generated for the area of code you're actively working on. You'll leave them on until you're ready to turn on the warnings for the entire project. You should use the `restore` rather than `disable` value so that you don't accidentally disable the context later when you've turned on nullable annotations for the entire project. Once you've turned on the nullable annotation context for the entire project, you can remove all the `#nullable` pragmas from that project.

The `NewsStoryViewModel` class is a data transfer object (DTO) and two of the properties are read/write strings:

```
public class NewsStoryViewModel
{
    public DateTimeOffset Published { get; set; }
    public string Title { get; set; }
    public string Uri { get; set; }
}
```

These two properties cause `CS8618`, "Non-nullable property is uninitialized". That's clear enough: both `string` properties have the default value of `null` when a `NewsStoryViewModel` is constructed. What's important to discover is how `NewsStoryViewModel` objects are constructed. Looking at this class, you can't tell if the `null` value is part of the design, or if these objects are set to non-null values whenever one is created. The news stories are created in the `GetNews` method of the `NewsService` class:

```
ISyndicationItem item = await feedReader.ReadItem();
var newsStory = _mapper.Map<NewsStoryViewModel>(item);
news.Add(newsStory);
```

There's quite a bit going on in the preceding block of code. This application uses the [AutoMapper](#) NuGet package

to construct a news item from an `ISyndicationItem`. You've discovered that the news story items are constructed and the properties are set in that one statement. That means the design for the `NewsStoryViewModel` indicates that these properties should never have the `null` value. These properties should be **nonnullable reference types**. That best expresses the original design intent. In fact, any `NewsStoryViewModel` is correctly instantiated with non-null values. That makes the following initialization code a valid fix:

```
public class NewsStoryViewModel
{
    public DateTimeOffset Published { get; set; }
    public string Title { get; set; } = default!;
    public string Uri { get; set; } = default!;
}
```

The assignment of `Title` and `Uri` to `default` which is `null` for the `string` type doesn't change the runtime behavior of the program. The `NewsStoryViewModel` is still constructed with null values, but now the compiler reports no warnings. The **null-forgiving operator**, the `!` character following the `default` expression tells the compiler that the preceding expression is not null. This technique may be expedient when other changes force much larger changes to a code base, but in this application there is a relatively quick and better solution: Make the `NewsStoryViewModel` an immutable type where all the properties are set in the constructor. Make the following changes to the `NewsStoryViewModel`:

```
#nullable enable
public class NewsStoryViewModel
{
    public NewsStoryViewModel(DateTimeOffset published, string title, string uri) =>
        (Published, Title, Uri) = (published, title, uri);

    public DateTimeOffset Published { get; set; }
    public string Title { get; set; }
    public string Uri { get; set; }
}
#nullable restore
```

Once that's done, you need to update the code that configures the AutoMapper so that it uses the constructor rather than setting properties. Open `NewsService.cs` and look for the following code at the bottom of the file:

```
public class NewsStoryProfile : Profile
{
    public NewsStoryProfile()
    {
        // Create the AutoMapper mapping profile between the 2 objects.
        // ISyndicationItem.Id maps to NewsStoryViewModel.Uri.
        CreateMap<ISyndicationItem, NewsStoryViewModel>()
            .ForMember(dest => dest.Uri, opts => opts.MapFrom(src => src.Id));
    }
}
```

That code maps properties of the `ISyndicationItem` object to the `NewsStoryViewModel` properties. You want the AutoMapper to provide the mapping using a constructor instead. Replace the above code with the following automapper configuration:

```

#nullable enable
public class NewsStoryProfile : Profile
{
    public NewsStoryProfile()
    {
        // Create the AutoMapper mapping profile between the 2 objects.
        // ISyndicationItem.Id maps to NewsStoryViewModel.Uri.
        CreateMap<ISyndicationItem, NewsStoryViewModel>()
            .ForCtorParam("published", opt => opt.MapFrom(src => src.Published))
            .ForCtorParam("title", opt => opt.MapFrom(src => src.Title))
            .ForCtorParam("uri", opt => opt.MapFrom(src => src.Id));
    }
}

```

Notice that because this class is small, and you've examined carefully, you should turn on the `#nullable enable` directive above this class declaration. The change to the constructor could have broken something, so it's worthwhile to run all the tests and test the application before moving on.

The first set of changes showed you how to discover when the original design indicated that variables shouldn't be set to `null`. The technique is referred to as **correct by construction**. You declare that an object and its properties cannot be `null` when it's constructed. The compiler's flow analysis provides assurance that those properties aren't set to `null` after construction. Note that this constructor is called by external code, and that code is **nullable oblivious**. The new syntax doesn't provide runtime checking. External code might circumvent the compiler's flow analysis.

Other times, the structure of a class provides different clues to the intent. Open the `Error.cshtml.cs` file in the *Pages* folder. The `ErrorViewModel` contains the following code:

```

public class ErrorModel : PageModel
{
    public string RequestId { get; set; }

    public bool ShowRequestId => !string.IsNullOrEmpty(RequestId);

    public void OnGet()
    {
        RequestId = Activity.Current?.Id ?? HttpContext.TraceIdentifier;
    }
}

```

Add the `#nullable enable` directive before the class declaration, and a `#nullable restore` directive after it. You'll get one warning that `RequestId` is not initialized. By looking at the class, you should decide that the `RequestId` property should be null in some cases. The existence of the `ShowRequestId` property indicates that missing values are possible. Because `null` is valid, add the `?` on the `string` type to indicate the `RequestId` property is a *nullable reference type*. The final class looks like the following example:

```

#nullable enable
public class ErrorModel : PageModel
{
    public string? RequestId { get; set; }

    public bool ShowRequestId => !string.IsNullOrEmpty(RequestId);

    public void OnGet()
    {
        RequestId = Activity.Current?.Id ?? HttpContext.TraceIdentifier;
    }
}
#nullable restore

```

Check for the uses of the property, and you see that in the associated page, the property is checked for null before rendering it in markup. That's a safe use of a nullable reference type, so you're done with this class.

Fixing nulls causes change

Frequently, the fix for one set of warnings creates new warnings in related code. Let's see the warnings in action by fixing the `index.cshtml.cs` class. Open the `index.cshtml.cs` file and examine the code. This file contains the code behind for the index page:

```
public class IndexModel : PageModel
{
    private readonly NewsService _newsService;

    public IndexModel(NewsService newsService)
    {
        _newsService = newsService;
    }

    public string ErrorText { get; private set; }

    public List<NewsStoryViewModel> NewsItems { get; private set; }

    public async Task OnGet()
    {
        string feedUrl = Request.Query["feedurl"];

        if (!string.IsNullOrEmpty(feedUrl))
        {
            try
            {
                NewsItems = await _newsService.GetNews(feedUrl);
            }
            catch (UriFormatException)
            {
                ErrorText = "There was a problem parsing the URL.";
                return;
            }
            catch (WebException ex) when (ex.Status == WebExceptionStatus.NameResolutionFailure)
            {
                ErrorText = "Unknown host name.";
                return;
            }
            catch (WebException ex) when (ex.Status == WebExceptionStatus.ProtocolError)
            {
                ErrorText = "Syndication feed not found.";
                return;
            }
            catch (AggregateException ae)
            {
                ae.Handle((x) =>
                {
                    if (x is XmlException)
                    {
                        ErrorText = "There was a problem parsing the feed. Are you sure that URL is a syndication feed?";
                        return true;
                    }
                    return false;
                });
            }
        }
    }
}
```

Add the `#nullable enable` directive and you'll see two warnings. Neither the `ErrorText` property nor the `NewsItems` property is initialized. An examination of this class would lead you to believe that both properties should be nullable reference types: Both have private setters. Exactly one is assigned in the `OnGet` method. Before making changes, look at the consumers of both properties. In the page itself, the `ErrorText` is checked against null before generating markup for any errors. The `NewsItems` collection is checked against `null`, and checked to ensure the collection has items. A quick fix would be to make both properties nullable reference types. A better fix would be to make the collection a nonnullable reference type, and add items to the existing collection when retrieving news. The first fix is to add the `?` to the `string` type for the `ErrorText`:

```
public string? ErrorText { get; private set; }
```

That change won't ripple through other code, because any access to the `ErrorText` property was already guarded by null checks. Next, initialize the `NewsItems` list and remove the property setter, making it a readonly property:

```
public List<NewsStoryViewModel> NewsItems { get; } = new List<NewsStoryViewModel>();
```

That fixed the warning but introduced an error. The `NewsItems` list is now **correct by construction**, but the code that sets the list in `OnGet` must change to match the new API. Instead of an assignment, call `AddRange` to add the news items to the existing list:

```
NewsItems.AddRange(await _newsService.GetNews(feedUrl));
```

Using `AddRange` instead of an assignment means that the `GetNews` method can return an `IEnumerable` instead of a `List`. That saves one allocation. Change the signature of the method, and remove the `ToList` call, as shown in the following code sample:

```

public async Task<IEnumerable<NewsStoryViewModel>> GetNews(string feedUrl)
{
    var news = new List<NewsStoryViewModel>();
    var feedUri = new Uri(feedUrl);

    using (var xmlReader = XmlReader.Create(feedUri.ToString(),
        new XmlReaderSettings { Async = true }))
    {
        try
        {
            var feedReader = new RssFeedReader(xmlReader);

            while (await feedReader.Read())
            {
                switch (feedReader.ElementType)
                {
                    // RSS Item
                    case SyndicationElementType.Item:
                        ISyndicationItem item = await feedReader.ReadItem();
                        var newsStory = _mapper.Map<NewsStoryViewModel>(item);
                        news.Add(newsStory);
                        break;

                    // Something else
                    default:
                        break;
                }
            }
        }
        catch (AggregateException ae)
        {
            throw ae.Flatten();
        }
    }

    return news.OrderByDescending(story => story.Published);
}

```

Changing the signature breaks one of tests as well. Open the `NewsServiceTests.cs` file in the `Services` folder of the `SimpleFeedReader.Tests` project. Navigate to the `Returns_News_Stories_Given_Valid_Uri` test and change the type of the `result` variable to `IEnumerable<NewsItem>`. Changing the type means the `Count` property is no longer available, so replace the `Count` property in the `Assert` with a call to `Any()`:

```

// Act
IEnumerable<NewsStoryViewModel> result =
    await _newsService.GetNews(feedUrl);

// Assert
Assert.True(result.Any());

```

You'll need to add a `using System.Linq` statement to the beginning of the file as well.

This set of changes highlights special consideration when updating code that includes generic instantiations. Both the list and the elements in the list of non-nullable types. Either or both could be nullable types. All the following declarations are allowed:

- `List<NewsStoryViewModel>` : nonnullable list of nonnullable view models.
- `List<NewsStoryViewModel?>` : nonnullable list of nullable view models.
- `List<NewsStoryViewModel?>` : nullable list of nonnullable view models.
- `List<NewsStoryViewModel?>?` : nullable list of nullable view models.

Interfaces with external code

You've made changes to the `NewsService` class, so turn on the `#nullable enable` annotation for that class. This won't generate any new warnings. However, careful examination of the class helps to illustrate some of the limitations of the compiler's flow analysis. Examine the constructor:

```
public NewsService(IMapper mapper)
{
    _mapper = mapper;
}
```

The `IMapper` parameter is typed as a nonnullable reference. It's called by ASP.NET Core infrastructure code, so the compiler doesn't really know that the `IMapper` will never be null. The default ASP.NET Core dependency injection (DI) container throws an exception if it can't resolve a necessary service, so the code is correct. The compiler can't validate all calls to your public APIs, even if your code is compiled with nullable annotation contexts enabled. Furthermore, your libraries may be consumed by projects that have not yet opted into using nullable reference types. Validate inputs to public APIs even though you've declared them as nonnullable types.

Get the code

You've fixed the warnings you identified in the initial test compile, so now you can turn on the nullable annotation context for both projects. Rebuild the projects; the compiler reports no warnings. You can get the code for the finished project in the [dotnet/samples](#) GitHub repository.

The new features that support nullable reference types help you find and fix potential errors in how you handle `null` values in your code. Enabling the nullable annotation context allows you to express your design intent: some variables should never be null, other variables may contain null values. These features make it easier for you to declare your design intent. Similarly, the nullable warning context instructs the compiler to issue warnings when you have violated that intent. Those warnings guide you to make updates that make your code more resilient and less likely to throw a `NullReferenceException` during execution. You can control the scope of these contexts so that you can focus on local areas of code to migrate while the remaining codebase is untouched. In practice, you can make this migration task a part of regular maintenance to your classes. This tutorial demonstrated the process to migrate an application to use nullable reference types. You can explore a larger real-world example of this process by examining the PR [Jon Skeet](#) made to incorporate nullable reference types into [NodaTime](#).

Tutorial: Generate and consume async streams using C# 8.0 and .NET Core 3.0

2/15/2019 • 8 minutes to read • [Edit Online](#)

C# 8.0 introduces **async streams**, which model a streaming source of data when the elements in the data stream may be retrieved or generated asynchronously. Async streams rely on new interfaces introduced in .NET Standard 2.1 and implemented in .NET Core 3.0 to provide a natural programming model for asynchronous streaming data sources.

In this tutorial, you'll learn how to:

- Create a data source that generates a sequence of data elements asynchronously.
- Consume that data source asynchronously.
- Recognize when the new interface and data source are preferred to earlier synchronous data sequences.

Prerequisites

You'll need to set up your machine to run .NET Core, including the C# 8.0 beta compiler. The C# 8 beta compiler is available starting with [Visual Studio 2019 preview 1](#), or [.NET Core 3.0 preview 1 SDK](#). Async streams are first available in .NET Core 3.0 preview 1.

You'll need to create a [GitHub access token](#) so that you can access the GitHub GraphQL endpoint. Select the following permissions for your GitHub Access Token:

- repo:status
- public_repo

Save the access token in a safe place so you can use it to gain access to the GitHub API endpoint.

WARNING

Keep your personal access token secure. Any software with your personal access token could make GitHub API calls using your access rights.

This tutorial assumes you're familiar with C# and .NET, including either Visual Studio or the .NET Core CLI.

Run the starter application

You can get the code for the starter application used in this tutorial from our [dotnet/samples](#) repository in the [csharp/tutorials/AsyncStreams](#) folder.

The starter application is a console application that uses the [GitHub GraphQL](#) interface to retrieve recent issues written in the [dotnet/docs](#) repository. Start by looking at the following code for the starter app `Main` method:

```

static async Task Main(string[] args)
{
    //Follow these steps to create a GitHub Access Token
    // https://help.github.com/articles/creating-a-personal-access-token-for-the-command-line/#creating-a-token
    //Select the following permissions for your GitHub Access Token:
    // - repo:status
    // - public_repo
    // Replace the 3rd parameter to the following code with your GitHub access token.
    var key = GetEnvVariable("GitHubKey",
        "You must store your GitHub key in the 'GitHubKey' environment variable",
        "");

    var client = new GitHubClient(new Octokit.ProductHeaderValue("IssueQueryDemo"))
    {
        Credentials = new Octokit.Credentials(key)
    };

    var progressReporter = new ProgressStatus((num) =>
    {
        Console.WriteLine($"Received {num} issues in total");
    });
    CancellationTokenSource cancellationSource = new CancellationTokenSource();

    try
    {
        var results = await runPagedQueryAsync(client, PagedIssueQuery, "docs",
            cancellationSource.Token, progressReporter);
        foreach(var issue in results)
            Console.WriteLine(issue);
    }
    catch (OperationCanceledException)
    {
        Console.WriteLine("Work has been cancelled");
    }
}

```

You can either set a `GitHubKey` environment variable to your personal access token, or you can replace the last argument in the call to `GetEnvVariable` with your personal access token. Don't put your access code in source code if you'll be saving the source with others, or putting it in a shared source repository.

After creating the GitHub client, the code in `Main` creates a progress reporting object and a cancellation token. Once those objects are created, `Main` calls `runPagedQueryAsync` to retrieve the most recent 250 created issues. After that task has finished, the results are displayed.

When you run the starter application, you can make some important observations about how this application runs. You'll see progress reported for each page returned from GitHub. You can observe a noticeable pause before GitHub returns each new page of issues. Finally, the issues are displayed only after all 10 pages have been retrieved from GitHub.

Examine the implementation

The implementation reveals why you observed the behavior discussed in the previous section. Examine the code for `runPagedQueryAsync`:

```

private static async Task<JArray> runPagedQueryAsync(GitHubClient client, string queryText, string repoName,
CancellationToken cancel, IProgress<int> progress)
{
    var issueAndPRQuery = new GraphQLRequest
    {
        Query = queryText
    };
    issueAndPRQuery.Variables["repo_name"] = repoName;

    JArray finalResults = new JArray();
    bool hasMorePages = true;
    int pagesReturned = 0;
    int issuesReturned = 0;

    // Stop with 10 pages, because these are large repos:
    while (hasMorePages && (pagesReturned++ < 10))
    {
        var postBody = issueAndPRQuery.ToJsonText();
        var response = await client.Connection.Post<string>(new Uri("https://api.github.com/graphql"),
            postBody, "application/json", "application/json");

        JObject results = JObject.Parse(response.HttpResponse.Body.ToString());

        int totalCount = (int)issues(results)["totalCount"];
        hasMorePages = (bool)pageInfo(results)["hasPreviousPage"];
        issueAndPRQuery.Variables["start_cursor"] = pageInfo(results)["startCursor"].ToString();
        issuesReturned += issues(results)["nodes"].Count();
        finalResults.Merge(issues(results)["nodes"]);
        progress?.Report(issuesReturned);
        cancel.ThrowIfCancellationRequested();
    }
    return finalResults;
}

JObject issues(JObject result) => (JObject)result["data"]["repository"]["issues"];
JObject pageInfo(JObject result) => (JObject)issues(result)["pageInfo"];
}

```

Let's concentrate on the paging algorithm and async structure of the preceding code. (You can consult the [GitHub GraphQL documentation](#) for details on the GitHub GraphQL API.) The `runPagedQueryAsync` method enumerates the issues from most recent to oldest. It requests 25 issues per page and examines the `pageInfo` structure of the response to continue with the previous page. That follows GraphQL's standard paging support for multi-page responses. The response includes a `pageInfo` object that includes a `hasPreviousPages` value and a `startCursor` value used to request the previous page. The issues are in the `nodes` array. The `runPagedQueryAsync` method appends these nodes to an array that contains all the results from all pages.

After retrieving and restoring a page of results, `runPagedQueryAsync` reports progress and checks for cancellation. If cancellation has been requested, `runPagedQueryAsync` throws an [OperationCanceledException](#).

There are several elements in this code that can be improved. Most importantly, `runPagedQueryAsync` must allocate storage for all the issues returned. This sample stops at 250 issues because retrieving all open issues would require much more memory to store all the retrieved issues. In addition, the protocols for supporting progress and supporting cancellation make the algorithm harder to understand on its first reading. You must look for the `progress` class to find where progress is reported. You also have to trace the communications through the `CancellationTokenSource` and its associated `CancellationToken` to understand where cancellation is requested and where it's granted.

Async streams provide a better way

Async streams and the associated language support address all those concerns. The code that generates the sequence can now use `yield return` to return elements in a method that was declared with the `async` modifier.

You can consume an async stream using an `await foreach` loop just as you consume any sequence using a `foreach` loop.

These new language features depend on three new interfaces added to .NET Standard 2.1 and implemented in .NET Core 3.0:

```
namespace System.Collections.Generic
{
    public interface IAsyncEnumerable<out T>
    {
        IAsyncEnumerator<T> GetAsyncEnumerator(CancellationToken cancellationToken = default);
    }

    public interface IAsyncEnumerator<out T> : IAsyncDisposable
    {
        T Current { get; }

        ValueTask<bool> MoveNextAsync();
    }
}

namespace System
{
    public interface IAsyncDisposable
    {
        ValueTask DisposeAsync();
    }
}
```

These three interfaces should be familiar to most C# developers. They behave in a manner similar to their synchronous counterparts:

- [System.Collections.Generic.IEnumerable<T>](#)
- [System.Collections.Generic.IEnumerator<T>](#)
- [System.IDisposable](#)

One type that may be unfamiliar is [System.Threading.Tasks.ValueTask](#). The `ValueTask` struct provides a similar API to the [System.Threading.Tasks.Task](#) class. `ValueTask` is used in these interfaces for performance reasons.

Convert to async streams

Next, convert the `runPagedQueryAsync` method to generate an async stream. First, change the signature of `runPagedQueryAsync` to return an `IAsyncEnumerable<JToken>`, and remove the cancellation token and progress objects from the parameter list as shown in the following code:

```
private static async IAsyncEnumerable<JToken> runPagedQueryAsync(GitHubClient client,
    string queryText, string repoName)
```

The starter code processes each page as the page is retrieved, as shown in the following code:

```
finalResults.Merge(issues(results)["nodes"]);
progress?.Report(issuesReturned);
cancel.ThrowIfCancellationRequested();
```

Replace those three lines with the following code:

```
foreach (JObject issue in issues(results)["nodes"])
    yield return issue;
```

You can also remove the declaration of `finalResults` earlier in this method and the `return` statement that follows the loop you modified.

You've finished the changes to generate an async stream. The finished method should resemble the code below:

```
private static async IAsyncEnumerable<JToken> runPagedQueryAsync(GitHubClient client,
    string queryText, string repoName)
{
    var issueAndPRQuery = new GraphQLRequest
    {
        Query = queryText
    };
    issueAndPRQuery.Variables["repo_name"] = repoName;

    bool hasMorePages = true;
    int pagesReturned = 0;
    int issuesReturned = 0;

    // Stop with 10 pages, because these are large repos:
    while (hasMorePages && (pagesReturned++ < 10))
    {
        var postBody = issueAndPRQuery.ToJsonText();
        var response = await client.Connection.Post<string>(new Uri("https://api.github.com/graphql"),
            postBody, "application/json", "application/json");

        JObject results = JObject.Parse(response.HttpResponse.Body.ToString());

        int totalCount = (int)issues(results)["totalCount"];
        hasMorePages = (bool)pageInfo(results)["hasPreviousPage"];
        issueAndPRQuery.Variables["start_cursor"] = pageInfo(results)["startCursor"].ToString();
        issuesReturned += issues(results)["nodes"].Count();

        foreach (JObject issue in issues(results)["nodes"])
            yield return issue;
    }

    JObject issues(JObject result) => (JObject)result["data"]["repository"]["issues"];
    JObject pageInfo(JObject result) => (JObject)issues(result)["pageInfo"];
}
```

Next, you change the code that consumes the collection to consume the async stream. Find the following code in `Main` that processes the collection of issues:

```
var progressReporter = new ProgressStatus((num) =>
{
    Console.WriteLine($"Received {num} issues in total");
});
CancellationTokenSource cancellationSource = new CancellationTokenSource();

try
{
    var results = await runPagedQueryAsync(client, PagedIssueQuery, "docs",
        cancellationSource.Token, progressReporter);
    foreach(var issue in results)
        Console.WriteLine(issue);
}
catch (OperationCanceledException)
{
    Console.WriteLine("Work has been cancelled");
}
```

Replace that code with the following `await foreach` loop:

```
await foreach (var issue in runPagedQueryAsync(client, PagedIssueQuery, "docs"))
    Console.WriteLine(issue);
```

You can get the code for the finished tutorial from the [dotnet/samples](#) repository in the [csharp/tutorials/AsyncStreams](#) folder.

Run the finished application

Run the application again. Contrast its behavior with the behavior of the starter application. The first page of results is enumerated as soon as it's available. There's an observable pause as each new page is requested and retrieved, then the next page's results are quickly enumerated. The `try / catch` block isn't needed to handle cancellation: the caller can stop enumerating the collection. Progress is clearly reported because the async stream generates results as each page is downloaded.

You can see improvements in memory use by examining the code. You no longer need to allocate a collection to store all the results before they're enumerated. The caller can determine how to consume the results and if a storage collection is needed.

Run both the starter and finished applications and you can observe the differences between the implementations for yourself. You can delete the GitHub access token you created when you started this tutorial after you've finished. If an attacker gained access to that token, they could access GitHub APIs using your credentials.

Tutorial: Using pattern matching features to extend data types

3/20/2019 • 14 minutes to read • [Edit Online](#)

C# 7 introduced basic pattern matching features. Those features are extended in C# 8 with new expressions and patterns. You can write functionality that behaves as though you extended types that may be in other libraries. Another use for patterns is to create functionality your application requires that isn't a fundamental feature of the type being extended.

In this tutorial, you'll learn how to:

- Recognize situations where pattern matching should be used.
- Use pattern matching expressions to implement behavior based on types and property values.
- Combine pattern matching with other techniques to create complete algorithms.

Prerequisites

You'll need to set up your machine to run .NET Core, including the C# 8.0 preview compiler. The C# 8 preview compiler is available with the latest [Visual Studio 2019 preview](#), or the latest [.NET Core 3.0 preview](#).

This tutorial assumes you're familiar with C# and .NET, including either Visual Studio or the .NET Core CLI.

Scenarios for pattern matching

Modern development often includes integrating data from multiple sources and presenting information and insights from that data in a single cohesive application. You and your team won't have control or access for all the types that represent the incoming data.

The classic object-oriented design would call for creating types in your application that represent each data type from those multiple data sources. Then, your application would work with those new types, build inheritance hierarchies, create virtual methods, and implement abstractions. Those techniques work, and sometimes they are the best tools. Other times you can write less code. You can write more clear code using techniques that separate the data from the operations that manipulate that data.

In this tutorial, you'll create and explore an application that takes incoming data from several external sources for a single scenario. You'll see how **pattern matching** provides an efficient way to consume and process that data in ways that weren't part of the original system.

Consider a major metro area that is using tolls and peak time pricing to manage traffic. You write an application that calculates tolls for a vehicle based on its type. Later enhancements incorporate pricing based on the number of occupants in the vehicle. Further enhancements add pricing based on the time and the day of the week.

From that brief description, you may have quickly sketched out an object hierarchy to model this system. However, your data is coming from multiple sources like other vehicle registration management systems. These systems provide different classes to model that data and you don't have a single object model you can use. In this tutorial, you'll use these simplified classes to model for the vehicle data from these external systems, as shown in the following code:

```

namespace ConsumerVehicleRegistration
{
    public class Car
    {
        public int Passengers { get; set; }
    }
}

namespace CommercialRegistration
{
    public class DeliveryTruck
    {
        public int GrossWeightClass { get; set; }
    }
}

namespace LiveryRegistration
{
    public class Taxi
    {
        public int Fares { get; set; }
    }

    public class Bus
    {
        public int Capacity { get; set; }
        public int Riders { get; set; }
    }
}

```

You can download the starter code from the [dotnet/samples](#) GitHub repository. You can see that the vehicle classes are from different systems, and are in different namespaces. No common base class, other than `System.Object` can be leveraged.

Pattern matching designs

The scenario used in this tutorial highlights the kinds of problems that pattern matching is well-suited to solve:

- The objects you need to work with aren't in an object hierarchy that matches your goals. You may be working with classes that are part of unrelated systems.
- The functionality you're adding isn't part of the core abstraction for these classes. The toll paid by a vehicle *changes* for different types of vehicles, but the toll isn't a core function of the vehicle.

When the *shape* of the data and the *operations* on that data are not described together, the pattern matching features in C# make it easier to work with.

Implement the basic toll calculations

The most basic toll calculation relies only on the vehicle type:

- A `Car` is \$2.00.
- A `Taxi` is \$3.50.
- A `Bus` is \$5.00.
- A `DeliveryTruck` is \$10.00

Create a new `TollCalculator` class, and implement pattern matching on the vehicle type to get the toll amount. The following code shows the initial implementation of the `TollCalculator`.

```

using System;
using CommercialRegistration;
using ConsumerVehicleRegistration;
using LiveryRegistration;

namespace toll_calculator
{
    public class TollCalculator
    {
        public decimal CalculateToll(object vehicle) =>
            vehicle switch
            {
                Car c           => 2.00m,
                Taxi t          => 3.50m,
                Bus b           => 5.00m,
                DeliveryTruck t => 10.00m,
                {}              => throw new ArgumentException(message: "Not a known vehicle type", paramName:
nameof(vehicle)),
                null            => throw new ArgumentNullException(nameof(vehicle))
            };
    }
}

```

The preceding code uses a **switch expression** (not the same as a `switch` statement) that tests the **type pattern**. A **switch expression** begins with the variable, `vehicle` in the preceding code, followed by the `switch` keyword. Next comes all the **switch arms** inside curly braces. The `switch` expression makes other refinements to the syntax that surrounds the `switch` statement. The `case` keyword is omitted, and the result of each arm is an expression. The last two arms show a new language feature. The `{ }` case matches any non-null object that didn't match an earlier arm. This arm catches any incorrect types passed to this method. The `{ }` case must follow the cases for each vehicle type. If the order were reversed, the `{ }` case would take precedence. Finally, the `null` pattern detects when a `null` is passed to this method. The `null` pattern can be last because the other type patterns match only a non-null object of the correct type.

You can test this code using the following code in `Program.cs`:

```

using System;
using CommercialRegistration;
using ConsumerVehicleRegistration;
using LiveryRegistration;

namespace toll_calculator
{
    class Program
    {
        static void Main(string[] args)
        {
            var tollCalc = new TollCalculator();

            var car = new Car();
            var taxi = new Taxi();
            var bus = new Bus();
            var truck = new DeliveryTruck();

            Console.WriteLine($"The toll for a car is {tollCalc.CalculateToll(car)}");
            Console.WriteLine($"The toll for a taxi is {tollCalc.CalculateToll(taxi)}");
            Console.WriteLine($"The toll for a bus is {tollCalc.CalculateToll(bus)}");
            Console.WriteLine($"The toll for a truck is {tollCalc.CalculateToll(truck)}");

            try
            {
                tollCalc.CalculateToll("this will fail");
            }
            catch (ArgumentException e)
            {
                Console.WriteLine("Caught an argument exception when using the wrong type");
            }
            try
            {
                tollCalc.CalculateToll(null);
            }
            catch (ArgumentNullException e)
            {
                Console.WriteLine("Caught an argument exception when using null");
            }
        }
    }
}

```

That code is included in the starter project, but is commented out. Remove the comments, and you can test what you've written.

You're starting to see how patterns can help you create algorithms where the code and the data are separate. The `switch` expression tests the type and produces different values based on the results. That's only the beginning.

Add occupancy pricing

The toll authority wants to encourage vehicles to travel at maximum capacity. They've decided to charge more when vehicles have fewer passengers, and encourage full vehicles by offering lower pricing:

- Cars and taxis with no passengers pay an extra \$0.50.
- Cars and taxis with two passengers get a 0.50 discount.
- Cars and taxis with three or more passengers get a \$1.00 discount.
- Buses that are less than 50% full pay an extra \$2.00.
- Buses that are more than 90% full get a \$1.00 discount.

These rules can be implemented using the **property pattern** in the same switch expression. The property pattern examines properties of the object once the type has been determined. The single case for a `Car` expands to four

different cases:

```
vehicle switch
{
    Car { Passengers: 0}      => 2.00m + 0.50m,
    Car { Passengers: 1 }     => 2.0m,
    Car { Passengers: 2 }     => 2.0m - 0.50m,
    Car c                     => 2.00m - 1.0m,

    // ...
};
```

The first three cases test the type as a `Car`, then check the value of the `Passengers` property. If both match, that expression is evaluated and returned.

You would also expand the cases for taxis in a similar manner:

```
vehicle switch
{
    // ...

    Taxi { Fares: 0}  => 3.50m + 1.00m,
    Taxi { Fares: 1 } => 3.50m,
    Taxi { Fares: 2 } => 3.50m - 0.50m,
    Taxi t             => 3.50m - 1.00m,

    // ...
};
```

In the preceding example, the `when` clause was omitted on the final case.

Next, implement the occupancy rules by expanding the cases for buses, as shown in the following example:

```
vehicle switch
{
    // ...

    Bus b when ((double)b.Riders / (double)b.Capacity) < 0.50 => 5.00m + 2.00m,
    Bus b when ((double)b.Riders / (double)b.Capacity) > 0.90 => 5.00m - 1.00m,
    Bus b => 5.00m,

    // ...
};
```

The toll authority isn't concerned with the number of passengers in the delivery trucks. Instead, they charge more based on the weight class of the trucks. Trucks over 5000 lbs are charged an extra \$5.00. Light trucks under 3000 lbs are given a \$2.00 discount. That rule is implemented with the following code:

```
vehicle switch
{
    // ...

    DeliveryTruck t when (t.GrossWeightClass > 5000) => 10.00m + 5.00m,
    DeliveryTruck t when (t.GrossWeightClass < 3000) => 10.00m - 2.00m,
    DeliveryTruck t => 10.00m,
};
```

The preceding code shows the `when` clause of a switch arm. You use the `when` clause to test conditions other than equality on a property. When you've finished, you'll have a method that looks much like the following:

```

vehicle switch
{
    Car { Passengers: 0}      => 2.00m + 0.50m,
    Car { Passengers: 1}      => 2.0m,
    Car { Passengers: 2}      => 2.0m - 0.50m,
    Car c                    => 2.00m - 1.0m,

    Taxi { Fares: 0}  => 3.50m + 1.00m,
    Taxi { Fares: 1 } => 3.50m,
    Taxi { Fares: 2}  => 3.50m - 0.50m,
    Taxi t            => 3.50m - 1.00m,

    Bus b when ((double)b.Riders / (double)b.Capacity) < 0.50 => 5.00m + 2.00m,
    Bus b when ((double)b.Riders / (double)b.Capacity) > 0.90 => 5.00m - 1.00m,
    Bus b => 5.00m,

    DeliveryTruck t when (t.GrossWeightClass > 5000) => 10.00m + 5.00m,
    DeliveryTruck t when (t.GrossWeightClass < 3000) => 10.00m - 2.00m,
    DeliveryTruck t => 10.00m,
};

}

```

Many of these switch arms are examples of **recursive patterns**. For example, `Car { Passengers: 1}` shows a constant pattern inside a property pattern.

You can make this code less repetitive by using nested switches. The `Car` and `Taxi` both have four different arms in the preceding examples. In both cases, you can create a type pattern that feeds into a property pattern. This technique is shown in the following code:

```

public decimal CalculateToll(object vehicle) =>
    vehicle switch
    {
        Car c => c.Passengers switch
        {
            0 => 2.00m + 0.5m,
            1 => 2.0m,
            2 => 2.0m - 0.5m,
            _ => 2.00m - 1.0m
        },
        Taxi t => t.Fares switch
        {
            0 => 3.50m + 1.00m,
            1 => 3.50m,
            2 => 3.50m - 0.50m,
            _ => 3.50m - 1.00m
        },
        Bus b when ((double)b.Riders / (double)b.Capacity) < 0.50 => 5.00m + 2.00m,
        Bus b when ((double)b.Riders / (double)b.Capacity) > 0.90 => 5.00m - 1.00m,
        Bus b => 5.00m,

        DeliveryTruck t when (t.GrossWeightClass > 5000) => 10.00m + 5.00m,
        DeliveryTruck t when (t.GrossWeightClass < 3000) => 10.00m - 2.00m,
        DeliveryTruck t => 10.00m,
        { } => throw new ArgumentException(message: "Not a known vehicle type", paramName: nameof(vehicle)),
        null => throw new ArgumentNullException(nameof(vehicle))
    };
}

```

In the preceding sample, using a recursive expression means you don't repeat the `Car` and `Taxi` arms containing child arms that test the property value. This technique isn't used for the `Bus` and `DeliveryTruck` arms because those arms are testing ranges for the property, not discrete values.

Add peak pricing

For the final feature, the toll authority wants to add time sensitive peak pricing. During the morning and evening rush hours, the tolls are doubled. That rule only affects traffic in one direction: inbound to the city in the morning, and outbound in the evening rush hour. During other times during the workday, tolls increase by 50%. Late night and early morning, tolls are reduced by 25%. During the weekend, it's the normal rate, regardless of the time.

You'll use pattern matching for this feature, but you'll integrate it with other techniques. You could build a single pattern match expression that would account for all the combinations of direction, day of the week, and time. The result would be a complicated expression. It would be hard to read and difficult to understand. That makes it hard to ensure correctness. Instead, combine those methods to build a tuple of values that concisely describes all those states. Then use pattern matching to calculate a multiplier for the toll. The tuple contains three discrete conditions:

- The day is either a weekday or a weekend.
- The band of time when the toll is collected.
- The direction is into the city or out of the city

The following table shows the combinations of input values and the peak pricing multiplier:

DAY	TIME	DIRECTION	PREMIUM
Weekday	morning rush	inbound	x 2.00
Weekday	morning rush	outbound	x 1.00
Weekday	daytime	inbound	x 1.50
Weekday	daytime	outbound	x 1.50
Weekday	evening rush	inbound	x 1.00
Weekday	evening rush	outbound	x 2.00
Weekday	overnight	inbound	x 0.75
Weekday	overnight	outbound	x 0.75
Weekend	morning rush	inbound	x 1.00
Weekend	morning rush	outbound	x 1.00
Weekend	daytime	inbound	x 1.00
Weekend	daytime	outbound	x 1.00
Weekend	evening rush	inbound	x 1.00
Weekend	evening rush	outbound	x 1.00
Weekend	overnight	inbound	x 1.00
Weekend	overnight	outbound	x 1.00

There are 16 different combinations of the three variables. By combining some of the conditions, you'll simplify the

final switch expression.

The system that collects the tolls uses a [DateTime](#) structure for the time when the toll was collected. Build member methods that create the variables from the preceding table. The following function uses a pattern matching switch expression to express whether a [DateTime](#) represents a weekend or a weekday:

```
private static bool IsWeekDay(DateTime timeOfToll) =>
    timeOfToll.DayOfWeek switch
    {
        DayOfWeek.Monday     => true,
        DayOfWeek.Tuesday    => true,
        DayOfWeek.Wednesday  => true,
        DayOfWeek.Thursday   => true,
        DayOfWeek.Friday     => true,
        DayOfWeek.Saturday   => false,
        DayOfWeek.Sunday     => false
    };
```

That method works, but it's repetitious. You can simplify it, as shown in the following code:

```
private static bool IsWeekDay(DateTime timeOfToll) =>
    timeOfToll.DayOfWeek switch
    {
        DayOfWeek.Saturday => false,
        DayOfWeek.Sunday   => false,
        _                  => true
    };
```

Next, add a similar function to categorize the time into the blocks:

```
private enum TimeBand
{
    MorningRush,
    Daytime,
    EveningRush,
    Overnight
}

private static TimeBand GetTimeBand(DateTime timeOfToll)
{
    int hour = timeOfToll.Hour;
    if (hour < 6)
        return TimeBand.OVERNIGHT;
    else if (hour < 10)
        return TimeBand.MORNINGRUSH;
    else if (hour < 16)
        return TimeBand.DAYTIME;
    else if (hour < 20)
        return TimeBand.EVENINGRUSH;
    else
        return TimeBand.OVERNIGHT;
}
```

The previous method doesn't use pattern matching. It's clearer using a familiar cascade of `if` statements. You do add a private `enum` to convert each range of time to a discrete value.

After you create those methods, you can use another `switch` expression with the **tuple pattern** to calculate the pricing premium. You could build a `switch` expression with all 16 arms:

```

public decimal PeakTimePremiumFull(DateTime timeOfToll, bool inbound) =>
    (IsWeekDay(timeOfToll), GetTimeBand(timeOfToll), inbound) switch
    {
        (true, TimeBand.MorningRush, true) => 2.00m,
        (true, TimeBand.MorningRush, false) => 1.00m,
        (true, TimeBand.Daytime, true) => 1.50m,
        (true, TimeBand.Daytime, false) => 1.50m,
        (true, TimeBand.EveningRush, true) => 1.00m,
        (true, TimeBand.EveningRush, false) => 2.00m,
        (true, TimeBand.Overnight, true) => 0.75m,
        (true, TimeBand.Overnight, false) => 0.75m,
        (false, TimeBand.MorningRush, true) => 1.00m,
        (false, TimeBand.MorningRush, false) => 1.00m,
        (false, TimeBand.Daytime, true) => 1.00m,
        (false, TimeBand.Daytime, false) => 1.00m,
        (false, TimeBand.EveningRush, true) => 1.00m,
        (false, TimeBand.EveningRush, false) => 1.00m,
        (false, TimeBand.Overnight, true) => 1.00m,
        (false, TimeBand.Overnight, false) => 1.00m,
    };

```

The above code works, but it can be simplified. All eight combinations for the weekend have the same toll. You can replace all eight with the following line:

```
(false, _, _) => 1.0m,
```

Both inbound and outbound traffic have the same multiplier during the weekday daytime and overnight hours. Those four switch arms can be replaced with the following two lines:

```
(true, TimeBand.Overnight, _) => 0.75m,
(true, TimeBand.Daytime, _) => 1.5m,
```

The code should look like the following code after those two changes:

```

public decimal PeakTimePremium(DateTime timeOfToll, bool inbound) =>
    (IsWeekDay(timeOfToll), GetTimeBand(timeOfToll), inbound) switch
    {
        (true, TimeBand.MorningRush, true) => 2.00m,
        (true, TimeBand.MorningRush, false) => 1.00m,
        (true, TimeBand.Daytime, _) => 1.50m,
        (true, TimeBand.EveningRush, true) => 1.00m,
        (true, TimeBand.EveningRush, false) => 2.00m,
        (true, TimeBand.Overnight, _) => 0.75m,
        (false, _, _) => 1.00m,
    };

```

Finally, you can remove the two rush hour times that pay the regular price. Once you remove those arms, you can replace the `false` with a discard (`_`) in the final switch arm. You'll have the following finished method:

```

public decimal PeakTimePremium(DateTime timeOfToll, bool inbound) =>
    (IsWeekDay(timeOfToll), GetTimeBand(timeOfToll), inbound) switch
    {
        (true, TimeBand.Overnight, _) => 0.75m,
        (true, TimeBand.Daytime, _) => 1.5m,
        (true, TimeBand.MorningRush, true) => 2.0m,
        (true, TimeBand.EveningRush, false) => 2.0m,
        (_, _, _) => 1.0m,
    };

```

This example highlights one of the advantages of pattern matching: the pattern branches are evaluated in order. If you rearrange them so that an earlier branch handles one of your later cases, the compiler warns you about the unreachable code. Those language rules made it easier to do the preceding simplifications with confidence that the code didn't change.

Pattern matching makes some types of code more readable and offers an alternative to object-oriented techniques when you can't add code to your classes. The cloud is causing data and functionality to live apart. The *shape* of the data and the *operations* on it aren't necessarily described together. In this tutorial, you consumed existing data in entirely different ways from its original function. Pattern matching gave you the ability to write functionality that overrode those types, even though you couldn't extend them.

Next steps

You can download the finished code from the [dotnet/samples](#) GitHub repository. Explore patterns on your own and add this technique into your regular coding activities. Learning these techniques gives you another way to approach problems and create new functionality.

Console Application

3/22/2019 • 12 minutes to read • [Edit Online](#)

This tutorial teaches you a number of features in .NET Core and the C# language. You'll learn:

- The basics of the .NET Core Command Line Interface (CLI)
- The structure of a C# Console Application
- Console I/O
- The basics of File I/O APIs in .NET
- The basics of the Task-based Asynchronous Programming in .NET

You'll build an application that reads a text file, and echoes the contents of that text file to the console. The output to the console is paced to match reading it aloud. You can speed up or slow down the pace by pressing the '<' (less than) or '>' (greater than) keys.

There are a lot of features in this tutorial. Let's build them one by one.

Prerequisites

You'll need to setup your machine to run .NET Core. You can find the installation instructions on the [.NET Core](#) page. You can run this application on Windows, Linux, macOS or in a Docker container. You'll need to install your favorite code editor.

Create the Application

The first step is to create a new application. Open a command prompt and create a new directory for your application. Make that the current directory. Type the command `dotnet new console` at the command prompt. This creates the starter files for a basic "Hello World" application.

Before you start making modifications, let's go through the steps to run the simple Hello World application. After creating the application, type `dotnet restore` at the command prompt. This command runs the NuGet package restore process. NuGet is a .NET package manager. This command downloads any of the missing dependencies for your project. As this is a new project, none of the dependencies are in place, so the first run will download the .NET Core framework. After this initial step, you will only need to run `dotnet restore` when you add new dependent packages, or update the versions of any of your dependencies.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

After restoring packages, you run `dotnet build`. This executes the build engine and creates your application executable. Finally, you execute `dotnet run` to run your application.

The simple Hello World application code is all in Program.cs. Open that file with your favorite text editor. We're about to make our first changes. At the top of the file, see a using statement:

```
using System;
```

This statement tells the compiler that any types from the `System` namespace are in scope. Like other Object Oriented languages you may have used, C# uses namespaces to organize types. This Hello World program is no different. You can see that the program is enclosed in the namespace with the name based on the name of the current directory. For this tutorial, let's change the name of the namespace to `TeleprompterConsole`:

```
namespace TeleprompterConsole
```

Reading and Echoing the File

The first feature to add is the ability to read a text file and display all that text to the console. First, let's add a text file. Copy the `sampleQuotes.txt` file from the GitHub repository for this [sample](#) into your project directory. This will serve as the script for your application. If you would like information on how to download the sample app for this topic, see the instructions in the [Samples and Tutorials](#) topic.

Next, add the following method in your `Program` class (right below the `Main` method):

```
static IEnumerable<string> ReadFrom(string file)
{
    string line;
    using (var reader = File.OpenText(file))
    {
        while ((line = reader.ReadLine()) != null)
        {
            yield return line;
        }
    }
}
```

This method uses types from two new namespaces. For this to compile you'll need to add the following two lines to the top of the file:

```
using System.Collections.Generic;
using System.IO;
```

The `IEnumerable<T>` interface is defined in the `System.Collections.Generic` namespace. The `File` class is defined in the `System.IO` namespace.

This method is a special type of C# method called an *Iterator method*. Enumerator methods return sequences that are evaluated lazily. That means each item in the sequence is generated as it is requested by the code consuming the sequence. Enumerator methods are methods that contain one or more `yield return` statements. The object returned by the `ReadFrom` method contains the code to generate each item in the sequence. In this example, that involves reading the next line of text from the source file, and returning that string. Each time the calling code requests the next item from the sequence, the code reads the next line of text from the file and returns it. When the file is completely read, the sequence indicates that there are no more items.

There are two other C# syntax elements that may be new to you. The `using` statement in this method manages resource cleanup. The variable that is initialized in the `using` statement (`reader`, in this example) must implement the `IDisposable` interface. That interface defines a single method, `Dispose`, that should be called when the resource should be released. The compiler generates that call when execution reaches the closing brace of the `using` statement. The compiler-generated code ensures that the resource is released even if an exception is thrown from the code in the block defined by the `using` statement.

The `reader` variable is defined using the `var` keyword. `var` defines an *implicitly typed local variable*. That means the type of the variable is determined by the compile-time type of the object assigned to the variable. Here, that is the return value from the [OpenText\(String\)](#) method, which is a [StreamReader](#) object.

Now, let's fill in the code to read the file in the `Main` method:

```
var lines = ReadFrom("sampleQuotes.txt");
foreach (var line in lines)
{
    Console.WriteLine(line);
}
```

Run the program (using `dotnet run`) and you can see every line printed out to the console.

Adding Delays and Formatting output

What you have is being displayed far too fast to read aloud. Now you need to add the delays in the output. As you start, you'll be building some of the core code that enables asynchronous processing. However, these first steps will follow a few anti-patterns. The anti-patterns are pointed out in comments as you add the code, and the code will be updated in later steps.

There are two steps to this section. First, you'll update the iterator method to return single words instead of entire lines. That's done with these modifications. Replace the `yield return line;` statement with the following code:

```
var words = line.Split(' ');
foreach (var word in words)
{
    yield return word + " ";
}
yield return Environment.NewLine;
```

Next, you need to modify how you consume the lines of the file, and add a delay after writing each word. Replace the `Console.WriteLine(line)` statement in the `Main` method with the following block:

```
Console.Write(line);
if (!string.IsNullOrWhiteSpace(line))
{
    var pause = Task.Delay(200);
    // Synchronously waiting on a task is an
    // anti-pattern. This will get fixed in later
    // steps.
    pause.Wait();
}
```

The `Task` class is in the [System.Threading.Tasks](#) namespace, so you need to add that `using` statement at the top of file:

```
using System.Threading.Tasks;
```

Run the sample, and check the output. Now, each single word is printed, followed by a 200 ms delay. However, the displayed output shows some issues because the source text file has several lines that have more than 80 characters without a line break. That can be hard to read while it's scrolling by. That's easy to fix. You'll just keep track of the length of each line, and generate a new line whenever the line length reaches a certain threshold.

Declare a local variable after the declaration of `words` in the `ReadFrom` method that holds the line length:

```
var lineLength = 0;
```

Then, add the following code after the `yield return word + " ";` statement (before the closing brace):

```
lineLength += word.Length + 1;
if (lineLength > 70)
{
    yield return Environment.NewLine;
    lineLength = 0;
}
```

Run the sample, and you'll be able to read aloud at its pre-configured pace.

Async Tasks

In this final step, you'll add the code to write the output asynchronously in one task, while also running another task to read input from the user if they want to speed up or slow down the text display, or stop the text display altogether. This has a few steps in it and by the end, you'll have all the updates that you need. The first step is to create an asynchronous `Task` returning method that represents the code you've created so far to read and display the file.

Add this method to your `Program` class (it's taken from the body of your `Main` method):

```
private static async Task ShowTeleprompter()
{
    var words = ReadFrom("sampleQuotes.txt");
    foreach (var word in words)
    {
        Console.Write(word);
        if (!string.IsNullOrWhiteSpace(word))
        {
            await Task.Delay(200);
        }
    }
}
```

You'll notice two changes. First, in the body of the method, instead of calling `Wait()` to synchronously wait for a task to finish, this version uses the `await` keyword. In order to do that, you need to add the `async` modifier to the method signature. This method returns a `Task`. Notice that there are no return statements that return a `Task` object. Instead, that `Task` object is created by code the compiler generates when you use the `await` operator. You can imagine that this method returns when it reaches an `await`. The returned `Task` indicates that the work has not completed. The method resumes when the awaited task completes. When it has executed to completion, the returned `Task` indicates that it is complete. Calling code can monitor that returned `Task` to determine when it has completed.

You can call this new method in your `Main` method:

```
ShowTeleprompter().Wait();
```

Here, in `Main`, the code does synchronously wait. You should use the `await` operator instead of synchronously waiting whenever possible. But, in a console application's `Main` method, you cannot use the `await` operator. That would result in the application exiting before all tasks have completed.

NOTE

If you use C# 7.1 or later, you can create console applications with `async` `Main` method.

Next, you need to write the second asynchronous method to read from the Console and watch for the '<' (less than), '>' (greater than) and 'X' or 'x' keys. Here's the method you add for that task:

```
private static async Task GetInput()
{
    var delay = 200;
    Action work = () =>
    {
        do {
            var key = Console.ReadKey(true);
            if (key.KeyChar == '>')
            {
                delay -= 10;
            }
            else if (key.KeyChar == '<')
            {
                delay += 10;
            }
            else if (key.KeyChar == 'X' || key.KeyChar == 'x')
            {
                break;
            }
        } while (true);
    };
    await Task.Run(work);
}
```

This creates a lambda expression to represent an `Action` delegate that reads a key from the Console and modifies a local variable representing the delay when the user presses the '<' (less than) or '>' (greater than) keys. The delegate method finishes when user presses the 'X' or 'x' keys, which allow the user to stop the text display at any time. This method uses `ReadKey()` to block and wait for the user to press a key.

To finish this feature, you need to create a new `async Task` returning method that starts both of these tasks (`GetInput` and `ShowTeleprompter`), and also manages the shared data between these two tasks.

It's time to create a class that can handle the shared data between these two tasks. This class contains two public properties: the delay, and a flag `Done` to indicate that the file has been completely read:

```

namespace TeleprompterConsole
{
    internal class TelePrompterConfig
    {
        public int DelayInMilliseconds { get; private set; } = 200;

        public void UpdateDelay(int increment) // negative to speed up
        {
            var newDelay = Min(DelayInMilliseconds + increment, 1000);
            newDelay = Max(newDelay, 20);
            DelayInMilliseconds = newDelay;
        }

        public bool Done { get; private set; }

        public void SetDone()
        {
            Done = true;
        }
    }
}

```

Put that class in a new file, and enclose that class in the `TeleprompterConsole` namespace as shown above. You'll also need to add a `using static` statement so that you can reference the `Min` and `Max` methods without the enclosing class or namespace names. A `using static` statement imports the methods from one class. This is in contrast with the `using` statements used up to this point that have imported all classes from a namespace.

```
using static System.Math;
```

Next, you need to update the `ShowTeleprompter` and `GetInput` methods to use the new `config` object. Write one final `Task` returning `async` method to start both tasks and exit when the first task finishes:

```

private static async Task RunTeleprompter()
{
    var config = new TelePrompterConfig();
    var displayTask = ShowTeleprompter(config);

    var speedTask = GetInput(config);
    await Task.WhenAny(displayTask, speedTask);
}

```

The one new method here is the `WhenAny(Task[])` call. That creates a `Task` that finishes as soon as any of the tasks in its argument list completes.

Next, you need to update both the `ShowTeleprompter` and `GetInput` methods to use the `config` object for the delay:

```

private static async Task ShowTeleprompter(TelePrompterConfig config)
{
    var words = ReadFrom("sampleQuotes.txt");
    foreach (var word in words)
    {
        Console.Write(word);
        if (!string.IsNullOrWhiteSpace(word))
        {
            await Task.Delay(config.DelayInMilliseconds);
        }
    }
    config.SetDone();
}

private static async Task GetInput(TelePrompterConfig config)
{
    Action work = () =>
    {
        do {
            var key = Console.ReadKey(true);
            if (key.KeyChar == '>')
                config.UpdateDelay(-10);
            else if (key.KeyChar == '<')
                config.UpdateDelay(10);
            else if (key.KeyChar == 'X' || key.KeyChar == 'x')
                config.SetDone();
        } while (!config.Done);
    };
    await Task.Run(work);
}

```

This new version of `ShowTeleprompter` calls a new method in the `TeleprompterConfig` class. Now, you need to update `Main` to call `RunTeleprompter` instead of `ShowTeleprompter`:

```
RunTeleprompter().Wait();
```

Conclusion

This tutorial showed you a number of the features around the C# language and the .NET Core libraries related to working in Console applications. You can build on this knowledge to explore more about the language, and the classes introduced here. You've seen the basics of File and Console I/O, blocking and non-blocking use of the Task-based asynchronous programming, a tour of the C# language and how C# programs are organized and the .NET Core Command Line Interface and tools.

For more information about File I/O, see the [File and Stream I/O](#) topic. For more information about asynchronous programming model used in this tutorial, see the [Task-based Asynchronous Programming](#) topic and the [Asynchronous programming](#) topic.

REST client

3/25/2019 • 14 minutes to read • [Edit Online](#)

Introduction

This tutorial teaches you a number of features in .NET Core and the C# language. You'll learn:

- The basics of the .NET Core Command Line Interface (CLI).
- An overview of C# Language features.
- Managing dependencies with NuGet
- HTTP Communications
- Processing JSON information
- Managing configuration with Attributes.

You'll build an application that issues HTTP Requests to a REST service on GitHub. You'll read information in JSON format, and convert that JSON packet into C# objects. Finally, you'll see how to work with C# objects.

There are a lot of features in this tutorial. Let's build them one by one.

If you prefer to follow along with the [final sample](#) for this topic, you can download it. For download instructions, see [Samples and Tutorials](#).

Prerequisites

You'll need to set up your machine to run .NET core. You can find the installation instructions on the [.NET Core](#) page. You can run this application on Windows, Linux, macOS or in a Docker container. You'll need to install your favorite code editor. The descriptions below use [Visual Studio Code](#), which is an open source, cross platform editor. However, you can use whatever tools you are comfortable with.

Create the Application

The first step is to create a new application. Open a command prompt and create a new directory for your application. Make that the current directory. Type the command `dotnet new console` at the command prompt. This creates the starter files for a basic "Hello World" application.

Before you start making modifications, let's go through the steps to run the simple Hello World application. After creating the application, type `dotnet restore` ([see note](#)) at the command prompt. This command runs the NuGet package restore process. NuGet is a .NET package manager. This command downloads any of the missing dependencies for your project. As this is a new project, none of the dependencies are in place, so the first run will download the .NET Core framework. After this initial step, you will only need to run `dotnet restore` ([see note](#)) when you add new dependent packages, or update the versions of any of your dependencies.

After restoring packages, you run `dotnet build`. This executes the build engine and creates your application. Finally, you execute `dotnet run` to run your application.

Adding New Dependencies

One of the key design goals for .NET Core is to minimize the size of the .NET installation. If an application needs additional libraries for some of its features, you add those dependencies into your C# project (*.csproj) file. For our example, you'll need to add the `System.Runtime.Serialization.Json` package so your application can process JSON responses.

Open your `csproj` project file. The first line of the file should appear as:

```
<Project Sdk="Microsoft.NET.Sdk">
```

Add the following immediately after this line:

```
<ItemGroup>
  <PackageReference Include="System.Runtime.Serialization.Json" Version="4.3.0" />
</ItemGroup>
```

Most code editors will provide completion for different versions of these libraries. You'll usually want to use the latest version of any package that you add. However, it is important to make sure that the versions of all packages match, and that they also match the version of the .NET Core Application framework.

After you've made these changes, you should run `dotnet restore` ([see note](#)) again so that the package is installed on your system.

Making Web Requests

Now you're ready to start retrieving data from the web. In this application, you'll read information from the [GitHub API](#). Let's read information about the projects under the [.NET Foundation](#) umbrella. You'll start by making the request to the GitHub API to retrieve information on the projects. The endpoint you'll use is:

<https://api.github.com/orgs/dotnet/repos>. You want to retrieve all the information about these projects, so you'll use an HTTP GET request. Your browser also uses HTTP GET requests, so you can paste that URL into your browser to see what information you'll be receiving and processing.

You use the [HttpClient](#) class to make web requests. Like all modern .NET APIs, [HttpClient](#) supports only async methods for its long-running APIs. Start by making an async method. You'll fill in the implementation as you build the functionality of the application. Start by opening the `program.cs` file in your project directory and adding the following method to the `Program` class:

```
private static async Task ProcessRepositories()
{
}
```

You'll need to add a `using` statement at the top of your `Main` method so that the C# compiler recognizes the `Task` type:

```
using System.Threading.Tasks;
```

If you build your project at this point, you'll get a warning generated for this method, because it does not contain any `await` operators and will run synchronously. Ignore that for now; you'll add `await` operators as you fill in the method.

Next, rename the namespace defined in the `namespace` statement from its default of `ConsoleApp` to `WebAPIClient`. We'll later define a `repo` class in this namespace.

Next, update the `Main` method to call this method. The `ProcessRepositories` method returns a `Task`, and you shouldn't exit the program before that task finishes. Therefore, you must use the `Wait` method to block and wait for the task to finish:

```
static void Main(string[] args)
{
    ProcessRepositories().Wait();
}
```

Now, you have a program that does nothing, but does it asynchronously. Let's improve it.

First you need an object that is capable to retrieve data from the web; you can use a [HttpClient](#) to do that. This object handles the request and the responses. Instantiate a single instance of that type in the [Program](#) class inside the Program.cs file.

```
namespace WebAPIClient
{
    class Program
    {
        private static readonly HttpClient client = new HttpClient();

        static void Main(string[] args)
        {
            //...
        }
    }
}
```

Let's go back to the [ProcessRepositories](#) method and fill in a first version of it:

```
private static async Task ProcessRepositories()
{
    client.DefaultRequestHeaders.Accept.Clear();
    client.DefaultRequestHeaders.Accept.Add(
        new MediaTypeWithQualityHeaderValue("application/vnd.github.v3+json"));
    client.DefaultRequestHeaders.Add("User-Agent", ".NET Foundation Repository Reporter");

    var stringTask = client.GetStringAsync("https://api.github.com/orgs/dotnet/repos");

    var msg = await stringTask;
    Console.WriteLine(msg);
}
```

You'll need to also add two new using statements at the top of the file for this to compile:

```
using System.Net.Http;
using System.Net.Http.Headers;
```

This first version makes a web request to read the list of all repositories under the dotnet foundation organization. (The GitHub ID for the .NET Foundation is 'dotnet'). The first few lines set up the [HttpClient](#) for this request. First, it is configured to accept the GitHub JSON responses. This format is simply JSON. The next line adds a User Agent header to all requests from this object. These two headers are checked by the GitHub server code, and are necessary to retrieve information from GitHub.

After you've configured the [HttpClient](#), you make a web request and retrieve the response. In this first version, you use the [HttpClient.GetStringAsync\(String\)](#) convenience method. This convenience method starts a task that makes the web request, and then when the request returns, it reads the response stream and extracts the content from the stream. The body of the response is returned as a [String](#). The string is available when the task completes.

The final two lines of this method await that task, and then print the response to the console. Build the app, and run it. The build warning is gone now, because the [ProcessRepositories](#) now does contain an [await](#) operator.

You'll see a long display of JSON formatted text.

Processing the JSON Result

At this point, you've written the code to retrieve a response from a web server, and display the text that is contained in that response. Next, let's convert that JSON response into C# objects.

The JSON Serializer converts JSON data into C# Objects. Your first task is to define a C# class type to contain the information you use from this response. Let's build this slowly, so start with a simple C# type that contains the name of the repository:

```
using System;

namespace WebAPIClient
{
    public class repo
    {
        public string name;
    }
}
```

Put the above code in a new file called 'repo.cs'. This version of the class represents the simplest path to process JSON data. The class name and the member name match the names used in the JSON packet, instead of following C# conventions. You'll fix that by providing some configuration attributes later. This class demonstrates another important feature of JSON serialization and deserialization: Not all the fields in the JSON packet are part of this class. The JSON serializer will ignore information that is not included in the class type being used. This feature makes it easier to create types that work with only a subset of the fields in the JSON packet.

Now that you've created the type, let's deserialize it. You'll need to create a [DataContractJsonSerializer](#) object. This object must know the CLR type expected for the JSON packet it retrieves. The packet from GitHub contains a sequence of repositories, so a `List<repo>` is the correct type. Add the following line to your `ProcessRepositories` method:

```
var serializer = new DataContractJsonSerializer(typeof(List<repo>));
```

You're using two new namespaces, so you'll need to add those as well:

```
using System.Collections.Generic;
using System.Runtime.Serialization.Json;
```

Next, you'll use the serializer to convert JSON into C# objects. Replace the call to [GetStringAsync\(String\)](#) in your `ProcessRepositories` method with the following two lines:

```
var streamTask = client.GetStreamAsync("https://api.github.com/orgs/dotnet/repos");
var repositories = serializer.ReadObject(await streamTask) as List<repo>;
```

Notice that you're now using [GetStreamAsync\(String\)](#) instead of [GetStringAsync\(String\)](#). The serializer uses a stream instead of a string as its source. Let's explain a couple features of the C# language that are being used in the second line above. The argument to [ReadObject\(Stream\)](#) is an `await` expression. Await expressions can appear almost anywhere in your code, even though up to now, you've only seen them as part of an assignment statement.

Secondly, the `as` operator converts from the compile time type of `object` to `List<repo>`. The declaration of [ReadObject\(Stream\)](#) declares that it returns an object of type [System.Object](#). [ReadObject\(Stream\)](#) will return the type you specified when you constructed it (`List<repo>` in this tutorial). If the conversion does not succeed, the

`as` operator evaluates to `null`, instead of throwing an exception.

You're almost done with this section. Now that you've converted the JSON to C# objects, let's display the name of each repository. Replace the lines that read:

```
var msg = await stringTask;    /**Deleted this  
Console.WriteLine(msg);
```

with the following:

```
foreach (var repo in repositories)  
    Console.WriteLine(repo.name);
```

Compile and run the application. It will print out the names of the repositories that are part of the .NET Foundation.

Controlling Serialization

Before you add more features, let's address the `repo` type and make it follow more standard C# conventions. You'll do this by annotating the `repo` type with *attributes* that control how the JSON Serializer works. In your case, you'll use these attributes to define a mapping between the JSON key names and the C# class and member names. The two attributes used are the [DataContractAttribute](#) and [DataMemberAttribute](#) attributes. By convention, all Attribute classes end in the suffix `Attribute`. However, you do not need to use that suffix when you apply an attribute.

The [DataContractAttribute](#) and [DataMemberAttribute](#) attributes are in a different library, so you'll need to add that library to your C# project file as a dependency. Add the following line to the `<ItemGroup>` section of your project file:

```
<PackageReference Include="System.Runtime.Serialization.Primitives" Version="4.3.0" />
```

After you save the file, run `dotnet restore` ([see note](#)) to retrieve this package.

Next, open the `repo.cs` file. Let's change the name to use Pascal Case, and fully spell out the name `Repository`. We still want to map JSON 'repo' nodes to this type, so you'll need to add the [DataContractAttribute](#) attribute to the class declaration. You'll set the `Name` property of the attribute to the name of the JSON nodes that map to this type:

```
[DataContract(Name="repo")]  
public class Repository
```

The [DataContractAttribute](#) is a member of the [System.Runtime.Serialization](#) namespace, so you'll need to add the appropriate `using` statement at the top of the file:

```
using System.Runtime.Serialization;
```

You changed the name of the `repo` class to `Repository`, so you'll need to make the same name change in `Program.cs` (some editors may support a rename refactoring that will make this change automatically):

```
var serializer = new DataContractJsonSerializer(typeof(List<Repository>));  
// ...  
var repositories = serializer.ReadObject(await streamTask) as List<Repository>;
```

Next, let's make the same change with the `name` field by using the [DataMemberAttribute](#) class. Make the following changes to the declaration of the `name` field in `repo.cs`:

```
[DataMember(Name="name")]  
public string Name;
```

This change means you need to change the code that writes the name of each repository in `program.cs`:

```
Console.WriteLine(repo.Name);
```

Do a `dotnet build` followed by a `dotnet run` to make sure you've got the mappings correct. You should see the same output as before. Before we process more properties from the web server, let's make one more change to the `Repository` class. The `Name` member is a publicly accessible field. That's not a good object-oriented practice, so let's change it to a property. For our purposes, we don't need any specific code to run when getting or setting the property, but changing to a property makes it easier to add those changes later without breaking any code that uses the `Repository` class.

Remove the field definition, and replace it with an [auto-implemented property](#):

```
public string Name { get; set; }
```

The compiler generates the body of the `get` and `set` accessors, as well as a private field to store the name. It would be similar to the following code that you could type by hand:

```
public string Name  
{  
    get { return this._name; }  
    set { this._name = value; }  
}  
private string _name;
```

Let's make one more change before adding new features. The `ProcessRepositories` method can do the async work and return a collection of the repositories. Let's return the `List<Repository>` from that method, and move the code that writes the information into the `Main` method.

Change the signature of `ProcessRepositories` to return a task whose result is a list of `Repository` objects:

```
private static async Task<List<Repository>> ProcessRepositories()
```

Then, just return the repositories after processing the JSON response:

```
var repositories = serializer.ReadObject(await streamTask) as List<Repository>;  
return repositories;
```

The compiler generates the `Task<T>` object for the return because you've marked this method as `async`. Then, let's modify the `Main` method so that it captures those results and writes each repository name to the console.

Your `Main` method now looks like this:

```
public static void Main(string[] args)
{
    var repositories = ProcessRepositories().Result;

    foreach (var repo in repositories)
        Console.WriteLine(repo.Name);
}
```

Accessing the `Result` property of a Task blocks until the task has completed. Normally, you would prefer to `await` the completion of the task, as in the `ProcessRepositories` method, but that isn't allowed in the `Main` method.

Reading More Information

Let's finish this by processing a few more of the properties in the JSON packet that gets sent from the GitHub API. You won't want to grab everything, but adding a few properties will demonstrate a few more features of the C# language.

Let's start by adding a few more simple types to the `Repository` class definition. Add these properties to that class:

```
[DataMember(Name="description")]
public string Description { get; set; }

[DataMember(Name="html_url")]
public Uri GitHubHomeUrl { get; set; }

[DataMember(Name="homepage")]
public Uri Homepage { get; set; }

[DataMember(Name="watchers")]
public int Watchers { get; set; }
```

These properties have built-in conversions from the string type (which is what the JSON packets contain) to the target type. The `Uri` type may be new to you. It represents a URI, or in this case, a URL. In the case of the `Uri` and `int` types, if the JSON packet contains data that does not convert to the target type, the serialization action will throw an exception.

Once you've added these, update the `Main` method to display those elements:

```
foreach (var repo in repositories)
{
    Console.WriteLine(repo.Name);
    Console.WriteLine(repo.Description);
    Console.WriteLine(repo.GitHubHomeUrl);
    Console.WriteLine(repo.Homepage);
    Console.WriteLine(repo.Watchers);
    Console.WriteLine();
}
```

As a final step, let's add the information for the last push operation. This information is formatted in this fashion in the JSON response:

```
2016-02-08T21:27:00Z
```

That format does not follow any of the standard .NET `DateTime` formats. Because of that, you'll need to write a

custom conversion method. You also probably don't want the raw string exposed to users of the `Repository` class. Attributes can help control that as well. First, define a `private` property that will hold the string representation of the date time in your `Repository` class:

```
[DataMember(Name="pushed_at")]
private string JsonDate { get; set; }
```

The `DataMemberAttribute` attribute informs the serializer that this should be processed, even though it is not a public member. Next, you need to write a public read-only property that converts the string to a valid `DateTime` object, and returns that `DateTime`:

```
[IgnoreDataMember]
public DateTime LastPush
{
    get
    {
        return DateTime.ParseExact(JsonDate, "yyyy-MM-ddTHH:mm:ssZ", CultureInfo.InvariantCulture);
    }
}
```

Let's go over the new constructs above. The `IgnoreDataMember` attribute instructs the serializer that this type should not be read to or written from any JSON object. This property contains only a `get` accessor. There is no `set` accessor. That's how you define a *read-only* property in C#. (Yes, you can create *write-only* properties in C#, but their value is limited.) The `ParseExact(String, String, IFormatProvider)` method parses a string and creates a `DateTime` object using a provided date format, and adds additional metadata to the `DateTime` using a `CultureInfo` object. If the parse operation fails, the property accessor throws an exception.

To use `InvariantCulture`, you will need to add the `System.Globalization` namespace to the `using` statements in `repo.cs`:

```
using System.Globalization;
```

Finally, add one more output statement in the console, and you're ready to build and run this app again:

```
Console.WriteLine(repo.LastPush);
```

Your version should now match the [finished sample](#).

Conclusion

This tutorial showed you how to make web requests, parse the result, and display properties of those results. You've also added new packages as dependencies in your project. You've seen some of the features of the C# language that support object-oriented techniques.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

Inheritance in C# and .NET

3/26/2019 • 26 minutes to read • [Edit Online](#)

This tutorial introduces you to inheritance in C#. Inheritance is a feature of object-oriented programming languages that allows you to define a base class that provides specific functionality (data and behavior) and to define derived classes that either inherit or override that functionality.

Prerequisites

This tutorial assumes that you've installed .NET Core. For installation instructions, see [.NET Core installation guide](#). You also need a code editor. This tutorial uses [Visual Studio Code](#), although you can use any code editor of your choice.

Running the examples

To create and run the examples in this tutorial, you use the `dotnet` utility from the command line. Follow these steps for each example:

1. Create a directory to store the example.
2. Enter the `dotnet new console` command at a command prompt to create a new .NET Core project.
3. Copy and paste the code from the example into your code editor.
4. Enter the `dotnet restore` command from the command line to load or restore the project's dependencies.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

1. Enter the `dotnet run` command to compile and execute the example.

Background: What is inheritance?

Inheritance is one of the fundamental attributes of object-oriented programming. It allows you to define a child class that reuses (inherits), extends, or modifies the behavior of a parent class. The class whose members are inherited is called the *base class*. The class that inherits the members of the base class is called the *derived class*.

C# and .NET support *single inheritance* only. That is, a class can only inherit from a single class. However, inheritance is transitive, which allows you to define an inheritance hierarchy for a set of types. In other words, type `D` can inherit from type `C`, which inherits from type `B`, which inherits from the base class type `A`. Because inheritance is transitive, the members of type `A` are available to type `D`.

Not all members of a base class are inherited by derived classes. The following members are not inherited:

- [Static constructors](#), which initialize the static data of a class.
- [Instance constructors](#), which you call to create a new instance of the class. Each class must define its own constructors.
- [Finalizers](#), which are called by the runtime's garbage collector to destroy instances of a class.

While all other members of a base class are inherited by derived classes, whether they are visible or not depends on their accessibility. A member's accessibility affects its visibility for derived classes as follows:

- **Private** members are visible only in derived classes that are nested in their base class. Otherwise, they are not visible in derived classes. In the following example, `A.B` is a nested class that derives from `A`, and `C` derives from `A`. The private `A.value` field is visible in `A.B`. However, if you remove the comments from the `C.GetValue` method and attempt to compile the example, it produces compiler error CS0122: "'A.value' is inaccessible due to its protection level."

```
using System;

public class A
{
    private int value = 10;

    public class B : A
    {
        public int GetValue()
        {
            return this.value;
        }
    }
}

public class C : A
{
    //    public int GetValue()
    //    {
    //        return this.value;
    //    }
}

public class Example
{
    public static void Main(string[] args)
    {
        var b = new A.B();
        Console.WriteLine(b.GetValue());
    }
}
// The example displays the following output:
//      10
```

- **Protected** members are visible only in derived classes.
- **Internal** members are visible only in derived classes that are located in the same assembly as the base class. They are not visible in derived classes located in a different assembly from the base class.
- **Public** members are visible in derived classes and are part of the derived class' public interface. Public inherited members can be called just as if they are defined in the derived class. In the following example, class `A` defines a method named `Method1`, and class `B` inherits from class `A`. The example then calls `Method1` as if it were an instance method on `B`.

```

public class A
{
    public void Method1()
    {
        // Method implementation.
    }
}

public class B : A
{ }

public class Example
{
    public static void Main()
    {
        B b = new B();
        b.Method1();
    }
}

```

Derived classes can also *override* inherited members by providing an alternate implementation. In order to be able to override a member, the member in the base class must be marked with the `virtual` keyword. By default, base class members are not marked as `virtual` and cannot be overridden. Attempting to override a non-virtual member, as the following example does, generates compiler error CS0506: "<member> cannot override inherited member <member> because it is not marked virtual, abstract, or override.

```

public class A
{
    public void Method1()
    {
        // Do something.
    }
}

public class B : A
{
    public override void Method1() // Generates CS0506.
    {
        // Do something else.
    }
}

```

In some cases, a derived class *must* override the base class implementation. Base class members marked with the `abstract` keyword require that derived classes override them. Attempting to compile the following example generates compiler error CS0534, "<class> does not implement inherited abstract member <member>", because class `B` provides no implementation for `A.Method1`.

```

public abstract class A
{
    public abstract void Method1();
}

public class B : A // Generates CS0534.
{
    public void Method3()
    {
        // Do something.
    }
}

```

Inheritance applies only to classes and interfaces. Other type categories (structs, delegates, and enums) do not support inheritance. Because of these rules, attempting to compile code like the following example produces compiler error CS0527: "Type 'ValueType' in interface list is not an interface." The error message indicates that, although you can define the interfaces that a struct implements, inheritance is not supported.

```
using System;

public struct ValueStructure : ValueType // Generates CS0527.
{
}
```

Implicit inheritance

Besides any types that they may inherit from through single inheritance, all types in the .NET type system implicitly inherit from [Object](#) or a type derived from it. The common functionality of [Object](#) is available to any type.

To see what implicit inheritance means, let's define a new class, `SimpleClass`, that is simply an empty class definition:

```
public class SimpleClass
{ }
```

You can then use reflection (which lets you inspect a type's metadata to get information about that type) to get a list of the members that belong to the `SimpleClass` type. Although you haven't defined any members in your `SimpleClass` class, output from the example indicates that it actually has nine members. One of these members is a parameterless (or default) constructor that is automatically supplied for the `SimpleClass` type by the C# compiler. The remaining eight are members of [Object](#), the type from which all classes and interfaces in the .NET type system ultimately implicitly inherit.

```

using System;
using System.Reflection;

public class Example
{
    public static void Main()
    {
        Type t = typeof(SimpleClass);
        BindingFlags flags = BindingFlags.Instance | BindingFlags.Static | BindingFlags.Public |
            BindingFlags.NonPublic | BindingFlags.FlattenHierarchy;
        MemberInfo[] members = t.GetMembers(flags);
        Console.WriteLine($"Type {t.Name} has {members.Length} members: ");
        foreach (var member in members)
        {
            string access = "";
            string stat = "";
            var method = member as MethodBase;
            if (method != null)
            {
                if (method.IsPublic)
                    access = " Public";
                else if (method.IsPrivate)
                    access = " Private";
                else if (method.IsFamily)
                    access = " Protected";
                else if (method.IsAssembly)
                    access = " Internal";
                else if (method.IsFamilyOrAssembly)
                    access = " Protected Internal ";
                if (method.IsStatic)
                    stat = " Static";
            }
            var output = $"{member.Name} ({member.MemberType}): {access}{stat}, Declared by
{member.DeclaringType}";
            Console.WriteLine(output);
        }
    }
}

// The example displays the following output:
// Type SimpleClass has 9 members:
// ToString (Method):  Public, Declared by System.Object
// Equals (Method):  Public, Declared by System.Object
// Equals (Method):  Public Static, Declared by System.Object
// ReferenceEquals (Method):  Public Static, Declared by System.Object
// GetHashCode (Method):  Public, Declared by System.Object
// GetType (Method):  Public, Declared by System.Object
// Finalize (Method):  Internal, Declared by System.Object
// MemberwiseClone (Method):  Internal, Declared by System.Object
// .ctor (Constructor):  Public, Declared by SimpleClass

```

Implicit inheritance from the `Object` class makes these methods available to the `SimpleClass` class:

- The public `ToString` method, which converts a `SimpleClass` object to its string representation, returns the fully qualified type name. In this case, the `ToString` method returns the string "SimpleClass".
- Three methods that test for equality of two objects: the public instance `Equals(Object)` method, the public static `Equals(Object, Object)` method, and the public static `ReferenceEquals(Object, Object)` method. By default, these methods test for reference equality; that is, to be equal, two object variables must refer to the same object.
- The public `GetHashCode` method, which computes a value that allows an instance of the type to be used in hashed collections.

- The public `GetType` method, which returns a `Type` object that represents the `SimpleClass` type.
- The protected `Finalize` method, which is designed to release unmanaged resources before an object's memory is reclaimed by the garbage collector.
- The protected `MemberwiseClone` method, which creates a shallow clone of the current object.

Because of implicit inheritance, you can call any inherited member from a `SimpleClass` object just as if it was actually a member defined in the `SimpleClass` class. For instance, the following example calls the `SimpleClass.ToString` method, which `SimpleClass` inherits from `Object`.

```
using System;

public class SimpleClass
{}

public class Example
{
    public static void Main()
    {
        SimpleClass sc = new SimpleClass();
        Console.WriteLine(sc.ToString());
    }
}
// The example displays the following output:
//      SimpleClass
```

The following table lists the categories of types that you can create in C# and the types from which they implicitly inherit. Each base type makes a different set of members available through inheritance to implicitly derived types.

TYPE CATEGORY	IMPLICITLY INHERITS FROM
class	<code>Object</code>
struct	<code>ValueType, Object</code>
enum	<code>Enum, ValueType, Object</code>
delegate	<code>MulticastDelegate, Delegate, Object</code>

Inheritance and an "is a" relationship

Ordinarily, inheritance is used to express an "is a" relationship between a base class and one or more derived classes, where the derived classes are specialized versions of the base class; the derived class is a type of the base class. For example, the `Publication` class represents a publication of any kind, and the `Book` and `Magazine` classes represent specific types of publications.

NOTE

A class or struct can implement one or more interfaces. While interface implementation is often presented as a workaround for single inheritance or as a way of using inheritance with structs, it is intended to express a different relationship (a "can do" relationship) between an interface and its implementing type than inheritance. An interface defines a subset of functionality (such as the ability to test for equality, to compare or sort objects, or to support culture-sensitive parsing and formatting) that the interface makes available to its implementing types.

Note that "is a" also expresses the relationship between a type and a specific instantiation of that type. In the

following example, `Automobile` is a class that has three unique read-only properties: `Make`, the manufacturer of the automobile; `Model`, the kind of automobile; and `Year`, its year of manufacture. Your `Automobile` class also has a constructor whose arguments are assigned to the property values, and it overrides the `Object.ToString` method to produce a string that uniquely identifies the `Automobile` instance rather than the `Automobile` class.

```
using System;

public class Automobile
{
    public Automobile(string make, string model, int year)
    {
        if (make == null)
            throw new ArgumentNullException("The make cannot be null.");
        else if (String.IsNullOrWhiteSpace(make))
            throw new ArgumentException("make cannot be an empty string or have space characters only.");
        Make = make;

        if (model == null)
            throw new ArgumentNullException("The model cannot be null.");
        else if (String.IsNullOrWhiteSpace(model))
            throw new ArgumentException("model cannot be an empty string or have space characters only.");
        Model = model;

        if (year < 1857 || year > DateTime.Now.Year + 2)
            throw new ArgumentException("The year is out of range.");
        Year = year;
    }

    public string Make { get; }

    public string Model { get; }

    public int Year { get; }

    public override string ToString() => $"{Year} {Make} {Model}";
}
```

In this case, you shouldn't rely on inheritance to represent specific car makes and models. For example, you don't need to define a `Packard` type to represent automobiles manufactured by the Packard Motor Car Company. Instead, you can represent them by creating an `Automobile` object with the appropriate values passed to its class constructor, as the following example does.

```
using System;

public class Example
{
    public static void Main()
    {
        var packard = new Automobile("Packard", "Custom Eight", 1948);
        Console.WriteLine(packard);
    }
}

// The example displays the following output:
//      1948 Packard Custom Eight
```

An is-a relationship based on inheritance is best applied to a base class and to derived classes that add additional members to the base class or that require additional functionality not present in the base class.

Designing the base class and derived classes

Let's look at the process of designing a base class and its derived classes. In this section, you'll define a base class,

`Publication`, which represents a publication of any kind, such as a book, a magazine, a newspaper, a journal, an article, etc. You'll also define a `Book` class that derives from `Publication`. You could easily extend the example to define other derived classes, such as `Magazine`, `Journal`, `Newspaper`, and `Article`.

The base `Publication` class

In designing your `Publication` class, you need to make several design decisions:

- What members to include in your base `Publication` class, and whether the `Publication` members provide method implementations or whether `Publication` is an abstract base class that serves as a template for its derived classes.

In this case, the `Publication` class will provide method implementations. The [Designing abstract base classes and their derived classes](#) section contains an example that uses an abstract base class to define the methods that derived classes must override. Derived classes are free to provide any implementation that is suitable for the derived type.

The ability to reuse code (that is, multiple derived classes share the declaration and implementation of base class methods and do not need to override them) is an advantage of non-abstract base classes. Therefore, you should add members to `Publication` if their code is likely to be shared by some or most specialized `Publication` types. If you fail to provide base class implementations efficiently, you'll end up having to provide largely identical member implementations in derived classes rather than a single implementation in the base class. The need to maintain duplicated code in multiple locations is a potential source of bugs.

Both to maximize code reuse and to create a logical and intuitive inheritance hierarchy, you want to be sure that you include in the `Publication` class only the data and functionality that is common to all or to most publications. Derived classes then implement members that are unique to the particular kinds of publication that they represent.

- How far to extend your class hierarchy. Do you want to develop a hierarchy of three or more classes, rather than simply a base class and one or more derived classes? For example, `Publication` could be a base class of `Periodical`, which in turn is a base class of `Magazine`, `Journal` and `Newspaper`.

For your example, you'll use the small hierarchy of a `Publication` class and a single derived class, `Book`. You could easily extend the example to create a number of additional classes that derive from `Publication`, such as `Magazine` and `Article`.

- Whether it makes sense to instantiate the base class. If it does not, you should apply the `abstract` keyword to the class. Otherwise, your `Publication` class can be instantiated by calling its class constructor. If an attempt is made to instantiate a class marked with the `abstract` keyword by a direct call to its class constructor, the C# compiler generates error CS0144, "Cannot create an instance of the abstract class or interface." If an attempt is made to instantiate the class by using reflection, the reflection method throws a [MemberAccessException](#).

By default, a base class can be instantiated by calling its class constructor. You do not have to explicitly define a class constructor. If one is not present in the base class' source code, the C# compiler automatically provides a default (parameterless) constructor.

For your example, you'll mark the `Publication` class as `abstract` so that it cannot be instantiated. An `abstract` class without any `abstract` methods indicates that this class represents an abstract concept that is shared among several concrete classes (like a `Book`, `Journal`).

- Whether derived classes must inherit the base class implementation of particular members, whether they have the option to override the base class implementation, or whether they must provide an implementation. You use the `abstract` keyword to force derived classes to provide an implementation. You use the `virtual` keyword to allow derived classes to override a base class method. By default, methods defined in the base class are *not* overridable.

The `Publication` class does not have any `abstract` methods, but the class itself is `abstract`.

- Whether a derived class represents the final class in the inheritance hierarchy and cannot itself be used as a base class for additional derived classes. By default, any class can serve as a base class. You can apply the `sealed` keyword to indicate that a class cannot serve as a base class for any additional classes. Attempting to derive from a sealed class generates compiler error CS0509, "cannot derive from sealed type <typeName>".

For your example, you'll mark your derived class as `sealed`.

The following example shows the source code for the `Publication` class, as well as a `PublicationType` enumeration that is returned by the `Publication.PublicationType` property. In addition to the members that it inherits from `Object`, the `Publication` class defines the following unique members and member overrides:

```
using System;

public enum PublicationType { Misc, Book, Magazine, Article };

public abstract class Publication
{
    private bool published = false;
    private DateTime datePublished;
    private int totalPages;

    public Publication(string title, string publisher, PublicationType type)
    {
        if (publisher == null)
            throw new ArgumentNullException("The publisher cannot be null.");
        else if (String.IsNullOrWhiteSpace(publisher))
            throw new ArgumentException("The publisher cannot consist only of white space.");
        Publisher = publisher;

        if (title == null)
            throw new ArgumentNullException("The title cannot be null.");
        else if (String.IsNullOrWhiteSpace(title))
            throw new ArgumentException("The title cannot consist only of white space.");
        Title = title;

        Type = type;
    }

    public string Publisher { get; }

    public string Title { get; }

    public PublicationType Type { get; }

    public string CopyrightName { get; private set; }

    public int CopyrightDate { get; private set; }

    public int Pages
    {
        get { return totalPages; }
        set
        {
            if (value <= 0)
                throw new ArgumentOutOfRangeException("The number of pages cannot be zero or negative.");
            totalPages = value;
        }
    }

    public string GetPublicationDate()
    {
        if (!published)
            .....
    }
}
```

```

        return "NYP";
    else
        return datePublished.ToString("d");
}

public void Publish(DateTime datePublished)
{
    published = true;
    this.datePublished = datePublished;
}

public void Copyright(string copyrightName, int copyrightDate)
{
    if (copyrightName == null)
        throw new ArgumentNullException("The name of the copyright holder cannot be null.");
    else if (String.IsNullOrWhiteSpace(copyrightName))
        throw new ArgumentException("The name of the copyright holder cannot consist only of white space.");
    CopyrightName = copyrightName;

    int currentYear = DateTime.Now.Year;
    if (copyrightDate < currentYear - 10 || copyrightDate > currentYear + 2)
        throw new ArgumentOutOfRangeException($"The copyright year must be between {currentYear - 10} and {currentYear + 1}");
    CopyrightDate = copyrightDate;
}

public override string ToString() => Title;
}

```

- A constructor

Because the `Publication` class is `abstract`, it cannot be instantiated directly from code like the following example:

```

var publication = new Publication("Tiddlywinks for Experts", "Fun and Games",
                                  PublicationType.Book);

```

However, its instance constructor can be called directly from derived class constructors, as the source code for the `Book` class shows.

- Two publication-related properties

`Title` is a read-only `String` property whose value is supplied by calling the `Publication` constructor.

`Pages` is a read-write `Int32` property that indicates how many total pages the publication has. The value is stored in a private field named `totalPages`. It must be a positive number or an `ArgumentOutOfRangeException` is thrown.

- Publisher-related members

Two read-only properties, `Publisher` and `Type`. The values are originally supplied by the call to the `Publication` class constructor.

- Publishing-related members

Two methods, `Publish` and `GetPublicationDate`, set and return the publication date. The `Publish` method sets a private `published` flag to `true` when it is called and assigns the date passed to it as an argument to the private `datePublished` field. The `GetPublicationDate` method returns the string "NYP" if the `published` flag is `false`, and the value of the `datePublished` field if it is `true`.

- Copyright-related members

The `Copyright` method takes the name of the copyright holder and the year of the copyright as arguments and assigns them to the `CopyrightName` and `CopyrightDate` properties.

- An override of the `ToString` method

If a type does not override the `Object.ToString` method, it returns the fully qualified name of the type, which is of little use in differentiating one instance from another. The `Publication` class overrides `Object.ToString` to return the value of the `Title` property.

The following figure illustrates the relationship between your base `Publication` class and its implicitly inherited `Object` class.

Object	Publication
Equals(Object)	Equals(Object)
Equals(Object, Object)	Equals(Object, Object)
Finalize()	Finalize()
GetHashCode()	GetHashCode()
GetType()	GetType()
MemberwiseClone()	MemberwiseClone()
ReferenceEquals()	ReferenceEquals()
ToString()	ToString()
#ctor()	#ctor(String, String, PublicationType)
Key	
Unique member	
Inherited member	
Overridden member	

The `Book` class

The `Book` class represents a book as a specialized type of publication. The following example shows the source code for the `Book` class.

```

using System;

public sealed class Book : Publication
{
    public Book(string title, string author, string publisher) :
        this(title, String.Empty, author, publisher)
    { }

    public Book(string title, string isbn, string author, string publisher) : base(title, publisher,
PublicationType.Book)
    {
        // isbn argument must be a 10- or 13-character numeric string without "-" characters.
        // We could also determine whether the ISBN is valid by comparing its checksum digit
        // with a computed checksum.
        //
        if (!String.IsNullOrEmpty(isbn)) {
            // Determine if ISBN length is correct.
            if (!(isbn.Length == 10 | isbn.Length == 13))
                throw new ArgumentException("The ISBN must be a 10- or 13-character numeric string.");
            ulong nISBN = 0;
            if (!UInt64.TryParse(isbn, out nISBN))
                throw new ArgumentException("The ISBN can consist of numeric characters only.");
        }
        ISBN = isbn;

        Author = author;
    }

    public string ISBN { get; }

    public string Author { get; }

    public Decimal Price { get; private set; }

    // A three-digit ISO currency symbol.
    public string Currency { get; private set; }

    // Returns the old price, and sets a new price.
    public Decimal SetPrice(Decimal price, string currency)
    {
        if (price < 0)
            throw new ArgumentOutOfRangeException("The price cannot be negative.");
        Decimal oldValue = Price;
        Price = price;

        if (currency.Length != 3)
            throw new ArgumentException("The ISO currency symbol is a 3-character string.");
        Currency = currency;

        return oldValue;
    }

    public override bool Equals(object obj)
    {
        Book book = obj as Book;
        if (book == null)
            return false;
        else
            return ISBN == book.ISBN;
    }

    public override int GetHashCode() => ISBN.GetHashCode();

    public override string ToString() => $"{{(String.IsNullOrEmpty(Author) ? "" : Author + ", ")}{Title}}";
}

```

In addition to the members that it inherits from `Publication`, the `Book` class defines the following unique members and member overrides:

- Two constructors

The two `Book` constructors share three common parameters. Two, *title* and *publisher*, correspond to parameters of the `Publication` constructor. The third is *author*, which is stored to a public immutable `Author` property. One constructor includes an *isbn* parameter, which is stored in the `ISBN` auto-property.

The first constructor uses the `this` keyword to call the other constructor. Constructor chaining is a common pattern in defining constructors. Constructors with fewer parameters provide default values when calling the constructor with the greatest number of parameters.

The second constructor uses the `base` keyword to pass the title and publisher name to the base class constructor. If you don't make an explicit call to a base class constructor in your source code, the C# compiler automatically supplies a call to the base class' default or parameterless constructor.

- A read-only `ISBN` property, which returns the `Book` object's International Standard Book Number, a unique 10- or 13-digit number. The ISBN is supplied as an argument to one of the `Book` constructors. The ISBN is stored in a private backing field, which is auto-generated by the compiler.
- A read-only `Author` property. The author name is supplied as an argument to both `Book` constructors and is stored in the property.
- Two read-only price-related properties, `Price` and `Currency`. Their values are provided as arguments in a `SetPrice` method call. The `Currency` property is the three-digit ISO currency symbol (for example, USD for the U.S. dollar). ISO currency symbols can be retrieved from the `ISOCurrencySymbol` property. Both of these properties are externally read-only, but both can be set by code in the `Book` class.
- A `SetPrice` method, which sets the values of the `Price` and `Currency` properties. Those values are returned by those same properties.
- Overrides to the `ToString` method (inherited from `Publication`) and the `Object.Equals(Object)` and `GetHashCode` methods (inherited from `Object`).

Unless it is overridden, the `Object.Equals(Object)` method tests for reference equality. That is, two object variables are considered to be equal if they refer to the same object. In the `Book` class, on the other hand, two `Book` objects should be equal if they have the same ISBN.

When you override the `Object.Equals(Object)` method, you must also override the `GetHashCode` method, which returns a value that the runtime uses to store items in hashed collections for efficient retrieval. The hash code should return a value that's consistent with the test for equality. Since you've overridden `Object.Equals(Object)` to return `true` if the ISBN properties of two `Book` objects are equal, you return the hash code computed by calling the `GetHashCode` method of the string returned by the `ISBN` property.

The following figure illustrates the relationship between the `Book` class and `Publication`, its base class.

Key

Unique member	
Inherited member	
Overridden member	

You can now instantiate a `Book` object, invoke both its unique and inherited members, and pass it as an argument to a method that expects a parameter of type `Publication` or of type `Book`, as the following example shows.

```

using System;
using static System.Console;

public class Example
{
    public static void Main()
    {
        var book = new Book("The Tempest", "0971655819", "Shakespeare, William",
                            "Public Domain Press");
        ShowPublicationInfo(book);
        book.Publish(new DateTime(2016, 8, 18));
        ShowPublicationInfo(book);

        var book2 = new Book("The Tempest", "Classic Works Press", "Shakespeare, William");
        WriteLine($"{book.Title} and {book2.Title} are the same publication: " +
                 $"{((Publication) book).Equals(book2)}");
    }

    public static void ShowPublicationInfo(Publication pub)
    {
        string pubDate = pub.GetPublicationDate();
        WriteLine($"{pub.Title}, " +
                 $"{(pubDate == "NYP" ? "Not Yet Published" : "published on " + pubDate):d} by
{pub.Publisher}");
    }
}

// The example displays the following output:
//      The Tempest, Not Yet Published by Public Domain Press
//      The Tempest, published on 8/18/2016 by Public Domain Press
//      The Tempest and The Tempest are the same publication: False

```

Designing abstract base classes and their derived classes

In the previous example, you defined a base class that provided an implementation for a number of methods to allow derived classes to share code. In many cases, however, the base class is not expected to provide an implementation. Instead, the base class is an *abstract class* that declares *abstract methods*; it serves as a template that defines the members that each derived class must implement. Typically in an abstract base class, the implementation of each derived type is unique to that type. You marked the class with the `abstract` keyword because it made no sense to instantiate a `Publication` object, although the class did provide implementations of functionality common to publications.

For example, each closed two-dimensional geometric shape includes two properties: `area`, the inner extent of the shape; and `perimeter`, or the distance along the edges of the shape. The way in which these properties are calculated, however, depends completely on the specific shape. The formula for calculating the perimeter (or circumference) of a circle, for example, is different from that of a triangle. The `Shape` class is an `abstract` class with `abstract` methods. That indicates derived classes share the same functionality, but those derived classes implement that functionality differently.

The following example defines an abstract base class named `Shape` that defines two properties: `Area` and `Perimeter`. In addition to marking the class with the `abstract` keyword, each instance member is also marked with the `abstract` keyword. In this case, `Shape` also overrides the `Object.ToString` method to return the name of the type, rather than its fully qualified name. And it defines two static members, `GetArea` and `GetPerimeter`, that allow callers to easily retrieve the area and perimeter of an instance of any derived class. When you pass an instance of a derived class to either of these methods, the runtime calls the method override of the derived class.

```
using System;

public abstract class Shape
{
    public abstract double Area { get; }

    public abstract double Perimeter { get; }

    public override string ToString() => GetType().Name;

    public static double GetArea(Shape shape) => shape.Area;

    public static double GetPerimeter(Shape shape) => shape.Perimeter;
}
```

You can then derive some classes from `Shape` that represent specific shapes. The following example defines three classes, `Triangle`, `Rectangle`, and `Circle`. Each uses a formula unique for that particular shape to compute the area and perimeter. Some of the derived classes also define properties, such as `Rectangle.Diagonal` and `Circle.Diameter`, that are unique to the shape that they represent.

```

using System;

public class Square : Shape
{
    public Square(double length)
    {
        Side = length;
    }

    public double Side { get; }

    public override double Area => Math.Pow(Side, 2);

    public override double Perimeter => Side * 4;

    public double Diagonal => Math.Round(Math.Sqrt(2) * Side, 2);
}

public class Rectangle : Shape
{
    public Rectangle(double length, double width)
    {
        Length = length;
        Width = width;
    }

    public double Length { get; }

    public double Width { get; }

    public override double Area => Length * Width;

    public override double Perimeter => 2 * Length + 2 * Width;

    public bool IsSquare() => Length == Width;

    public double Diagonal => Math.Round(Math.Sqrt(Math.Pow(Length, 2) + Math.Pow(Width, 2)), 2);
}

public class Circle : Shape
{
    public Circle(double radius)
    {
        Radius = radius;
    }

    public override double Area => Math.Round(Math.PI * Math.Pow(Radius, 2), 2);

    public override double Perimeter => Math.Round(Math.PI * 2 * Radius, 2);

    // Define a circumference, since it's the more familiar term.
    public double Circumference => Perimeter;

    public double Radius { get; }

    public double Diameter => Radius * 2;
}

```

The following example uses objects derived from `Shape`. It instantiates an array of objects derived from `Shape` and calls the static methods of the `Shape` class, which wraps return `Shape` property values. The runtime retrieves values from the overridden properties of the derived types. The example also casts each `Shape` object in the array to its derived type and, if the cast succeeds, retrieves properties of that particular subclass of `Shape`.

```
using System;

public class Example
{
    public static void Main()
    {
        Shape[] shapes = { new Rectangle(10, 12), new Square(5),
                           new Circle(3) };
        foreach (var shape in shapes) {
            Console.WriteLine($"{shape}: area, {Shape.GetArea(shape)}; " +
                $"perimeter, {Shape.GetPerimeter(shape)}");
            var rect = shape as Rectangle;
            if (rect != null) {
                Console.WriteLine($"    Is Square: {rect.IsSquare()}, Diagonal: {rect.Diagonal}");
                continue;
            }
            var sq = shape as Square;
            if (sq != null) {
                Console.WriteLine($"    Diagonal: {sq.Diagonal}");
                continue;
            }
        }
    }
    // The example displays the following output:
    //     Rectangle: area, 120; perimeter, 44
    //     Is Square: False, Diagonal: 15.62
    //     Square: area, 25; perimeter, 20
    //     Diagonal: 7.07
    //     Circle: area, 28.27; perimeter, 18.85
}
```

Working with LINQ

3/8/2019 • 15 minutes to read • [Edit Online](#)

Introduction

This tutorial teaches you features in .NET Core and the C# language. You'll learn:

- How to generate sequences with LINQ.
- How to write methods that can be easily used in LINQ queries.
- How to distinguish between eager and lazy evaluation.

You'll learn these techniques by building an application that demonstrates one of the basic skills of any magician: the [faro shuffle](#). Briefly, a faro shuffle is a technique where you split a card deck exactly in half, then the shuffle interleaves each one card from each half to rebuild the original deck.

Magicians use this technique because every card is in a known location after each shuffle, and the order is a repeating pattern.

For your purposes, it is a light hearted look at manipulating sequences of data. The application you'll build will construct a card deck, and then perform a sequence of shuffles, writing the sequence out each time. You'll also compare the updated order to the original order.

This tutorial has multiple steps. After each step, you can run the application and see the progress. You can also see the [completed sample](#) in the `dotnet/samples` GitHub repository. For download instructions, see [Samples and Tutorials](#).

Prerequisites

You'll need to setup your machine to run .NET core. You can find the installation instructions on the [.NET Core](#) page. You can run this application on Windows, Ubuntu Linux, OS X or in a Docker container. You'll need to install your favorite code editor. The descriptions below use [Visual Studio Code](#) which is an open source, cross platform editor. However, you can use whatever tools you are comfortable with.

Create the Application

The first step is to create a new application. Open a command prompt and create a new directory for your application. Make that the current directory. Type the command `dotnet new console` at the command prompt. This creates the starter files for a basic "Hello World" application.

If you've never used C# before, [this tutorial](#) explains the structure of a C# program. You can read that and then return here to learn more about LINQ.

Creating the Data Set

Before you begin, make sure that the following lines are at the top of the `Program.cs` file generated by `dotnet new console`:

```
// Program.cs
using System;
using System.Collections.Generic;
using System.Linq;
```

If these three lines (`using` statements) aren't at the top of the file, our program will not compile.

Now that you have all of the references that you'll need, consider what constitutes a deck of cards. Commonly, a deck of playing cards has four suits, and each suit has thirteen values. Normally, you might consider creating a `Card` class right off the bat and populating a collection of `Card` objects by hand. With LINQ, you can be more concise than the usual way of dealing with creating a deck of cards. Instead of creating a `Card` class, you can create two sequences to represent suites and ranks, respectively. You'll create a really simple pair of [iterator methods](#) that will generate the ranks and suits as `IEnumerable<T>`s of strings:

```
// Program.cs
// The Main() method

static IEnumerable<string> Suits()
{
    yield return "clubs";
    yield return "diamonds";
    yield return "hearts";
    yield return "spades";
}

static IEnumerable<string> Ranks()
{
    yield return "two";
    yield return "three";
    yield return "four";
    yield return "five";
    yield return "six";
    yield return "seven";
    yield return "eight";
    yield return "nine";
    yield return "ten";
    yield return "jack";
    yield return "queen";
    yield return "king";
    yield return "ace";
}
```

Place these underneath the `Main` method in your `Program.cs` file. These two methods both utilize the `yield return` syntax to produce a sequence as they run. The compiler builds an object that implements `IEnumerable<T>` and generates the sequence of strings as they are requested.

Now, use these iterator methods to create the deck of cards. You'll place the LINQ query in our `Main` method. Here's a look at it:

```
// Program.cs
static void Main(string[] args)
{
    var startingDeck = from s in Suits()
                        from r in Ranks()
                        select new { Suit = s, Rank = r };

    // Display each card that we've generated and placed in startingDeck in the console
    foreach (var card in startingDeck)
    {
        Console.WriteLine(card);
    }
}
```

The multiple `from` clauses produce a [SelectMany](#), which creates a single sequence from combining each element in the first sequence with each element in the second sequence. The order is important for our purposes. The first element in the first source sequence (Suits) is combined with every element in the second sequence (Ranks). This

produces all thirteen cards of first suit. That process is repeated with each element in the first sequence (Suits). The end result is a deck of cards ordered by suits, followed by values.

It's important to keep in mind that whether you choose to write your LINQ in the query syntax used above or use method syntax instead, it's always possible to go from one form of syntax to the other. The above query written in query syntax can be written in method syntax as:

```
var startingDeck = Suits().SelectMany(suit => Ranks().Select(rank => new { Suit = suit, Rank = rank }));
```

The compiler translates LINQ statements written with query syntax into the equivalent method call syntax. Therefore, regardless of your syntax choice, the two versions of the query produce the same result. Choose which syntax works best for your situation: for instance, if you're working in a team where some of the members have difficulty with method syntax, try to prefer using query syntax.

Go ahead and run the sample you've built at this point. It will display all 52 cards in the deck. You may find it very helpful to run this sample under a debugger to observe how the `Suits()` and `Ranks()` methods execute. You can clearly see that each string in each sequence is generated only as it is needed.

```
C:\>dotnet run
{ Suit = clubs, Rank = two }
{ Suit = clubs, Rank = three }
{ Suit = clubs, Rank = four }
{ Suit = clubs, Rank = five }
{ Suit = clubs, Rank = six }
{ Suit = clubs, Rank = seven }
{ Suit = clubs, Rank = eight }
{ Suit = clubs, Rank = nine }
{ Suit = clubs, Rank = ten }
{ Suit = clubs, Rank = jack }
{ Suit = clubs, Rank = queen }
{ Suit = clubs, Rank = king }
{ Suit = clubs, Rank = ace }
{ Suit = diamonds, Rank = two }
{ Suit = diamonds, Rank = three }
{ Suit = diamonds, Rank = four }
{ Suit = diamonds, Rank = five }
{ Suit = diamonds, Rank = six }
{ Suit = diamonds, Rank = seven }
{ Suit = diamonds, Rank = eight }
{ Suit = diamonds, Rank = nine }
{ Suit = diamonds, Rank = ten }
```

Manipulating the Order

Next, focus on how you're going to shuffle the cards in the deck. The first step in any good shuffle is to split the deck in two. The `Take` and `Skip` methods that are part of the LINQ APIs provide that feature for you. Place them underneath the `foreach` loop:

```
// Program.cs
public static void Main(string[] args)
{
    var startingDeck = from s in Suits()
                       from r in Ranks()
                       select new { Suit = s, Rank = r };

    foreach (var c in startingDeck)
    {
        Console.WriteLine(c);
    }

    // 52 cards in a deck, so 52 / 2 = 26
    var top = startingDeck.Take(26);
    var bottom = startingDeck.Skip(26);
}
```

However, there's no shuffle method to take advantage of in the standard library, so you'll have to write your own. The shuffle method you'll be creating illustrates several techniques that you'll use with LINQ-based programs, so each part of this process will be explained in steps.

In order to add some functionality to how you interact with the `IEnumerable<T>` you'll get back from LINQ queries, you'll need to write some special kinds of methods called [extension methods](#). Briefly, an extension method is a special purpose *static method* that adds new functionality to an already-existing type without having to modify the original type you want to add functionality to.

Give your extension methods a new home by adding a new *static* class file to your program called `Extensions.cs`, and then start building out the first extension method:

```
// Extensions.cs
using System;
using System.Collections.Generic;
using System.Linq;

namespace LinqFaroShuffle
{
    public static class Extensions
    {
        public static IEnumerable<T> InterleaveSequenceWith<T>(this IEnumerable<T> first, IEnumerable<T> second)
        {
            // Your implementation will go here soon enough
        }
    }
}
```

Look at the method signature for a moment, specifically the parameters:

```
public static IEnumerable<T> InterleaveSequenceWith<T> (this IEnumerable<T> first, IEnumerable<T> second)
```

You can see the addition of the `this` modifier on the first argument to the method. That means you call the method as though it were a member method of the type of the first argument. This method declaration also follows a standard idiom where the input and output types are `IEnumerable<T>`. That practice enables LINQ methods to be chained together to perform more complex queries.

Naturally, since you split the deck into halves, you'll need to join those halves together. In code, this means you'll be enumerating both of the sequences you acquired through `Take` and `Skip` at once, *interleaving* the elements, and creating one sequence: your now-shuffled deck of cards. Writing a LINQ method that works with two sequences requires that you understand how `IEnumerable<T>` works.

The `IEnumerable<T>` interface has one method: `GetEnumerator`. The object returned by `GetEnumerator` has a method to move to the next element, and a property that retrieves the current element in the sequence. You will use those two members to enumerate the collection and return the elements. This Interleave method will be an iterator method, so instead of building a collection and returning the collection, you'll use the `yield return` syntax shown above.

Here's the implementation of that method:

```

public static IEnumerable<T> InterleaveSequenceWith<T>
    (this IEnumerable<T> first, IEnumerable<T> second)
{
    var firstIter = first.GetEnumerator();
    var secondIter = second.GetEnumerator();

    while (firstIter.MoveNext() && secondIter.MoveNext())
    {
        yield return firstIter.Current;
        yield return secondIter.Current;
    }
}

```

Now that you've written this method, go back to the `Main` method and shuffle the deck once:

```

// Program.cs
public static void Main(string[] args)
{
    var startingDeck = from s in Suits()
                        from r in Ranks()
                        select new { Suit = s, Rank = r };

    foreach (var c in startingDeck)
    {
        Console.WriteLine(c);
    }

    var top = startingDeck.Take(26);
    var bottom = startingDeck.Skip(26);
    var shuffle = top.InterleaveSequenceWith(bottom);

    foreach (var c in shuffle)
    {
        Console.WriteLine(c);
    }
}

```

Comparisons

How many shuffles it takes to set the deck back to its original order? To find out, you'll need to write a method that determines if two sequences are equal. After you have that method, you'll need to place the code that shuffles the deck in a loop, and check to see when the deck is back in order.

Writing a method to determine if the two sequences are equal should be straightforward. It's a similar structure to the method you wrote to shuffle the deck. Only this time, instead of `yield return`ing each element, you'll compare the matching elements of each sequence. When the entire sequence has been enumerated, if every element matches, the sequences are the same:

```

public static bool SequenceEquals<T>
    (this IEnumerable<T> first, IEnumerable<T> second)
{
    var firstIter = first.GetEnumerator();
    var secondIter = second.GetEnumerator();

    while (firstIter.MoveNext() && secondIter.MoveNext())
    {
        if (!firstIter.Current.Equals(secondIter.Current))
        {
            return false;
        }
    }

    return true;
}

```

This shows a second LINQ idiom: terminal methods. They take a sequence as input (or in this case, two sequences), and return a single scalar value. When using terminal methods, they are always the final method in a chain of methods for a LINQ query, hence the name "terminal".

You can see this in action when you use it to determine when the deck is back in its original order. Put the shuffle code inside a loop, and stop when the sequence is back in its original order by applying the `SequenceEquals()` method. You can see it would always be the final method in any query, because it returns a single value instead of a sequence:

```

// Program.cs
static void Main(string[] args)
{
    // Query for building the deck

    // Shuffling using InterleaveSequenceWith<T>();

    var times = 0;
    // We can re-use the shuffle variable from earlier, or you can make a new one
    shuffle = startingDeck;
    do
    {
        shuffle = shuffle.Take(26).InterleaveSequenceWith(shuffle.Skip(26));

        foreach (var card in shuffle)
        {
            Console.WriteLine(card);
        }
        Console.WriteLine();
        times++;
    }

    } while (!startingDeck.SequenceEquals(shuffle));

    Console.WriteLine(times);
}

```

Run the code you've got so far and take note of how the deck rearranges on each shuffle. After 8 shuffles (iterations of the do-while loop), the deck returns to the original configuration it was in when you first created it from the starting LINQ query.

Optimizations

The sample you've built so far executes an *out shuffle*, where the top and bottom cards stay the same on each run. Let's make one change: we'll use an *in shuffle* instead, where all 52 cards change position. For an in shuffle, you interleave the deck so that the first card in the bottom half becomes the first card in the deck. That means the last

card in the top half becomes the bottom card. This is a simple change to a singular line of code. Update the current shuffle query by switching the positions of [Take](#) and [Skip](#). This will change the order of the top and bottom halves of the deck:

```
shuffle = shuffle.Skip(26).InterleaveSequenceWith(shuffle.Take(26));
```

Run the program again, and you'll see that it takes 52 iterations for the deck to reorder itself. You'll also start to notice some serious performance degradations as the program continues to run.

There are a number of reasons for this. You can tackle one of the major causes of this performance drop: inefficient use of [lazy evaluation](#).

Briefly, lazy evaluation states that the evaluation of a statement is not performed until its value is needed. LINQ queries are statements that are evaluated lazily. The sequences are generated only as the elements are requested. Usually, that's a major benefit of LINQ. However, in a use such as this program, this causes exponential growth in execution time.

Remember that we generated the original deck using a LINQ query. Each shuffle is generated by performing three LINQ queries on the previous deck. All these are performed lazily. That also means they are performed again each time the sequence is requested. By the time you get to the 52nd iteration, you're regenerating the original deck many, many times. Let's write a log to demonstrate this behavior. Then, you'll fix it.

In your `Extensions.cs` file, type in or copy the method below. This extension method creates a new file called `debug.log` within your project directory and records what query is currently being executed to the log file. This extension method can be appended to any query to mark that the query executed.

```
public static IEnumerable<T> LogQuery<T>
    (this IEnumerable<T> sequence, string tag)
{
    // File.AppendText creates a new file if the file doesn't exist.
    using (var writer = File.AppendText("debug.log"))
    {
        writer.WriteLine($"Executing Query {tag}");
    }

    return sequence;
}
```

Next, instrument the definition of each query with a log message:

```

// Program.cs
public static void Main(string[] args)
{
    var startingDeck = (from s in Suits().LogQuery("Suit Generation")
                        from r in Ranks().LogQuery("Rank Generation")
                        select new { Suit = s, Rank = r }).LogQuery("Starting Deck");

    foreach (var c in startingDeck)
    {
        Console.WriteLine(c);
    }

    Console.WriteLine();
    var times = 0;
    var shuffle = startingDeck;

    do
    {
        // Out shuffle
        /*
        shuffle = shuffle.Take(26)
            .LogQuery("Top Half")
            .InterleaveSequenceWith(shuffle.Skip(26))
            .LogQuery("Bottom Half")
            .LogQuery("Shuffle");
        */

        // In shuffle
        shuffle = shuffle.Skip(26).LogQuery("Bottom Half")
            .InterleaveSequenceWith(shuffle.Take(26).LogQuery("Top Half"))
            .LogQuery("Shuffle");

        foreach (var c in shuffle)
        {
            Console.WriteLine(c);
        }

        times++;
        Console.WriteLine(times);
    } while (!startingDeck.SequenceEquals(shuffle));

    Console.WriteLine(times);
}

```

Notice that you don't log every time you access a query. You log only when you create the original query. The program still takes a long time to run, but now you can see why. If you run out of patience running the in shuffle with logging turned on, switch back to the out shuffle. You'll still see the lazy evaluation effects. In one run, it executes 2592 queries, including all the value and suit generation.

You can improve the performance of the code here to reduce the number of executions you make. A simple fix you can make is to *cache* the results of the original LINQ query that constructs the deck of cards. Currently, you're executing the queries again and again every time the do-while loop goes through an iteration, re-constructing the deck of cards and reshuffling it every time. To cache the deck of cards, you can leverage the LINQ methods [ToArray](#) and [ToList](#); when you append them to the queries, they'll perform the same actions you've told them to, but now they'll store the results in an array or a list, depending on which method you choose to call. Append the LINQ method [ToArray](#) to both queries and run the program again:

```

public static void Main(string[] args)
{
    var startingDeck = (from s in Suits().LogQuery("Suit Generation")
                        from r in Ranks().LogQuery("Value Generation")
                        select new { Suit = s, Rank = r })
                        .LogQuery("Starting Deck")
                        .ToArray();

    foreach (var c in startingDeck)
    {
        Console.WriteLine(c);
    }

    Console.WriteLine();

    var times = 0;
    var shuffle = startingDeck;

    do
    {
        /*
        shuffle = shuffle.Take(26)
            .LogQuery("Top Half")
            .InterleaveSequenceWith(shuffle.Skip(26).LogQuery("Bottom Half"))
            .LogQuery("Shuffle")
            .ToArray();
        */

        shuffle = shuffle.Skip(26)
            .LogQuery("Bottom Half")
            .InterleaveSequenceWith(shuffle.Take(26).LogQuery("Top Half"))
            .LogQuery("Shuffle")
            .ToArray();

        foreach (var c in shuffle)
        {
            Console.WriteLine(c);
        }

        times++;
        Console.WriteLine(times);
    } while (!startingDeck.SequenceEquals(shuffle));

    Console.WriteLine(times);
}

```

Now the out shuffle is down to 30 queries. Run again with the in shuffle and you'll see similar improvements: it now executes 162 queries.

Please note that this example is **designed** to highlight the use cases where lazy evaluation can cause performance difficulties. While it's important to see where lazy evaluation can impact code performance, it's equally important to understand that not all queries should run eagerly. The performance hit you incur without using `ToArray` is because each new arrangement of the deck of cards is built from the previous arrangement. Using lazy evaluation means each new deck configuration is built from the original deck, even executing the code that built the `startingDeck`. That causes a large amount of extra work.

In practice, some algorithms run well using eager evaluation, and others run well using lazy evaluation. For daily usage, lazy evaluation is usually a better choice when the data source is a separate process, like a database engine. For databases, lazy evaluation allows more complex queries to execute only one round trip to the database process and back to the rest of your code. LINQ is flexible whether you choose to utilize lazy or eager evaluation, so measure your processes and pick whichever kind of evaluation gives you the best performance.

Conclusion

In this project, you covered:

- using LINQ queries to aggregate data into a meaningful sequence
- writing Extension methods to add our own custom functionality to LINQ queries
- locating areas in our code where our LINQ queries might run into performance issues like degraded speed
- lazy and eager evaluation in regards to LINQ queries and the implications they might have on query performance

Aside from LINQ, you learned a bit about a technique magicians use for card tricks. Magicians use the Faro shuffle because they can control where every card moves in the deck. Now that you know, don't spoil it for everyone else!

For more information on LINQ, see:

String interpolation in C#

2/28/2019 • 5 minutes to read • [Edit Online](#)

This tutorial shows you how to use [string interpolation](#) to format and include expression results in a result string. The examples assume that you are familiar with basic C# concepts and .NET type formatting. If you are new to string interpolation or .NET type formatting, check out the [interactive string interpolation tutorial](#) first. For more information about formatting types in .NET, see the [Formatting Types in .NET](#) topic.

NOTE

The C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

Introduction

The [string interpolation](#) feature is built on top of the [composite formatting](#) feature and provides a more readable and convenient syntax to include formatted expression results in a result string.

To identify a string literal as an interpolated string, prepend it with the `$` symbol. You can embed any valid C# expression that returns a value in an interpolated string. In the following example, as soon as an expression is evaluated, its result is converted into a string and included in a result string:

```
double a = 3;
double b = 4;
Console.WriteLine($"Area of the right triangle with legs of {a} and {b} is {0.5 * a * b}");
Console.WriteLine($"Length of the hypotenuse of the right triangle with legs of {a} and {b} is
{CalculateHypotenuse(a, b)}");

double CalculateHypotenuse(double leg1, double leg2) => Math.Sqrt(leg1 * leg1 + leg2 * leg2);

// Expected output:
// Area of the right triangle with legs of 3 and 4 is 6
// Length of the hypotenuse of the right triangle with legs of 3 and 4 is 5
```

As the example shows, you include an expression in an interpolated string by enclosing it with braces:

```
{<interpolatedExpression>}
```

At compile time, an interpolated string is typically transformed into a [String.Format](#) method call. That makes all the capabilities of the [string composite formatting](#) feature available to you to use with interpolated strings as well.

The compiler may substitute a [String.Format](#) for [String.Concat](#) if the analyzed behavior would be equivalent to concatenation.

How to specify a format string for an interpolated expression

You specify a format string that is supported by the type of the expression result by following the interpolated expression with a colon (":") and the format string:

```
{<interpolatedExpression>:<formatString>}
```

The following example shows how to specify standard and custom format strings for expressions that produce date and time or numeric results:

```
var date = new DateTime(1731, 11, 25);
Console.WriteLine($"On {date:dddd, MMMM dd, yyyy} Leonhard Euler introduced the letter e to denote {Math.E:F5}
in a letter to Christian Goldbach.");
// Expected output:
// On Sunday, November 25, 1731 Leonhard Euler introduced the letter e to denote 2.71828 in a letter to
Christian Goldbach.
```

For more information, see the [Format String Component](#) section of the [Composite Formatting](#) topic. That section provides links to the topics that describe standard and custom format strings supported by .NET base types.

How to control the field width and alignment of the formatted interpolated expression

You specify the minimum field width and the alignment of the formatted expression result by following the interpolated expression with a comma (",") and the constant expression:

```
{<interpolatedExpression>,<alignment>}
```

If the *alignment* value is positive, the formatted expression result is right-aligned; if negative, it's left-aligned.

If you need to specify both alignment and a format string, start with the alignment component:

```
{<interpolatedExpression>,<alignment>:<formatString>}
```

The following example shows how to specify alignment and uses pipe characters ("|") to delimit text fields:

```
const int NameAlignment = -9;
const int ValueAlignment = 7;

double a = 3;
double b = 4;
Console.WriteLine($"Three classical Pythagorean means of {a} and {b}:");
Console.WriteLine($"|{"Arithmetic",NameAlignment}|{0.5 * (a + b),ValueAlignment:F3}|");
Console.WriteLine($"|{"Geometric",NameAlignment}|{Math.Sqrt(a * b),ValueAlignment:F3}|");
Console.WriteLine($"|{"Harmonic",NameAlignment}|{2 / (1 / a + 1 / b),ValueAlignment:F3}|");

// Expected output:
// Three classical Pythagorean means of 3 and 4:
// |Arithmetic| 3.500|
// |Geometric| 3.464|
// |Harmonic | 3.429|
```

As the example output shows, if the length of the formatted expression result exceeds specified field width, the *alignment* value is ignored.

For more information, see the [Alignment Component](#) section of the [Composite Formatting](#) topic.

How to use escape sequences in an interpolated string

Interpolated strings support all escape sequences that can be used in ordinary string literals. For more information, see [String escape sequences](#).

To interpret escape sequences literally, use a [verbatim](#) string literal. A verbatim interpolated string starts with the `$` character followed by the `@` character.

To include a brace, `{"` or `"}`, in a result string, use two braces, `"{{" or "}}"`. For more information, see the [Escaping Braces](#) section of the [Composite Formatting](#) topic.

The following example shows how to include braces in a result string and construct a verbatim interpolated string:

```
var xs = new int[] { 1, 2, 7, 9 };
var ys = new int[] { 7, 9, 12 };
Console.WriteLine($"Find the intersection of the {{{string.Join(", ",xs)}}} and {{{string.Join(", ",ys)}}} sets.");
var userName = "Jane";
var stringWithEscapes = $"C:\\Users\\{userName}\\Documents";
var verbatimInterpolated = ${@"C:\\Users\\{userName}\\Documents"};
Console.WriteLine(stringWithEscapes);
Console.WriteLine(verbatimInterpolated);

// Expected output:
// Find the intersection of the {1, 2, 7, 9} and {7, 9, 12} sets.
// C:\\Users\\Jane\\Documents
// C:\\Users\\Jane\\Documents
```

How to use a ternary conditional operator `? :` in an interpolated expression

As the colon (`:`) has special meaning in an item with an interpolated expression, in order to use a [conditional operator](#) in an expression, enclose it in parentheses, as the following example shows:

```
var rand = new Random();
for (int i = 0; i < 7; i++)
{
    Console.WriteLine($"Coin flip: {((rand.NextDouble() < 0.5 ? "heads" : "tails"))}");
}
```

How to create a culture-specific result string with string interpolation

By default, an interpolated string uses the current culture defined by the [CultureInfo.CurrentCulture](#) property for all formatting operations. Use implicit conversion of an interpolated string to a [System.FormattableString](#) instance and call its [ToString\(IFormatProvider\)](#) method to create a culture-specific result string. The following example shows how to do that:

```

var cultures = new System.Globalization.CultureInfo[]
{
    System.Globalization.CultureInfo.GetCultureInfo("en-US"),
    System.Globalization.CultureInfo.GetCultureInfo("en-GB"),
    System.Globalization.CultureInfo.GetCultureInfo("nl-NL"),
    System.Globalization.CultureInfo.InvariantCulture
};

var date = DateTime.Now;
var number = 31_415_926.536;
FormattableString message = $"{date,20}{number,20:N3}";
foreach (var culture in cultures)
{
    var cultureSpecificMessage = message.ToString(culture);
    Console.WriteLine($"{culture.Name,-10}{cultureSpecificMessage}");
}

// Expected output is like:
// en-US      5/17/18 3:44:55 PM      31,415,926.536
// en-GB      17/05/2018 15:44:55      31,415,926.536
// nl-NL      17-05-18 15:44:55      31.415.926,536
//          05/17/2018 15:44:55      31,415,926.536

```

As the example shows, you can use one [FormattableString](#) instance to generate multiple result strings for various cultures.

How to create a result string using the invariant culture

Along with the [FormattableString.ToString\(IFormatProvider\)](#) method, you can use the static [FormattableString.Invariant](#) method to resolve an interpolated string to a result string for the [InvariantCulture](#). The following example shows how to do that:

```

string messageInInvariantCulture = FormattableString.Invariant($"Date and time in invariant culture:
{DateTime.Now}");
Console.WriteLine(messageInInvariantCulture);

// Expected output is like:
// Date and time in invariant culture: 05/17/2018 15:46:24

```

Conclusion

This tutorial describes common scenarios of string interpolation usage. For more information about string interpolation, see the [String interpolation](#) topic. For more information about formatting types in .NET, see the [Formatting Types in .NET](#) and [Composite formatting](#) topics.

Using Attributes in C#

2/28/2019 • 7 minutes to read • [Edit Online](#)

Attributes provide a way of associating information with code in a declarative way. They can also provide a reusable element that can be applied to a variety of targets.

Consider the `[Obsolete]` attribute. It can be applied to classes, structs, methods, constructors, and more. It *declares* that the element is obsolete. It's then up to the C# compiler to look for this attribute, and do some action in response.

In this tutorial, you'll be introduced to how to add attributes to your code, how to create and use your own attributes, and how to use some attributes that are built into .NET Core.

Prerequisites

You'll need to setup your machine to run .NET core. You can find the installation instructions on the [.NET Core](#) page. You can run this application on Windows, Ubuntu Linux, macOS or in a Docker container. You'll need to install your favorite code editor. The descriptions below use [Visual Studio Code](#) which is an open source, cross platform editor. However, you can use whatever tools you are comfortable with.

Create the Application

Now that you've installed all the tools, create a new .NET Core application. To use the command line generator, execute the following command in your favorite shell:

```
dotnet new console
```

This command will create barebones .NET core project files. You will need to execute `dotnet restore` to restore the dependencies needed to compile this project.

NOTE

Starting with .NET Core 2.0 SDK, you don't have to run `dotnet restore` because it's run implicitly by all commands that require a restore to occur, such as `dotnet new`, `dotnet build` and `dotnet run`. It's still a valid command in certain scenarios where doing an explicit restore makes sense, such as [continuous integration builds in Azure DevOps Services](#) or in build systems that need to explicitly control the time at which the restore occurs.

To execute the program, use `dotnet run`. You should see "Hello, World" output to the console.

How to add attributes to code

In C#, attributes are classes that inherit from the `Attribute` base class. Any class that inherits from `Attribute` can be used as a sort of "tag" on other pieces of code. For instance, there is an attribute called `ObsoleteAttribute`. This is used to signal that code is obsolete and shouldn't be used anymore. You can place this attribute on a class, for instance, by using square brackets.

```
[Obsolete]
public class MyClass
{
}
```

Note that while the class is called `ObsoleteAttribute`, it's only necessary to use `[Obsolete]` in the code. This is a convention that C# follows. You can use the full name `[ObsoleteAttribute]` if you choose.

When marking a class obsolete, it's a good idea to provide some information as to *why* it's obsolete, and/or *what* to use instead. Do this by passing a string parameter to the `Obsolete` attribute.

```
[Obsolete("ThisClass is obsolete. Use ThisClass2 instead.")]
public class ThisClass
{
}
```

The string is being passed as an argument to an `ObsoleteAttribute` constructor, just as if you were writing `var attr = new ObsoleteAttribute("some string")`.

Parameters to an attribute constructor are limited to simple types/literals:

`bool, int, double, string, Type, enums, etc` and arrays of those types. You can not use an expression or a variable. You are free to use positional or named parameters.

How to create your own attribute

Creating an attribute is as simple as inheriting from the `Attribute` base class.

```
public class MySpecialAttribute : Attribute
{
}
```

With the above, I can now use `[MySpecial]` (or `[MySpecialAttribute]`) as an attribute elsewhere in the code base.

```
[MySpecial]
public class SomeOtherClass
{
}
```

Attributes in the .NET base class library like `ObsoleteAttribute` trigger certain behaviors within the compiler. However, any attribute you create acts only as metadata, and doesn't result in any code within the attribute class being executed. It's up to you to act on that metadata elsewhere in your code (more on that later in the tutorial).

There is a 'gotcha' here to watch out for. As mentioned above, only certain types are allowed to be passed as arguments when using attributes. However, when creating an attribute type, the C# compiler won't stop you from creating those parameters. In the below example, I've created an attribute with a constructor that compiles just fine.

```
public class GotchaAttribute : Attribute
{
    public GotchaAttribute(Foo myClass, string str) {

    }
}
```

However, you will be unable to use this constructor with attribute syntax.

```
[Gotcha(new Foo(), "test")] // does not compile
public class AttributeFail
{
}
```

The above will cause a compiler error like

```
Attribute constructor parameter 'myClass' has type 'Foo', which is not a valid attribute parameter type
```

How to restrict attribute usage

Attributes can be used on a number of "targets". The above examples show them on classes, but they can also be used on:

- Assembly
- Class
- Constructor
- Delegate
- Enum
- Event
- Field
- GenericParameter
- Interface
- Method
- Module
- Parameter
- Property
- ReturnValue
- Struct

When you create an attribute class, by default, C# will allow you to use that attribute on any of the possible attribute targets. If you want to restrict your attribute to certain targets, you can do so by using the

```
AttributeUsageAttribute
```

on your attribute class. That's right, an attribute on an attribute!

```
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Struct)]
public class MyAttributeForClassAndStructOnly : Attribute
{}
```

If you attempt to put the above attribute on something that's not a class or a struct, you will get a compiler error like

```
Attribute 'MyAttributeForClassAndStructOnly' is not valid on this declaration type. It is only valid on 'class, struct' declarations
```

```
public class Foo
{
    // if the below attribute was uncommented, it would cause a compiler error
    // [MyAttributeForClassAndStructOnly]
    public Foo()
    { }
}
```

How to use attributes attached to a code element

Attributes act as metadata. Without some outward force, they won't actually do anything.

To find and act on attributes, [Reflection](#) is generally needed. I won't cover Reflection in-depth in this tutorial, but the basic idea is that Reflection allows you to write code in C# that examines other code.

For instance, you can use Reflection to get information about a class(add `using System.Reflection;` at the head of your code):

```
TypeInfo typeInfo = typeof(MyClass).GetTypeInfo();
Console.WriteLine("The assembly qualified name of MyClass is " + typeInfo.AssemblyQualifiedName);
```

That will print out something like:

```
The assembly qualified name of MyClass is ConsoleApplication.MyClass, attributes, Version=1.0.0.0,
Culture=neutral, PublicKeyToken=null
```

Once you have a `TypeInfo` object (or a `MemberInfo`, `FieldInfo`, etc), you can use the `GetCustomAttributes` method. This will return a collection of `Attribute` objects. You can also use `GetCustomAttribute` and specify an Attribute type.

Here's an example of using `GetCustomAttributes` on a `MethodInfo` instance for `MyClass` (which we saw earlier has an `[Obsolete]` attribute on it).

```
var attrs = typeInfo.GetCustomAttributes();
foreach(var attr in attrs)
    Console.WriteLine("Attribute on MyClass: " + attr.GetType().Name);
```

That will print to console: `Attribute on MyClass: ObsoleteAttribute`. Try adding other attributes to `MyClass`.

It's important to note that these `Attribute` objects are instantiated lazily. That is, they won't be instantiated until you use `GetCustomAttribute` or `GetCustomAttributes`. They are also instantiated each time. Calling `GetCustomAttributes` twice in a row will return two different instances of `ObsoleteAttribute`.

Common attributes in the base class library (BCL)

Attributes are used by many tools and frameworks. NUnit uses attributes like `[Test]` and `[TestFixture]` that are used by the NUnit test runner. ASP.NET MVC uses attributes like `[Authorize]` and provides an action filter framework to perform cross-cutting concerns on MVC actions. [PostSharp](#) uses the attribute syntax to allow aspect-oriented programming in C#.

Here are a few notable attributes built into the .NET Core base class libraries:

- `[Obsolete]`. This one was used in the above examples, and it lives in the `System` namespace. It is useful to provide declarative documentation about a changing code base. A message can be provided in the form of a string, and another boolean parameter can be used to escalate from a compiler warning to a compiler error.
- `[Conditional]`. This attribute is in the `System.Diagnostics` namespace. This attribute can be applied to

methods (or attribute classes). You must pass a string to the constructor. If that string doesn't match a `#define` directive, then any calls to that method (but not the method itself) will be removed by the C# compiler. Typically this is used for debugging (diagnostics) purposes.

- `[CallerMemberName]`. This attribute can be used on parameters, and lives in the `System.Runtime.CompilerServices` namespace. This is an attribute that is used to inject the name of the method that is calling another method. This is typically used as a way to eliminate 'magic strings' when implementing `INotifyPropertyChanged` in various UI frameworks. As an example:

```
public class MyUIClass : INotifyPropertyChanged
{
    public event PropertyChangedEventHandler PropertyChanged;

    public void RaisePropertyChanged([CallerMemberName] string propertyName = null)
    {
        PropertyChanged?.Invoke(this, new PropertyChangedEventArgs(propertyName));
    }

    private string _name;
    public string Name
    {
        get { return _name; }
        set
        {
            if (value != _name)
            {
                _name = value;
                RaisePropertyChanged(); // notice that "Name" is not needed here explicitly
            }
        }
    }
}
```

In the above code, you don't have to have a literal `"Name"` string. This can help prevent typo-related bugs and also makes for smoother refactoring/renameing.

Summary

Attributes bring declarative power to C#. But they are a form of code as meta-data, and don't act by themselves.

A Tour of the C# Language

3/14/2019 • 4 minutes to read • [Edit Online](#)

C# (pronounced "See Sharp") is a simple, modern, object-oriented, and type-safe programming language. C# has its roots in the C family of languages and will be immediately familiar to C, C++, Java, and JavaScript programmers.

C# is an object-oriented language, but C# further includes support for **component-oriented** programming. Contemporary software design increasingly relies on software components in the form of self-contained and self-describing packages of functionality. Key to such components is that they present a programming model with properties, methods, and events; they have attributes that provide declarative information about the component; and they incorporate their own documentation. C# provides language constructs to support directly these concepts, making C# a very natural language in which to create and use software components.

Several C# features aid in the construction of robust and durable applications: **Garbage collection** automatically reclaims memory occupied by unreachable unused objects; **exception handling** provides a structured and extensible approach to error detection and recovery; and the **type-safe** design of the language makes it impossible to read from uninitialized variables, to index arrays beyond their bounds, or to perform unchecked type casts.

C# has a **unified type system**. All C# types, including primitive types such as `int` and `double`, inherit from a single root `object` type. Thus, all types share a set of common operations, and values of any type can be stored, transported, and operated upon in a consistent manner. Furthermore, C# supports both user-defined reference types and value types, allowing dynamic allocation of objects as well as in-line storage of lightweight structures.

To ensure that C# programs and libraries can evolve over time in a compatible manner, much emphasis has been placed on **versioning** in C#'s design. Many programming languages pay little attention to this issue, and, as a result, programs written in those languages break more often than necessary when newer versions of dependent libraries are introduced. Aspects of C#'s design that were directly influenced by versioning considerations include the separate `virtual` and `override` modifiers, the rules for method overload resolution, and support for explicit interface member declarations.

Hello world

The "Hello, World" program is traditionally used to introduce a programming language. Here it is in C#:

```
using System;
class Hello
{
    static void Main()
    {
        Console.WriteLine("Hello, World");
    }
}
```

C# source files typically have the file extension `.cs`. Assuming that the "Hello, World" program is stored in the file `hello.cs`, the program might be compiled using the command line:

```
csc hello.cs
```

which produces an executable assembly named `hello.exe`. The output produced by this application when it is run

is:

```
Hello, World
```

IMPORTANT

The `csc` command compiles for the full framework, and may not be available on all platforms.
